Disclaimer

Recovery plans delineate such reasonable actions as may be necessary, based upon the best scientific and commercial data available, for the conservation and survival of listed species. Plans are published by the National Marine Fisheries Service (NMFS), sometimes prepared with the assistance of recovery teams, contractors, State agencies and others. Recovery plans do not necessarily represent the views, official positions or approval of any individuals or agencies involved in the plan formulation, other than NMFS. They represent the official position of NMFS only after they have been signed by the Assistant Administrator. Recovery plans are guidance and planning documents only; identification of an action to be implemented by any public or private party does not create a legal obligation beyond existing legal requirements. Nothing in this plan should be construed as a commitment or requirement that any General agency obligate or pay funds in any one fiscal year in excess of appropriations made by Congress for that fiscal year in contravention of the Anti-Deficiency Act, 31 U.S.C 1341, or any other law or regulation. Approved recovery plans are subject to modification as dictated by new findings, changes in species status, and the completion of recovery actions.

Executive Summary

Need for Recovery

Thousands of coho salmon once returned to spawn in the rivers and streams of Northern California and Southern Oregon. Not long ago, these watersheds provided conditions that supported robust and resilient populations of coho salmon that could persist under dynamic environmental conditions. The combined effects of fish harvest, hatcheries, hydropower operations, and habitat alterations caused by land management led to declines in these populations. The National Marine Fisheries Service's (NMFS) evaluation of declining coho salmon abundance and productivity, as well as range reductions and diminished life-history diversity, supported the decision to list the Southern Oregon/Northern California Coast (SONCC) Evolutionarily Significant Unit (ESU) of coho salmon as a threatened species under the Endangered Species Act (ESA) in 1997, a decision that was reaffirmed in 2005.

Recovery can only be achieved through coordinated efforts to build strong conservation partnerships. Conservation partners may be individuals, groups, and government or non-government organizations including NMFS, industry, or tribes who have an interest in the recovery of SONCC coho salmon. The ESA envisions recovery plans as the central organizing tool for guiding each species' recovery process. The recovery plan is a road map to recovery – it lays out where we need to go and how best to get there. The SONCC Coho Salmon ESU recovery plan (Plan) was developed to provide a roadmap to recovery of this species which conservation partners can follow together. Specifically, the Plan is designed to guide implementation of prioritized actions needed to conserve and recover the species by providing an informed, strategic, and voluntary approach to recovery that is based on the best available science. Use of a recovery plan ensures that recovery efforts target limited resources effectively and efficiently. The Plan also provides recovery targets to work toward, as well as criteria by which progress toward recovery will be tracked.

Current Species Status (Chapter 2)

The SONCC Coho Salmon ESU includes all naturally spawned populations of coho salmon in coastal streams between Cape Blanco, Oregon and Punta Gorda, California, as well as coho salmon produced by three artificial propagation programs: Cole Rivers Hatchery, Trinity River Hatchery, and Iron Gate Hatchery. An ESU is comprised of groups of populations with geographic and evolutionary similarities that are considered a "species" under the ESA. NMFS originally listed the SONCC coho salmon ESU as threatened under the ESA in 1997 (62 FR 24588, May 6, 1997). In 2005, following a reassessment of its status and after applying NMFS' hatchery listing policy, NMFS reaffirmed its status as threatened and also added several hatchery programs to the listed ESU (70 FR 37160, June 28, 2005).

NMFS issued guidelines in 1990 (55 FR 24296, June 15, 1990) for assigning listing and recovery priorities. Three criteria are assessed to determine NMFS' species' priority for recovery plan development, implementation, and resource allocation: 1) magnitude of threat; 2) recovery potential; and 3) existing conflict with activities such as construction and development. The recovery priority number for the SONCC coho salmon ESU is 1, as reported in the 2011-2012

Biennial Report to Congress on the Recovery Program for Threatened and Endangered Species (NMFS 2013).

In 2006, NMFS modeled the historic population structure of the SONCC coho salmon ESU (Williams et al. 2006; Chapter 2, this volume). Each population is described in terms of its modeled capacity to support rearing juvenile coho salmon, based on the intrinsic ability of the habitat to support this life stage. This capacity is described as Intrinsic Potential or IP. Williams et al. (2006) calculated the number of kilometers of IP for each population. The role each population played in the historic function of the ESU is primarily based on how much IP it contains. Populations with more than 34 IP-km are described as independent because, due to their size, they are not dependent on strays from nearby populations to persist over time. Populations with from 5 to 34 IP-km are described as dependent because they are too small to persist without immigration from independent populations. NMFS grouped populations with similar geologic and genetic features into seven diversity strata (Williams et al. 2006). Williams et al. (2006) originally described 45 populations in the SONCC coho salmon ESU (Williams et al. 2006), but this recovery plan describes 40 populations, due to the recalculation of the amount of IP in some populations and exclusion of populations with less than 5 IP-km. Figure ES-1 shows the SONCC coho salmon ESU, including all 40 populations and seven diversity strata.

Populations with extremely low numbers of spawning adults can suffer from depensatory effects, which are problems with successful reproduction such as spawners being too scarce to find each other. The number of spawners needed to avoid depensatory effects is called the depensation threshold. Based on the amount of IP-km in each population, this recovery plan describes the extinction risk of each independent population. An independent population with spawner numbers below the depensation threshold is at high risk of extinction. Currently, over three quarters of SONCC coho salmon independent populations are at high risk of extinction (Figure ES-2). In a recovered ESU, these populations would be at moderate or low risk of extinction.

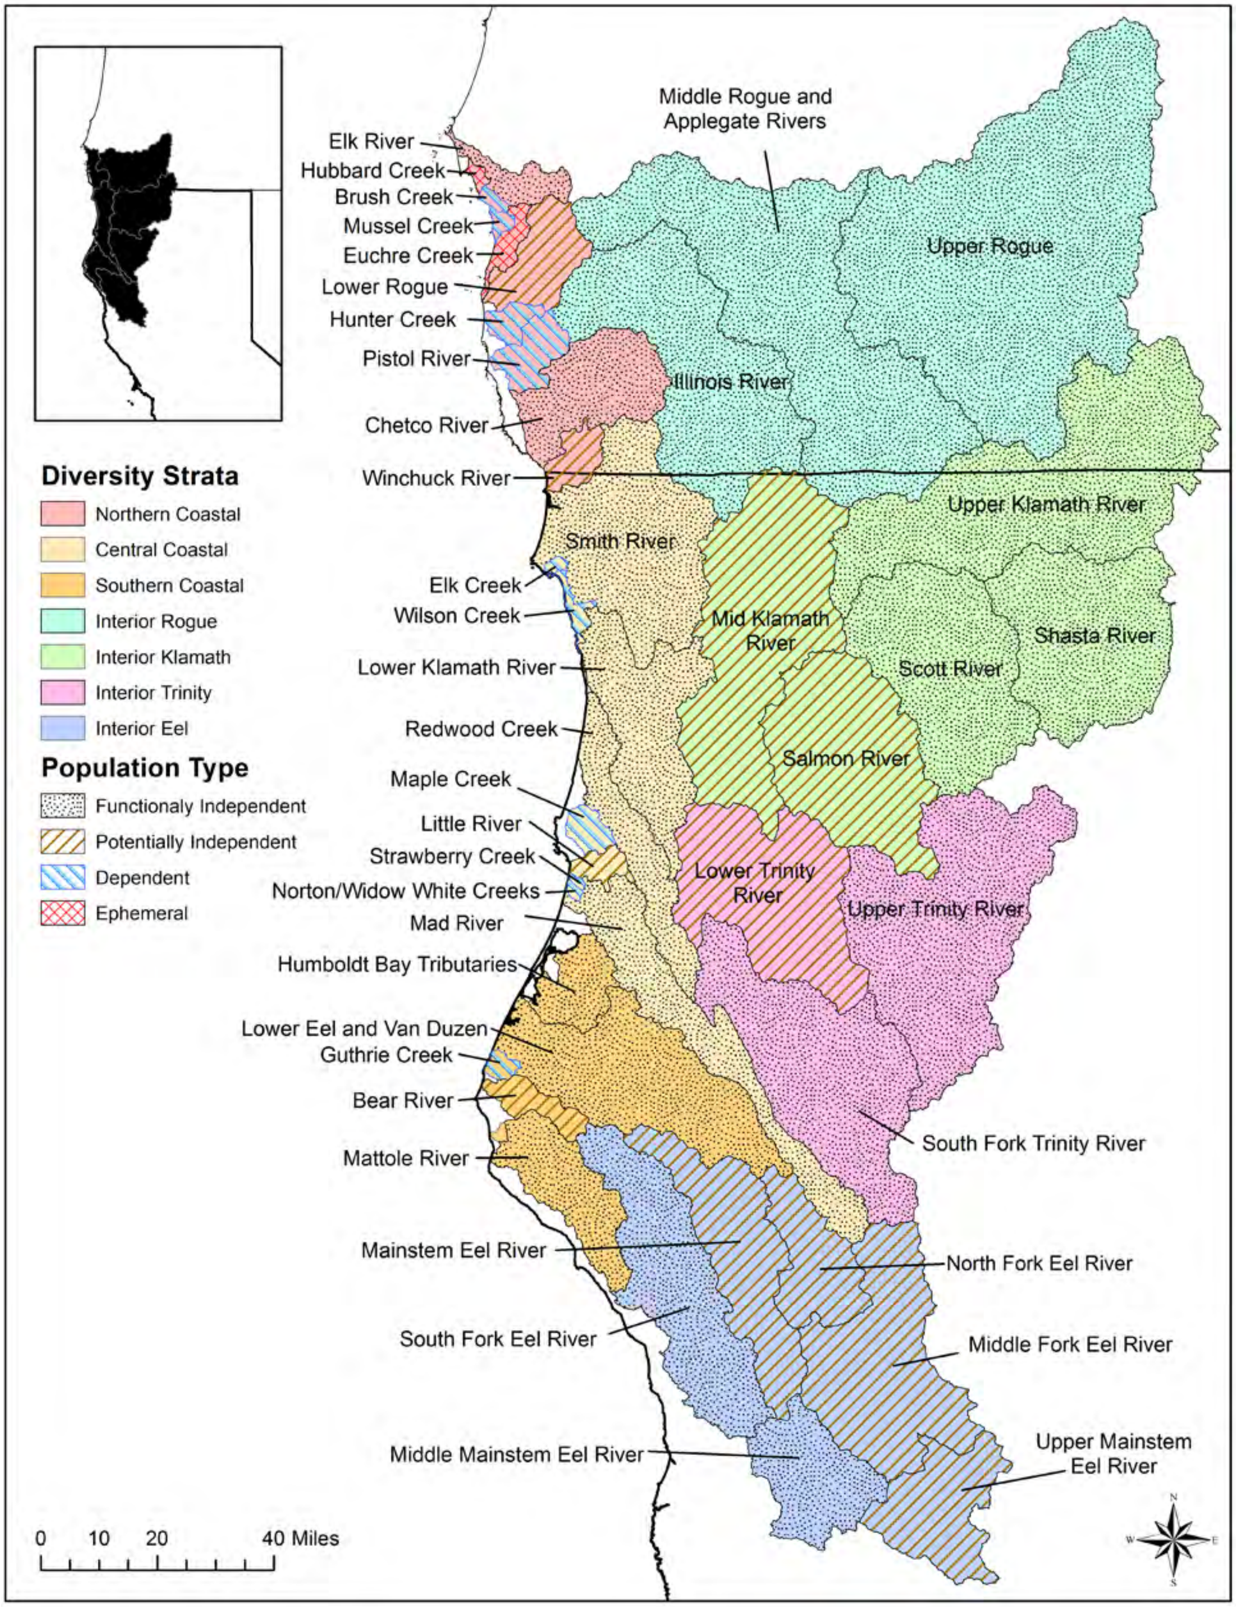

Figure ES-1. Populations and diversity strata of the SONCC coho salmon ESU.

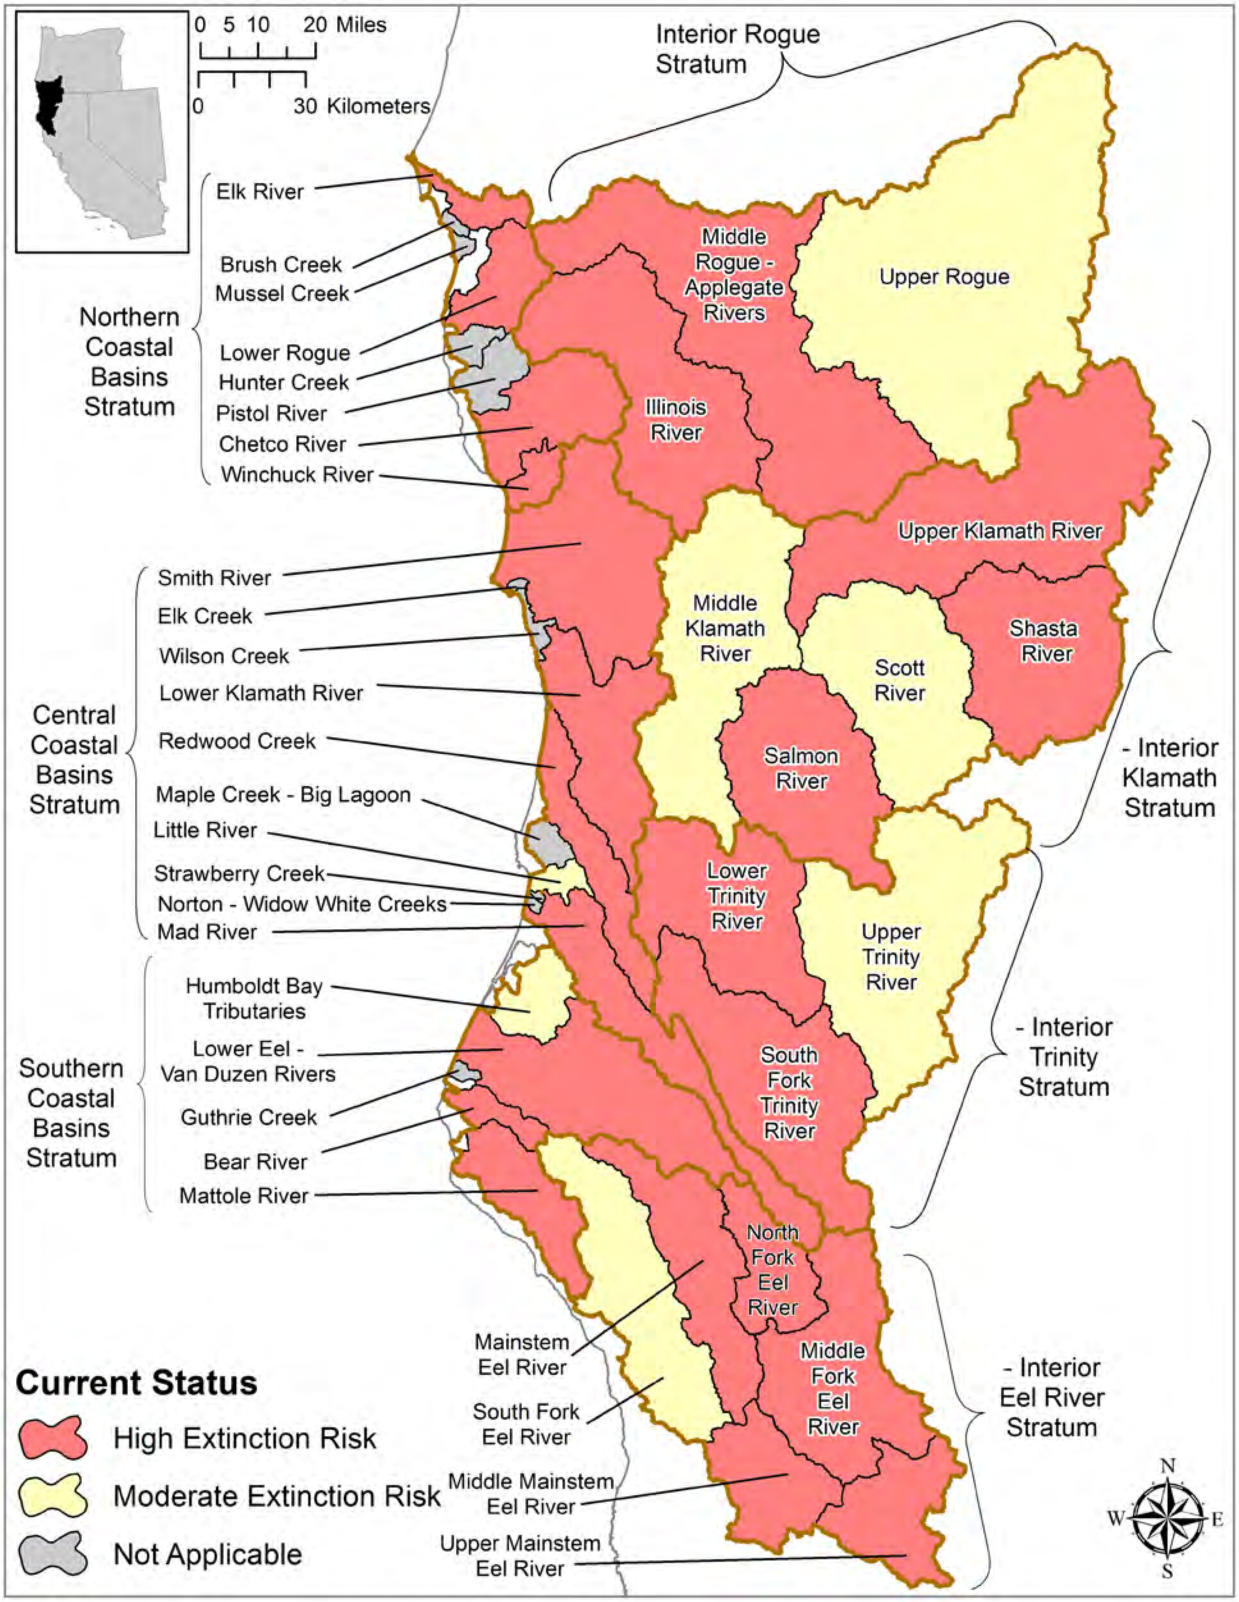

Figure ES-2. Current extinction risk of independent populations in the SONCC coho salmon ESU.

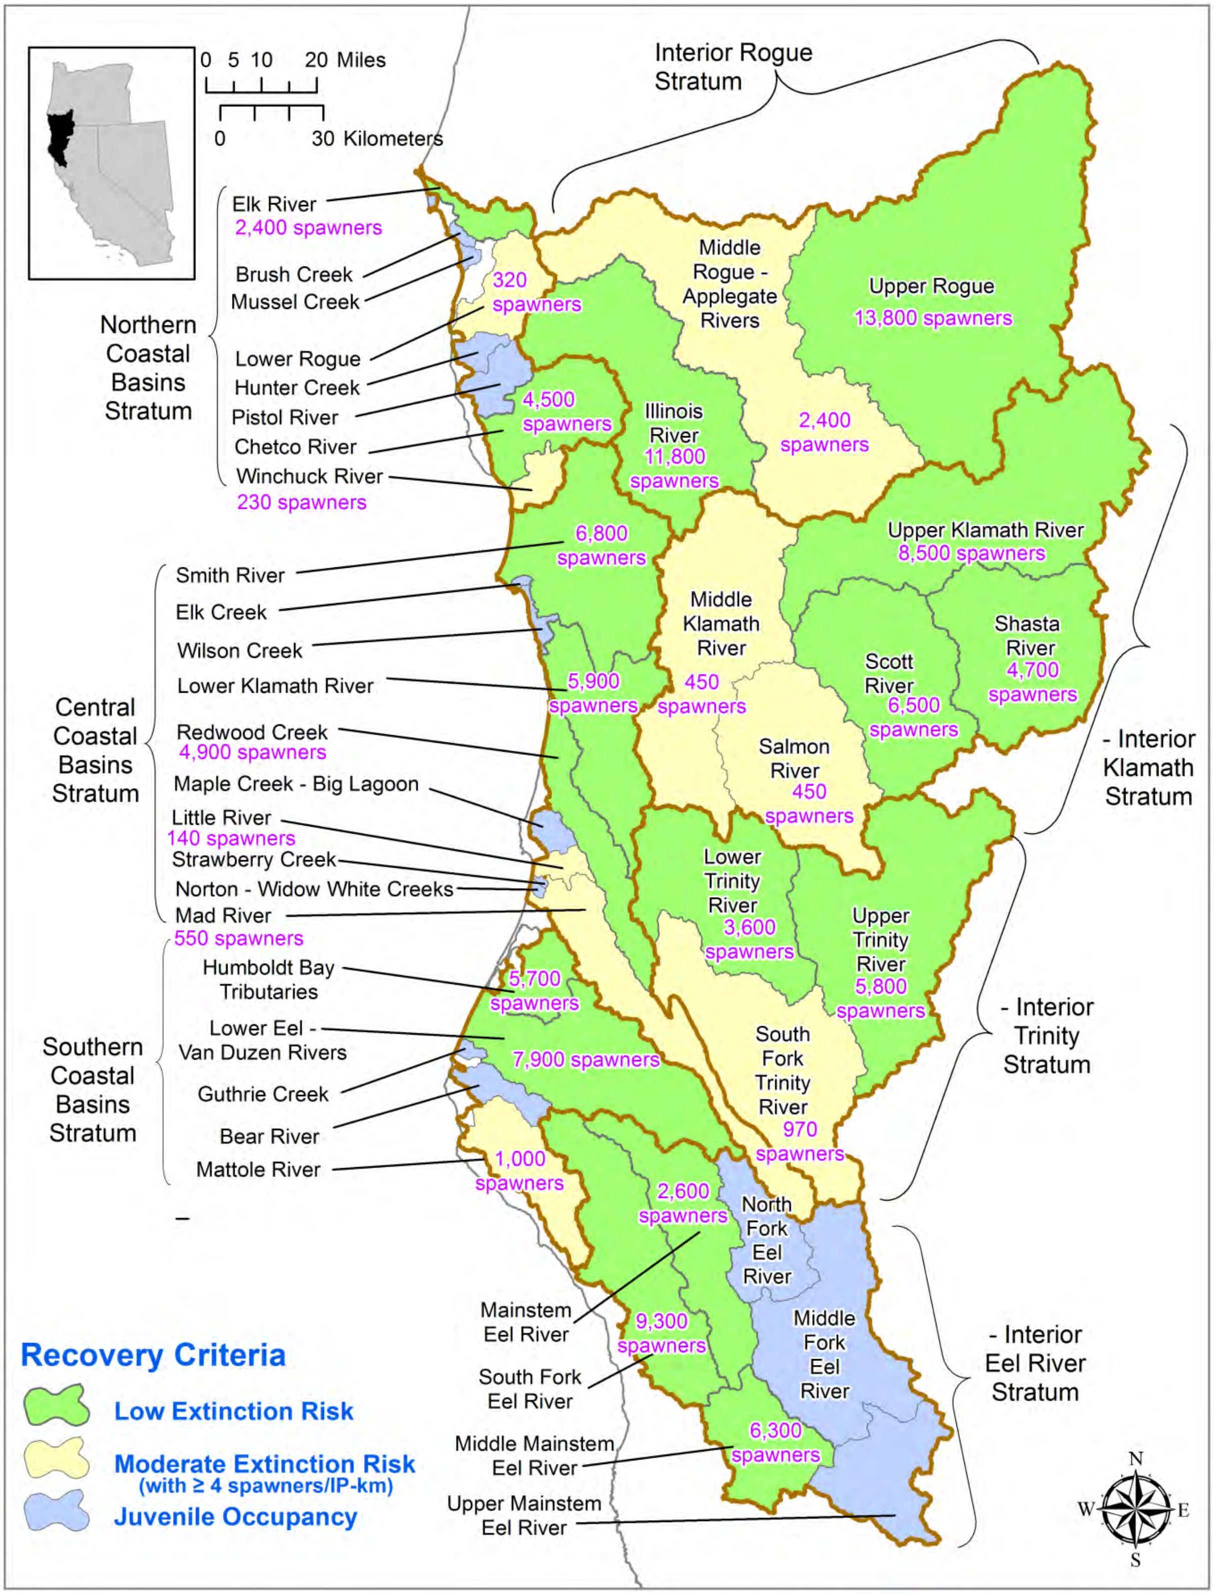

Figure ES-3. Minimum target extinction risk and recovery criteria for each population.

Stresses and Threats (Chapters 3 and 7 to 46)

Stresses are the physical, biological, or chemical conditions and associated ecological processes that that may impede SONCC coho salmon recovery. These are the factors that the fish feel, such as disease, limited habitat access, insufficient instream flows, impaired water quality, and insufficient amount and quality of habitat. Threats are those activities or impacts that cause or contribute to stresses such as hydropower, diversions, land management, invasive species, fish harvest, timber harvest, and hatcheries. The Plan includes recovery actions to restore various aspects of coho salmon habitat, and SONCC coho salmon recovery also depends on ongoing efforts to change past and current practices that diminish salmon habitat.

Chapter 3 describes the stresses and threats that NMFS believes are currently limiting populations from producing enough adults to avoid a high risk of extinction. Chapters 7 to 46 rank these stresses and threats for each population, and contain tables that describe the actions needed to reduce these stresses and threats. Chapters 7 to 46 also describe the key limiting stresses and threats for each population. Key limiting stresses and threats are those stresses and threats that are the most pressing factors limiting recovery of populations. Recovery actions to address key limiting stresses and threats often have a higher priority than those to address other stresses and threats. The key limiting stresses and threats for each population are shown in Table ES-1.

The lack of floodplain and channel structure is a key limiting stress in nearly all coastal populations and about half of interior populations. Good floodplain structure is present when the river retains areas off the main channel such as ponds and old oxbows. These areas are particularly important for coho salmon as they provide refuge from high winter flows. Good channel structure is present when there are sufficient pools and instream structure, such as complex wood jams. In coastal populations, the most common key limiting threat (52% of populations) is channelization, which results in straightening and simplification of the stream channel and reduction of off-channel habitat. In a third of all populations and 63% of interior populations, the amount of water in streams and rivers is insufficient for coho salmon needs, making altered hydrologic function another prevalent key limiting stress. In 35% of all populations and 71% of interior populations, dams and diversions are a key limiting threat, as they lead to a reduction in the amount of water in streams and rivers.

Table ES-1. SONCC coho salmon ESU populations and their key limiting stresses and threats.

Stratum	Populations	Key Limiting Stresses		Key Limiting Threats	
Northern Coastal Basin	Elk River	Structure	Water Quality	Agriculture	Channelization
	Brush Creek	Structure	Riparian	Roads	Timber Harvest
	Mussel Creek	Structure	Riparian	Timber Harvest	Channelization
	Lower Rogue River	Structure	Water Quality	Roads	Development
	Hunter Creek	Structure	Riparian	Roads	Timber Harvest
	Pistol Creek	Structure	Riparian	Roads	Timber Harvest
	Chetco River	Structure	Riparian	Channelization	Development
	Winchuck River	Structure	Water Quality	Channelization	Development
Central Coastal Basin	Smith River	Structure	Estuary	Channelization	Agriculture
	Elk Creek	Structure	Riparian	Channelization	Development
	Wilson Creek	Structure	Riparian	Roads	Timber Harvest
	Lower Klamath River	Structure	Sediment	Channelization	Agriculture

	South Fork Eel River	Structure	Hydro Function	Dam/Diversion	Roads
	North Fork Eel River	Water Quality	Sediment	Roads	Fire

Recovery Strategy (Chapters 4 and 6)

The goal of this Plan is to recover the SONCC coho salmon ESU to the point where the species no longer needs the protections afforded by the Federal ESA and can be removed from the ESA list of threatened and endangered species. A recovered SONCC coho salmon ESU will be naturally self-sustaining, and the factors that caused it to be listed will be sufficiently reduced to allow it to persist over time.

The strategy to recover SONCC coho salmon is to carry out recovery actions to restore habitat and reduce stresses and threats, so that populations will rebuild to the levels needed to play their respective roles in recovery, as described in Figure ES-3. These levels are associated with target minimum extinction risks, also shown in Figure ES-3.

Each population must play a role in rebuilding to a recovered ESU. These roles are described in Williams et al. (2008). A certain number of independent populations must be at low risk of extinction to achieve recovery. These populations are called "Core populations" in this plan. A subset of remaining independent populations must be at moderate risk of extinction (and recover to hundreds to low thousands of fish). These populations are called "Non-Core 1 populations". The remaining populations don't need a minimum number of fish, instead they must have sufficient habitat occupied by juvenile fish. These populations are called "Dependent" and "Non-Core 2" populations. Figure ES-4 shows the role of each population.

In 2008, NMFS developed an assessment framework to track the SONCC coho salmon ESU's progress toward recovery (Williams et al. 2008 and Chapters 2 and 4 of this plan). The framework describes a needed configuration of populations with different numbers of spawning adults in various populations such that populations will play different roles in recovery (i.e., when describing core, non-core, dependent) but does not identify which independent populations will be core and which will be non-core. This recovery plan describes which populations will be core and non-core, and identifies the number of spawning adults needed and the needed spatial distribution of juvenile fish for each population. The number of spawning adults needed is based on the population's role in recovery and on the amount of modeled IP-km in each population.

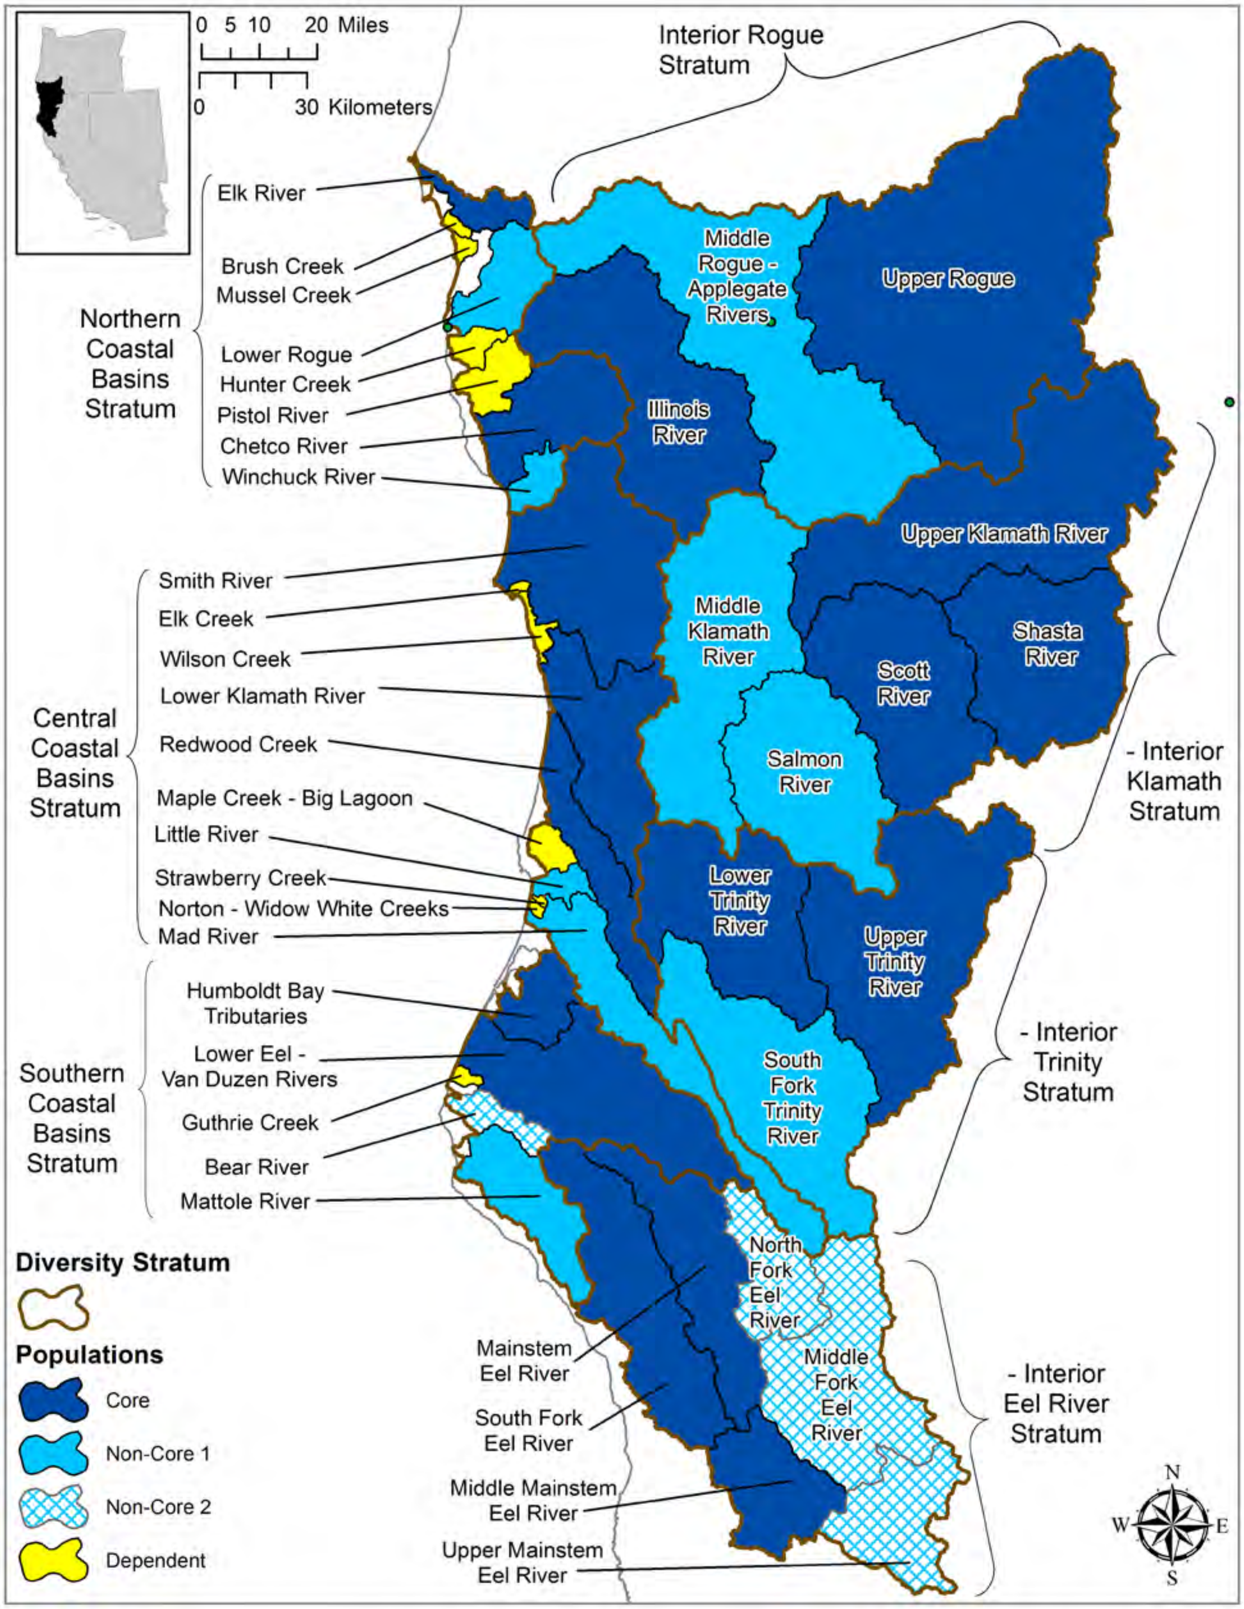

Figure ES-4. The role of each population in the recovery of the SONCC coho salmon ESU.

Table ES-2 shows the recovery objectives and criteria for each population type. There are recovery objectives for four biological parameters of each population: spawner abundance, productivity (growth rate), spatial structure, and diversity (Table ES-2). The Plan's recovery criteria, explained in Chapter 4 and shown in Table ES-2, describe how progress toward each recovery objective will be measured.

Table ES-2. Recovery objectives and criteria by Viable Salmonid Population parameter.

VSP Parameter	Population Role	Biological Recovery Objective	Biological Recovery Criteria[1]
Abundance	Core	Achieve a low risk of extinction[2]	The geometric mean of wild adults over 12 years meets or exceeds the "low risk threshold" of spawners for each core population[2,3,4]
	Non-Core 1	Achieve a moderate or low risk of extinction[2]	The annual number of wild adults is greater than or equal to four spawners per IP-km for each non-core population[2]
Productivity	Core and Non-Core 1	Population growth rate is not negative	Slope of regression of the geometric mean of wild adults over the time series ≥ zero[4]
Spatial Structure	Core and Non-Core 1	Ensure populations are widely distributed	Annual within-population juvenile distribution ≥ 80%[4] of habitat[5,6] (outside of a temperature mask[7])
	Non-Core 2 and Dependent	Achieve inter- and intra-stratum connectivity	≥ 80% of accessible habitat[4] is occupied in years[8] following spawning of cohorts that experienced high marine survival[9]
Diversity	Core and Non-Core 1	Achieve low or moderate hatchery impacts on wild fish	Proportion of hatchery-origin adults (pHOS) < 0.05
	Core and Non-Core 1	Achieve life-history diversity	Variation is present in migration timing, age structure, size and behavior. The variation in these parameters[10] is retained.

[1] All applicable criteria must be met for each population in order for the ESU to be viable.
[2] See Table 4-2 for specific spawner abundance requirements needed to meet this objective.
[3] In the Shasta River, Upper Trinity River, and Upper Rogue River populations, IP above some anthropogenic dams was excluded from the spawner target, so the low-risk threshold for these populations is based on the IP downstream of those dams.
[4] Assess for at least 12 years, striving for a coefficient of variation (CV) of 15% or less at the population level (Crawford and Rumsey 2011).
[5] Based on available rearing habitat within the watershed (Wainwright et al. 2008). For purposes of these biological recovery criteria, "available" means accessible. 80% of habitat occupied relates to a truth value of +1.0,(true: juveniles occupy a high proportion of the available rearing habitat within the watershed (p. 56, Wainwright et al. 2008).
[6] The average for each of the three year classes over the 12 year period used for delisting evaluation must each meet this criterion. Strive to detect a 15% change in distribution with 80% certainty (Crawford and Rumsey 2011).
[7] Williams et al. (2008) identified a threshold air temperature, above which juvenile coho salmon generally do not occur, and identified areas with air temperatures over this threshold. These areas are considered to be within the temperature mask.
[8] If young-of-year are sampled, sampling would occur the spring following spawning of the cohorts experiencing high marine survival. If 1+ juveniles are sampled, sampling would occur approximately 1.5 years after spawning of the cohorts experiencing high marine survival, but before outmigration to the estuary and ocean.
[9] High marine survival is defined as 10.2% for wild fish and 8% for hatchery fish; Sharr et al. 2000. If marine survival is not high, then this criterion does not apply.
[10] This variation is documented in the population profiles in Chapters 7 to 46 of this plan.

Recovery Actions

Chapters 5 and 7 to 46 include over 4,000 recovery action steps and their respective priorities. Recovery actions are designed to address acute issues by reducing threats, and to restore processes which create and maintain good coho salmon habitat by reducing stresses. Recovery actions include removal of or establishment of passage at dams; reducing unpermitted diversions; ensuring sufficient water quantity and quality; restoring in-channel habitat and upslope ecological function; and creating suitable estuarine nurseries. In addition, managing fisheries, reducing detrimental effects of land use activities; decreasing disease and non-native predator species, and operating hatcheries consistent with recovery goals are essential. Each recovery action is assigned a priority. The priority of each action is based on whether it will prevent a significant decline in the population or habitat, whether it addresses a key limiting stress or threat, whether it would help a population at high risk of extinction, and whether it would benefit coho salmon immediately.

Monitoring & Adaptive Management (Chapter 5)

Monitoring is necessary to assess the recovery of SONCC coho salmon by determining if specific recovery criteria are met, and to evaluate whether changes in the recovery strategy are necessary. The Plan identifies acceptable sampling standards and the necessary data to be collected over time, including measuring the abundance and distribution of coho salmon in each population. The adaptive management element offers a feedback loop for continuous scientific evaluation of the foundational scientific framework, monitoring, and recovery action aspects of the Plan so that new information can suggest whether to add or discontinue actions or strategies. Web-based recovery action implementation tracking tools are under development.

Benefits of Recovery

Achieving delisting of SONCC coho salmon by implementation of the recovery actions identified in the Plan is estimated to cost approximately $5 billion over the amount of time needed to recover the species (just over 100 years). Approximately $1.6 billion of that total cost is associated with monitoring actions required to meet delisting criteria. While a significant investment, the recovery of SONCC coho salmon will concurrently result in a wide array of economic, societal and ecosystem benefits. The largest economic returns resulting from recovered coho salmon populations are associated with sport and commercial fishing. For example, the California commercial and recreational salmon fisheries are estimated to generate a total of $118-279 million[1] in income annually, and provide roughly two to three thousand jobs. These figures will increase as salmon runs increase, providing both economic gains and more commercial and recreational fishing opportunities. With a revived sport and commercial fishery, these substantial economic gains and the creation of jobs would be realized across the SONCC coho salmon range, most notably for river communities and coastal counties.

[1] Employment impacts of CA salmon fishery closures in 2008 and 2009. University of the Pacific. Available at: http://forecast.pacific.edu/BFC%20salmon%20jobs.pdf

The economy will also be stimulated through the employment of workers needed to implement recovery projects. Habitat restoration projects stimulate job creation at a level comparable to traditional infrastructure investments such as mass transit, roads, or water projects[2]. Every dollar invested in watershed restoration projects travels through the state's economy. Design, implementation, and maintenance of habitat restoration projects require hiring consultants, contractors, employees, and field crews, and purchasing equipment, goods and services. People hired to carry out such projects spend their wages on goods and services in their local communities. In Oregon, 90% of investments in habitat restoration have been shown to stay in the state[2].

Many of the actions identified in this plan are designed to improve watershed-wide processes which benefit many native species of plants and animals (including other state and federally protected species) by restoring ecosystem functions. In addition, restoration of habitat provides substantial benefits for human communities such as: improving and protecting the quality of important surface and ground water supplies; reducing damage from flooding resulting from floodplain development; and controlling invasive exotic animal and plant species which can threaten water supplies and increase flooding risk. Restoring and maintaining healthy watersheds also enhances important human uses of aquatic habitats, including outdoor recreation, ecological education, field based research, aesthetic benefits, and the preservation of tribal and cultural heritage.

Summary

The Plan provides a comprehensive roadmap for the recovery of SONCC coho salmon to be followed by conservation partners. Recovery will require implementation of actions that conserve and restore the key biological, ecological, and landscape processes that support the ecosystems upon which coho salmon populations depend. The Plan identifies specific recovery actions that protect or restore coho salmon or their habitat and outlines a monitoring and evaluation program to guide its adaptive management elements so that the most effective means of achieving recovery will be utilized. Biological recovery goals, objectives and measurable criteria, and web-based management tools, will provide for a mechanism to track recovery progress. Salmon recovery is best viewed as an opportunity to diversify and strengthen the economy while enhancing the quality of life for present and future generations.

1. Background

1.1 Introduction

Populations of coho salmon (*Oncorhynchus kisutch*) once ranged across the western part of North America from the coastal river basins of Alaska to interior areas of Washington and probably inhabited most coastal streams in Washington, Oregon, and northern and central California (62 FR 24588, May 6, 1997). These populations were sufficiently large that they were able to withstand changing environmental conditions. Fisheries for these and other salmonids supported vibrant communities across the Pacific Northwest. Salmon were a critical part of healthy ecosystems in rivers and the ocean.

Part of the range of coho salmon occurs in the Southern Oregon/Northern California Coast (SONCC) Recovery Domain, which encompasses the rivers from Punta Gorda, California to Cape Blanco, Oregon. The coho salmon which occupy this area make up the SONCC coho salmon Evolutionarily Significant Unit (ESU). An ESU is a salmon stock that is considered a distinct population and hence a “species” under the Endangered Species Act. An ESU must meet two criteria: it must be substantially reproductively isolated from other nonspecific population units, and it must represent an important component of the evolutionary legacy of the species (57 FR 58612, November 20, 1991).

In the late 1990s, the populations that make up the SONCC Coho Salmon ESU were small, poorly distributed, and subject to factors that threatened their continued existence. Consequently, the ESU was listed as threatened under the Endangered Species Act (ESA) in 1997 (62 FR 24588, May 6, 1997), a finding that was reaffirmed in 2005 (70 FR 37160, June 28, 2005). A “threatened” species is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range (ESA Section 3(20)). An “endangered” species is one that is in danger of extinction throughout all or a significant portion of its range (ESA Section 3(6)). The status of the species has continued to worsen since listing (Good et al. 2005, Williams et al. 2011), despite fishing prohibitions and habitat improvements.

The ESU continues to face challenges, as shown in the Rogue River. The Rogue River has the longest time series of coho salmon adult abundance information in the ESU, and its populations are among those in the best condition. Nonetheless, coho salmon returns there are a small fraction of what they once were. The Rogue River is the only river in the ESU with data on coho abundance in the 1800s. Based on extrapolations from cannery pack data, up to 114,000 adult coho salmon returned to the Rogue River in the late 1800s even after heavy fishing pressure had occurred for years (Meengs and Lackey 2005). Figure 1-1 shows the estimated number of adult coho salmon spawners that returned to the Rogue River from 1980 to 2010, based on counts at Huntley Park (Oregon State University (OSU) 2010), as well as the recovery target for all populations in the Rogue River as presented in this recovery plan. The number of adults has been consistently below that needed for the Rogue River to play its role in recovery of the SONCC coho salmon ESU.

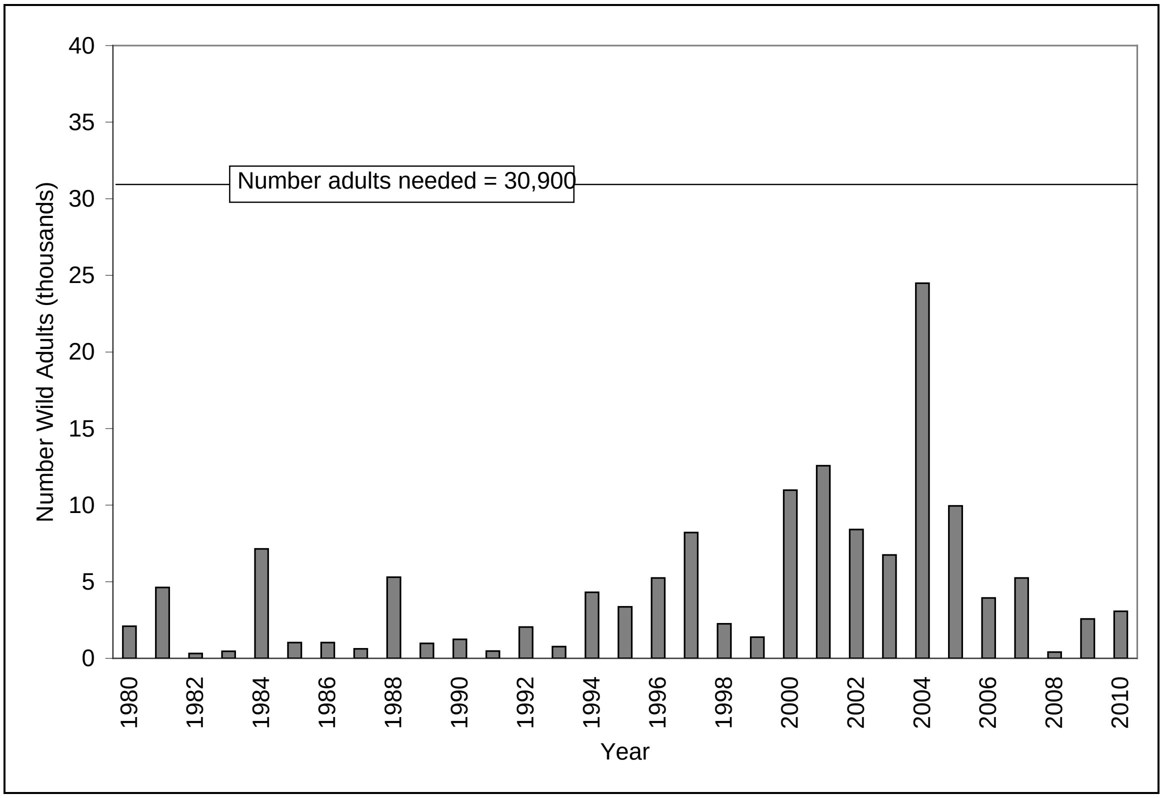

Figure 1-1. Estimates of the run size of wild Rogue basin coho salmon past Huntley Park, 1980-2010 (Oregon Department of Fish and Wildlife [ODFW] 2012), compared to number needed from Rogue River for ESU recovery.

1.2 What is a recovery plan?

"Recovery" is the process by which listed species and their ecosystems are restored and their future is safeguarded to the point that protections under the ESA are no longer needed (NMFS 2010). When a species is listed under the ESA, a recovery plan generally must be prepared (ESA Section 4(f)(1)). The ESA envisions recovery plans as the central organizing tool for guiding each species' recovery process. The recovery plan is a road map to recovery – it lays out where we need to go and how best to get there. The plan organizes, coordinates, and prioritizes the many possible actions that may be taken to achieve recovery of a species. Use of a recovery plan ensures that recovery efforts target limited resources effectively and efficiently.

Recovery plans are guidance documents. No agency or entity is required by the ESA to implement a recovery plan. However, recovery plans describe how Federal agencies can best meet their responsibilities under the ESA. Specifically, section 7(a)(1) of the ESA calls on all Federal agencies to "utilize their authorities in furtherance of the purposes of this Act by carrying out programs for the conservation of endangered species and threatened species…" In addition to outlining strictly proactive measures to achieve the species' recovery, plans provide context and a framework for implementation of other provisions of the ESA with respect to a particular species, such as section (7)(a)(2) consultations on Federal agency activities, development of Habitat Conservation Plans or Safe Harbor agreements under Section 10, or special rules for threatened species under section 4(d).

1.3 Achieving Recovery

Federal agencies have neither the funds nor the authority to bring about all the actions necessary to sufficiently improve the condition of this species. Partnerships are a critical component of SONCC coho salmon recovery: partnerships between private landowners, tribes, and local, state, and federal government agencies; between non-governmental organizations and landowners; and between federal, state, and local agencies. A recovered ESU can provide ecosystem, recreation, and economic benefits to communities. All of these entities have a common interest in bringing healthy coho salmon populations and their ecosystems back to California's north coast and Oregon's south coast. The states of California and Oregon have been proactive in determining the recovery needs of coho salmon.

1.3.1 Oregon Plan for Salmon and Steelhead

The Oregon Coastal Salmon Restoration Initiative (OCSRI) is a planning process which began in 1995 with the following mission: "To restore our coastal salmon populations and fisheries to productive and sustainable levels that will provide substantial environmental, cultural, and economic benefits." In 1997, the State of Oregon released the Oregon Plan, a conservation plan designed to restore salmon to a level at which they can once again be a part of people's lives (State of Oregon 1997). The Oregon Plan included the following goals:

- Goal 1: An infrastructure will exist to provide long-term continuity in leadership, direction, and oversight of salmon restoration.
- Goal 2: Opportunities will exist for a wide range of natural resource uses that are consistent with salmon restoration.
- Goal 3: Achievement of overall OCSRI goals will be based to the greatest extent on existing laws and environmental protections, rather than new ones.
- Goal 4: An adequate funding base will be established and maintained to support the OCSRI.
- Goal 5: Oregon's expectations for sustainability of interrelated natural resources will more accurately reflect a scientific understanding of the physical and biological constraints of the ecosystem.
- Goal 6: Sufficient freshwater and estuarine habitat will be available to support healthy populations of anadromous salmonids throughout coastal river basins.
- Goal 7: Populations of salmonids in coastal river basins will achieve levels of natural production consistent with overall restoration goals.
- Goal 8: A science-based system will support evaluation of progress of the OCSRI Conservation Plan and will provide a basis for making appropriate future changes to management programs.

Report of Oregon Expert Panel

ODFW (2008b) convened a panel of fisheries and watershed scientists as an initial step in their development of a recovery plan for Oregon's SONCC coho salmon populations. Deliberations of the expert panel provided ODFW with initial, strategic guidance on limiting factors and threats to recovery. The panel identified limiting factors and threats affecting each SONCC coho salmon population in Oregon by considering the impacts across the entire life cycle. The results of the expert panel deliberations are described in each Oregon population profile.

1.3.2 Recovery Strategy for California Coho Salmon

Coho salmon north of San Francisco were listed as threatened under the California Endangered Species Act in 2002. In 2004, the California Fish and Game Commission approved the Recovery Strategy for California Coho Salmon (CDFG 2004a). The plan identified six goals to achieve delisting:

- Goal I: Maintain and improve the number of key populations and increase the number of populations and cohorts of coho salmon.
- Goal II: Maintain and increase the number of spawning adults.
- Goal III: Maintain the range, and maintain and increase distribution of coho salmon.
- Goal IV: Maintain existing habitat essential for coho salmon.
- Goal V: Enhance and restore habitat within the range of coho salmon.
- Goal VI: Reach and maintain coho salmon population levels to allow for the resumption of Tribal, recreational, and commercial fisheries for coho salmon in California.

1.4 Listing of Species

The SONCC coho salmon ESU was listed as threatened in 1997, and this status was reaffirmed in 2005 (62 FR 24588, May 6, 1997 and 70 FR 37160, June 28, 2005). This ESU includes all naturally spawned coho salmon populations between Punta Gorda, California and Cape Blanco, Oregon as well as three artificial propagation programs: The Cole Rivers Hatchery (ODFW stock #52), Trinity River Hatchery, and Iron Gate Hatchery coho hatchery programs. The decision to list the SONCC coho salmon ESU was largely based on information regarding decreased abundance, reduced distribution, and degraded habitat. There are far fewer streams and rivers supporting coho salmon in this ESU now compared to historical conditions, and numerous basin-specific extirpations of coho salmon have been documented (Brown et al. 1994, NMFS 1996, CDFG 2004a, Good et al. 2005, Gustafson et al. 2007). At the time of listing, the major factors in the decline of the species were thought to originate from long-standing, human-induced actions (e.g., habitat degradation, harvest, water diversions, and artificial propagation), combined with natural environmental variability (62 FR 24588, May 6, 1997).

The SONCC coho salmon ESU is made up of 45 ephemeral, dependent, and independent populations (Williams et al. 2006). Five of these populations are not part of the recovery strategy described in this plan. Three were excluded due to reductions in IP (see Appendix A), and two were determined to be too small to persist and therefore were excluded from further consideration.

According to Section 4(a)(1) of the ESA and NMFS listing regulations (50 Code of Federal Regulations [CFR] Part 424), a species may be found to be endangered or threatened based on any one or a combination of five factors: (A) the present or threatened destruction, modification, or curtailment of its habitat or range; (B) overutilization for commercial, recreational, scientific, or educational purposes; (C) disease or predation; (D) the inadequacy of existing regulatory mechanisms; or (E) other natural or human-made factors affecting its continued existence. The effect of these factors on SONCC coho salmon was considered when the species was listed. The descriptions of each of the factors that follow summarize the final rule from the listing of the SONCC coho salmon ESU (62 FR 24588, May 6, 1997). Chapter 3, as well as Chapters 7 to 46, describes the state of current stresses and threats.

1.4.1 Factor A: Present or Threatened Destruction, Modification, or Curtailment of its Habitat or Range

The habitat factors for the decline of SONCC coho salmon are as follows: Channel morphology changes, substrate changes, loss of instream roughness, loss of estuarine habitat, loss of wetlands, loss/degradation of riparian areas, declines in water quality (e.g., elevated water temperatures, reduced dissolved oxygen, altered biological communities, toxics, elevated pH, and altered stream fertility), altered streamflows, fish passage impediments, elimination of habitat, and direct take (62 FR 24588, May 6, 1997). The major activities responsible for the decline of coho salmon were identified as follows: logging, road building, grazing and mining activities, urbanization, stream channelization, dams, wetland loss, beaver trapping, water withdrawals, and unscreened diversions for irrigation (62 FR 24588, May 6, 1997).

1.4.2 Factor B: Overutilization for Commercial, Recreational, Scientific, or Educational Purposes

Overfishing in non-tribal fisheries was identified as a significant factor in the decline of coho salmon (62 FR 24588, May 6, 1997). Significant overfishing occurred from the time marine survival turned poor for many stocks (ca. 1976) until the mid-1990s when harvest was substantially curtailed. This overfishing compromised escapement levels. The contribution of recreational fisheries to the decline was unknown at the time of listing. Tribal harvest was not considered to be a major factor for the decline of coho salmon in either the Klamath River basin or Trinity River basin (62 FR 24588, May 6, 1997). Collection for scientific research and educational programs was believed to have little or no impact on coho salmon populations in the SONCC coho salmon ESU at the time of listing (62 FR 24588, May 6, 1997).

1.4.3 Factor C: Disease or Predation

At the time of listing, disease and predation were not believed to be major factors contributing to the overall decline of coho salmon, although it was recognized that they may have had substantial impacts in local areas (62 FR 24588, May 6, 1997).

1.4.4 Factor D: Inadequacy of Existing Regulatory Mechanisms

Habitat Management

Federal lands owned by the U.S. Forest Service (in California and Oregon) and Bureau of Land Management (in California) are managed under the Northwest Forest Plan. The Northwest Forest Plan has important benefits for coho salmon, but its overall effectiveness in conserving SONCC coho salmon is limited by the extent of federal lands and the fact that Federal land ownership is often not uniformly distributed. Federal lands are often located in the upper reaches of watersheds or river basins, upstream of much of the most suitable coho salmon rearing habitat. In addition, in some areas Federal lands are distributed in a checkerboard fashion, which results in fragmented landscapes.

NMFS determined California's forest practice rules (CFPRs), which regulate timber harvest, contained provisions that can be protective of coho salmon if fully implemented, but found the ability of these rules to protect coho salmon could be improved (62 FR 24588, May 6, 1997). In particular, the CFPRs did not adequately address large woody debris recruitment, streamside tree retention to maintain bank stability, and canopy retention standards that assure stream temperatures are properly functioning for all life stages of coho salmon. NMFS was not able to assess the adequacy of the T&I rules due to the lack of published documentation that the rules are functioning to protect coho salmon (62 FR 24588, May 6, 1997). In 2010, California's Anadromous Salmonid Protection (ASP) rules replaced its Threatened or Impaired Watershed Rules, which had originally been adopted in July 2000. The ASP rules are described in Chapter 3.

NMFS (62 FR 24588, May 6, 1997) determined that Oregon's Forest Practices Act (OFPA) did not have implementing rules that adequately protect coho salmon habitat. NMFS (62 FR 24588, May 6, 1997) determined that there was a low probability that adequate LWD recruitment could be achieved under the requirements of the OFPA. The OFPA was also found to not adequately consider and manage timber harvest and road construction on sensitive, unstable slopes subject to mass wasting, nor did it address cumulative effects. In particular, the OFPA was found to not provide adequate protection for the production and introduction of large woody debris (LWD) to medium, small, and non-fish bearing streams (62 FR 24588, May 6, 1997).

The Army Corps of Engineers (ACOE) regulates removal and fill activities under section 404 of the Clean Water Act (CWA), and the Oregon Division of State Lands (DSL) manages the state-permitted portion of the removal fill laws. At the time of listing, neither the ACOE nor the DSL had in place any process to address the additive effects of the continued development of waterfront, riverine, coastal, and wetland properties (62 FR 24588, May 6, 1997).

Implementation of the CWA was found to have not been effective in adequately protecting fishery resources, especially with respect to non-point sources of pollution (62 FR 24588, May 6, 1997). Total Maximum Daily Loads (TMDLs) are calculations of the maximum amount of pollutant (e.g., sediment, temperature) that a water body can receive and still safely meet water quality standards. TMDLs are a method for quantitative assessment of environmental problems which affect drinking water, aquatic life, recreation, and other uses of rivers, lakes, and streams. NMFS expected that TMDLs would be able to significantly protect SONCC coho salmon in the long-term, but their effectiveness was as yet unknown because few, if any, TMDLs had been developed for water bodies in the range of SONCC coho salmon at the time of listing (62 FR 24588, May 6, 1997).

At the time of listing, the impacts to fish habitat from agricultural activities had historically not been closely regulated, but Oregon's Department of Agriculture had recently completed guidance for development of Agricultural Water Quality Management Plans. It was unknown whether these agricultural management plans would adequately address salmonid habitat factors (62 FR 24588, May 6, 1997).

Harvest Management

The final rule described fishery regulations implemented in 1994 which are more protective of SONCC coho salmon than were historical regulations (62 FR 24588, May 6, 1997). Specifically, in 1994 the Pacific Fishery Management Council (PFMC) recommended harvest rates below those allowed at that time, and the PFMC recommended prohibiting the retention of coho salmon south of Cape Falcon, Oregon, resulting in the closure of commercial ocean fishing for coho salmon in California in 1994. Oregon began marking all hatchery fish to aid in more accurate estimates of natural returns. Oregon regulations for ocean fisheries within 3 miles of shore had generally conformed to these more protective regulations. In 1995, ocean recreational fishing for coho salmon was closed from Cape Falcon to Horse Mountain.

1.4.5 Factor E: Other Natural or Human-made Factors

NMFS determined that long-term trends in rainfall and marine productivity associated with atmospheric conditions in the North Pacific Ocean likely have a major influence on coho salmon production (62 FR 24588, May 6, 1997). The effects of extended drought on water supplies and water temperatures were recognized as a major concern for California populations of coho salmon. Poor ocean conditions were believed to have played a prominent role in the decline of coho salmon populations in Oregon and California (62 FR 24588, May 6, 1997).

The widespread use of artificial propagation of coho salmon was recognized to have had a significant negative impact on the production of West Coast coho salmon (62 FR 24588, May 6, 1997). Potential problems associated with hatchery programs include: genetic impacts on indigenous, naturally-reproducing populations; disease transmission; predation on wild fish; depletion of wild stock to increase brood stock; and replacement rather than supplementation of wild stocks through competition and continued annual introduction of hatchery fish. Advancement and compression of run timing has also been a common effect of hatchery programs.

1.5 Critical Habitat Designation

Critical habitat for SONCC coho salmon was designated as all accessible reaches of rivers (including estuarine areas and tributaries) between Cape Blanco, Oregon, and Punta Gorda, California (64 FR 24049, May 5, 1999). Critical habitat includes all waterways, substrate, and adjacent riparian zones below longstanding, naturally impassable barriers (i.e., natural waterfalls in existence for at least several hundred years). Tribal lands that were excluded in the critical habitat designation include: Big Lagoon Rancheria, Blue Lake Rancheria, Elk Valley Rancheria, Hoopa Valley Indian Reservation, Karuk Reservation, Laytonville Rancheria, Quartz Valley Reservation, Resighini Rancheria, Round Valley Reservation, Sherwood Valley Rancheria, Smith River Rancheria, and Yurok Reservation.

In the critical habitat designation, NMFS identified five essential habitat types for SONCC coho salmon: (1) spawning areas; (2) adult migration corridors; (3) juvenile summer and winter rearing areas; (4) juvenile migration corridors; and (5) areas for growth and development to adulthood. Spawning and rearing are often located in small headwater streams and side channels. Adult and juvenile migration corridors include these tributaries as well as mainstem reaches and estuarine zones. Growth and development to adulthood occurs primarily in near-and off-shore marine waters, although final maturation takes place in freshwater tributaries when the adults return to spawn (64 FR 24049, May 5, 1999). Within these areas, essential features of coho salmon critical habitat include adequate substrate, water quality, water quantity, water temperature, water velocity, cover/shelter, food, riparian vegetation, space, and safe passage conditions. In addition, designated freshwater and estuarine critical habitat includes riparian areas that provide the following functions: shade, sediment, nutrient or chemical regulation, stream bank stability, and input of large woody debris or organic matter (64 FR 24049, May 5, 1999).

1.6 ESA Section 4(d) Protective Regulations

Section 9 of the ESA prohibits take of species listed as endangered. Section 4(d) of the ESA provides that, whenever any species is listed as threatened, NMFS shall issue regulations deemed necessary and advisable to provide for the conservation of such species. These protective regulations (commonly referred to as a “4(d) rule”) may prohibit take of threatened species while limiting the prohibition under certain circumstances. The 4(d) rule applies to ocean and inland areas and to any authority, agency, or private individual subject to U.S. jurisdiction. NMFS initially promulgated a 4(d) protective regulation for this ESU in 2000 (65 FR 42422, July 10, 2000) and subsequently amended the regulations which are codified at 50 CFR § 223.203. This protective regulation generally prohibits the take of any SONCC coho salmon with an intact adipose fin, with limits on this general prohibition. The limits on the general prohibition of take described in 50 CFR 223.203 are summarized below.

1. Take of threatened salmonids by employees or designees of Federal agencies, CDFW, ODFW, or other governmental entity with co-management authority for the listed salmonids, if this take is necessary to 1. Aid a sick, injured or stranded salmonid, 2. Dispose of a dead salmonid, or 3. Salvage a dead salmonid which may be useful for scientific study.
2. Fishery harvest activities managed in accordance with a NMFS-approved Fishery Management and Evaluation Plan, and implemented in accordance with a letter of concurrence from NMFS.
3. Hatcheries managed under a state or Federal Hatchery and Genetics Management Plan (HGMP) which has been approved by NMFS as meeting specific criteria.
4. Scientific research activities conducted or overseen by employees or contractors of the Oregon Department of Fish and Wildlife (ODFW) or California Department of Fish and Wildlife (CDFW).

5. Habitat restoration activities conducted as part of a watershed conservation plan which has been certified by the states of California or Oregon as consistent with their watershed conservation plan guidelines. NMFS has found these state guidelines to provide for plans that meet specific criteria.
6. Physical diversion of water from a stream or lake, provided that NMFS or its authorized officer has agreed in writing that the diversion facility is screened, maintained, and operated in compliance with applicable criteria.
7. Routine road maintenance activities which contribute to the attainment and maintenance of properly functioning condition (the sustained presence of natural habitat-forming processes that are necessary for the long-term survival of salmonids through the full range of environmental variation).
8. Municipal, residential, commercial, and industrial development (including redevelopment) activities provided that such development occurs pursuant to city, county, or regional government ordinances or plans that NMFS has determined (in writing) are adequately protective of listed species.

1.7 Addition of hatchery stocks to SONCC coho salmon ESU

NMFS established a policy on the role of artificially propagated Pacific salmon and steelhead in listing determinations under the ESA (70 FR 37204, June 28, 2005). Specifically, this policy: (1) establishes criteria for including hatchery stocks in ESUs and DPSs; (2) provides direction for considering hatchery fish in extinction risk assessments of ESUs and DPSs; (3) requires that hatchery fish determined to be part of an ESU be included in any listing of an ESU or DPS; (4) affirms NMFS' commitment to conserving natural salmon and steelhead populations and the ecosystems upon which they depend; and (5) affirms NMFS' commitment to fulfilling trust and treaty obligations with regard to the harvest of some Pacific salmon and steelhead populations, consistent with the conservation and recovery of listed salmon ESUs and steelhead DPSs.

To determine whether a hatchery program is part of an ESU or DPS, NMFS convened the Salmon and Steelhead Hatchery Advisory Group (SSHAG), which divided existing hatchery programs into categories (SSHAG 2003). Using this information and the policy described above, among other things, NMFS completed new status reviews and ESA-listing determinations for 16 ESUs of Pacific salmon, including the SONCC coho salmon ESU (70 FR 37160, June 28, 2005). This listing determination added three artificial propagation programs to the SONCC coho salmon ESU: Cole Rivers Hatchery, Trinity River Hatchery, and Iron Gate Hatchery coho salmon hatchery programs. NMFS determined these artificially propagated stocks were no more divergent relative to the local natural population(s) than what would be expected between closely related natural populations within the ESU.

1.8 Status reviews

1.8.1 2005 Status Review

In 2004, NMFS convened a biological review team (BRT) to evaluate the status of SONCC coho salmon. The BRT report (Good et al. 2005) concluded that the SONCC Coho Salmon ESU should remain at a threatened status. The BRT found that data did not suggest any marked change, either positive or negative, in the abundance or distribution of coho salmon within the

SONCC coho salmon ESU. They stated that coho salmon populations continued to be depressed relative to historical numbers, and there were strong indications that breeding groups had been lost from a significant percentage of streams within their historical range (Good et al. 2005). The BRT noted that the 2001 broodyear appeared to be one of the strongest perhaps of the last decade, following a number of relatively weak years (Good et al. 2005). Risk factors identified in previous status reviews such as severe declines from historical run sizes, the apparent frequency of local extinctions, long-term trends that were clearly downward, and degraded freshwater habitat and associated reduction in carrying capacity continued to concern the BRT. The BRT noted that several risk factors had been reduced, including termination of hatchery production of coho salmon at Mad River and Rowdy Creek and restrictions on recreational and commercial harvest of coho salmon since 1994 (Good et al. 2005). A new risk identified by the BRT was the introduction of nonnative Sacramento pikeminnow (*Ptychocheilus grandis*) to the Eel River (Good et al. 2005).

1.8.2 2011 Status Review

The most recent status review concluded the ESU remains threatened (NMFS 2011). Monitoring indicates that abundance of coho salmon decreased for many populations in the ESU since the last status review. Population trends are downward. Additionally, a majority of independent populations are well below low-risk abundance targets, and many may also be below the high-risk depensation thresholds established by Williams et al. (2008). None of the seven diversity strata appear to support a single viable population. However, all of the diversity strata are occupied by coho salmon.

In the status review, NMFS expressed concern about these recent declines in abundance of coho salmon across the ESU, regardless of what the contributing factor(s) may have been (e.g., marine survival conditions and drought). The negative short-term trends observed in the limited number of time series were not unexpected given the apparent low marine survival in recent years (<1% for the 2004 to 2006 year classes). However, as population sizes have decreased other factors (e.g., small population dynamics) may be adversely affecting coho salmon populations in spite of the improved ocean conditions that occurred from 2007 to 2009. The declining abundance trends and low spawner abundance for most populations in the ESU underscore the importance of addressing freshwater habitat conditions across the ESU so that all populations are sufficiently resilient to withstand fluctuations in marine survival.

The threats discussed in the five factor analysis were found to be largely unchanged since the last status review with the exception of those associated with natural or manmade factors (NMFS 2011). In particular, threats from poor ocean conditions, drought, climate change, and small population size (depensation and stochastic processes) have or are likely to have increased and may be responsible for the observed declines in abundance. The marine survival of hatchery fish from the Cole Rivers Hatchery on the Rogue River was extremely low for the 2005 and 2006 brood years (i.e., 0.05% and 0.07%, respectively) and the average ocean conditions in 2010 (Peterson et al. 2013) suggest there may be poor marine survival for the 2011 spawning season. Drought conditions occurred for three consecutive years (2007-2009) that decreased instream flows and habitat conditions for juvenile coho salmon and very likely reduced their freshwater survival. Although it is unclear whether significant habitat changes are occurring from climate change, the authors expect a wide range of future detrimental changes to coho salmon habitat.

Lastly, because many coho salmon populations in this ESU are low in abundance, and may well be below their depensation thresholds, their risk of extinction may also be increasing.

1.9 Life-history

Coho salmon is an anadromous fish species that generally exhibits a relatively simple 3-year life cycle. Adults typically begin their freshwater spawning migration in the late summer and fall, spawn by mid-winter, and then die. The run and spawning times vary between and within populations. Depending on river temperatures, eggs incubate in ‘‘redds’’ (gravel nests excavated by spawning females) for 1.5 to 4 months before hatching as ‘‘alevins’’ (a larval life stage dependent on food stored in a yolk sac). Once most of the yolk sac is absorbed, the 30 to 35 millimeter fish (then termed “fry”) begin emerging from the gravel in search of shallow stream margins for foraging and safety (NRC 2004). Coho salmon fry typically transition to the juvenile stage by about mid-June when they are about 50 to 60 mm, and both stages are collectively referred to as “young of the year.” Juveniles develop vertical dark bands or “parr marks”, and begin partitioning available instream habitat through aggressive agonistic interactions with other juvenile fish (Quinn 2005). Juveniles rear in fresh water for up to 15 months, then migrate to the ocean as ‘‘smolts’’ in the spring. Coho salmon typically spend 2 growing seasons in the ocean before returning to their natal stream to spawn as 3 year-olds. Some precocious males, called ‘‘jacks,’’ return to spawn after only 6 months at sea.

1.9.1 Spawning and Incubation

Females tend to prepare their redds (gravel nests) and spawn soon after arriving on spawning grounds between November and January with spawning timing varying by watershed within the ESU (Weitkamp et al. 1995). Coho salmon generally choose spawning sites near the head of a riffle, just below a pool where there is abundant small- to medium-size gravel (Shapovalov and Taft 1954). The number of fertilized eggs deposited in each redd is based on each female’s individual fecundity and fertilization success; fecundity ranges between 1,400 to 3,000 eggs (Sandercock 1991). These eggs are dispersed among pockets within the redd (Sandercock 1991). Larger females tend to produce larger and more abundant eggs. Migration distance can also influence egg production, with longer migrations inhibiting egg size and/or quantity (Kinnison et al. 2001). All these differences drive population-specific differences in fecundity and egg size (Beacham 1982, Hjort and Schreck 1982, Taylor and McPhail 1985, Swain and Holtby 1989, Fleming and Gross 1990, Murray et al. 1990).

Once spawning is complete, the female will cover the redd with gravel and guard it until her death (approximately 4 to 15 days; Weitkamp et al. 1995). Ultimately the success of reproduction depends on a number of environmental and biological factors that occur within the redd, the spawning site, and the watershed. Many of these factors are linked to the timing of reproduction.

Embryonic development begins when an egg is fertilized, and developmental rate and incubation period are inversely related to water temperature. In most streams in Oregon and California, incubation takes place between November and April and lasts from 38 to 48 days depending on water temperature (Shapovalov and Taft 1954). Alevins are the larval stage which hatches from the egg and is dependent on food stored in a yolk sac. Alevins remain in the redd after hatching, develop into fry in the redd, then emerge. The time between hatching and fry emergence is dependent on temperature as well as dissolved oxygen levels in the redd; fry can remain in the redd for 4 to 10 weeks. The total emergence period can last between 10 and 47 days. Fry emergence takes place between March and July, with peak emergence in March and May (Shapovalov and Taft 1954, Koski 1966). Fry are approximately 30 mm in length when they emerge, with earlier emergence linked to larger size and greater growth opportunity (Mason and Chapman 1965, Sandercock 1991). The percentage of eggs and alevins that survive to emergence is dependent on stream and riverbed conditions. Winter flooding, with its associated scour and gravel movement, accounts for a high proportion of losses. Low flows, freezing, heavy silt loads, bird and insect predation, and infection can also lead to mortality. Under very harsh conditions, no eggs or alevins will survive. Under average conditions between 15 to 27 percent will survive to emergence (Neave 1949, Crone and Bond 1976) and in favorable conditions between 65 to 85 percent will survive (Shapovalov and Taft 1954). Studies from California and Oregon found average survival to be between 27.1 percent and 74.3 percent (Briggs 1953, Koski 1966).

1.9.2 Rearing and Outmigration

After emergence, fry seek out shallow water along stream margins. Juvenile rearing usually occurs in tributary streams with a gradient of 3 percent or less, although they may move up streams with as much as 5 percent gradient (Agrawal et al 2005, Leidy et al. 2005). Juveniles have been found in streams as small as 1 to 2 meters wide. Typical juvenile rearing habitat consists of slow moving, complex pool habitat commonly found within small, heavily forested tributary streams (Moyle 2002, Quinn 2005). When rootwads, large woody debris, or other types of cover are present, growth is bolstered (Nielsen 1992). Increased growth is essential for juveniles because larger size confers higher over-wintering survival (Quinn and Peterson 1996).

The dominant life-history pattern is for juvenile coho salmon to feed and rear within the streams of their natal watershed for a year before migrating to the ocean. However, they may spend up to two years rearing in freshwater (Bell and Duffy 2007, Ransom 2007), or emigrate to an estuary shortly after emerging from spawning gravels (Tschaplinski 1988). The occurrence of age-0 "ocean-type" coho salmon migrants to the estuary, stream-estuary ecotone, or lower main-stem reaches has been documented throughout the range of coho salmon and is thought to be an alternative life-history strategy (Chapman et al. 1961; Chapman 1962; Hartman et al. 1982; Murphy et al. 1984; Rodgers et al. 1987, Au 1972, Kahler et al. 2001, Ryall and Levings 1987, Miller and Sadro 2003, Pinnix et al. 2013). Recent studies documenting various coho salmon juvenile life histories (Bennett et al. 2011, Roni et al. 2012, Pinnix et al. 2013, Quinn et al. 2013, Bennett et al. 2014, Jones et al. 2014) suggest coho salmon juveniles may have at least four life-history strategies in some basins (Bennett et al. 2014, Jones et al. 2014; Figure 1-2).

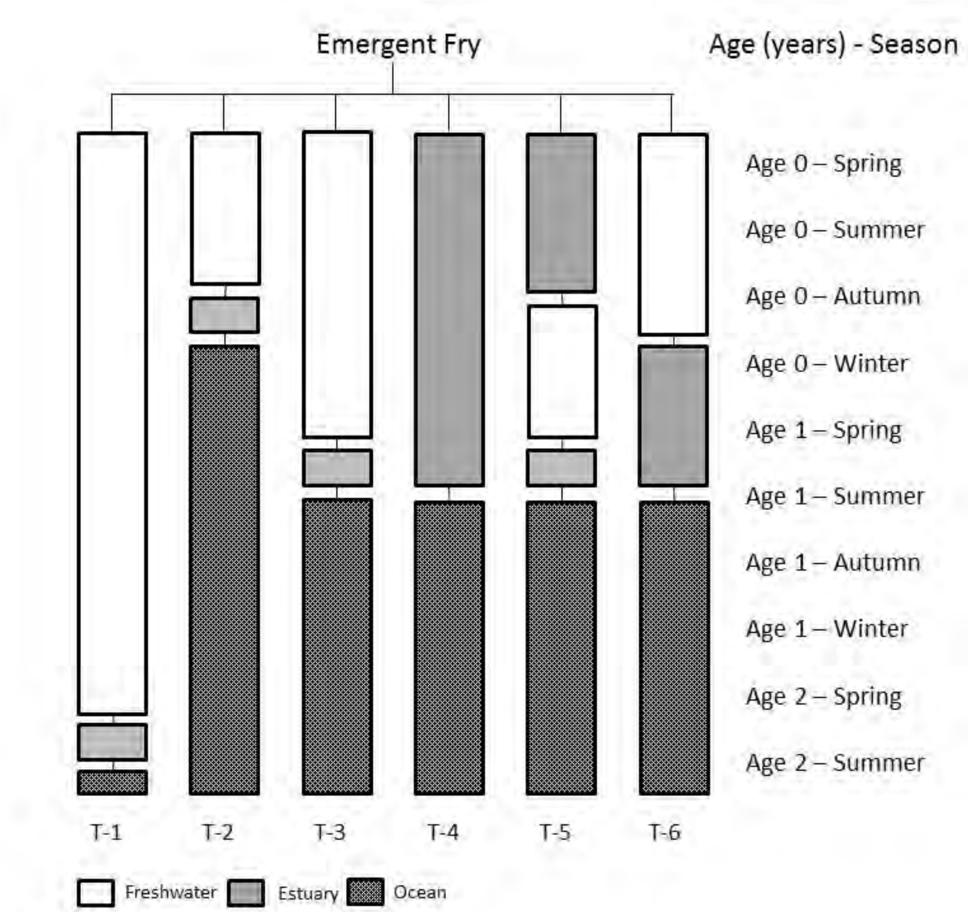

Figure 1-2. Types of life-history strategies of coho salmon juveniles. Figure modified from Jones et al. 2014.

In California and Oregon, some ocean-type coho salmon rear in the estuary during the spring, summer, and fall then return upstream to overwinter (Miller and Sadro 2003, Jones et al. 2014). This primarily occurs in watersheds with adequate estuarine rearing habitat (Merrell and Koski 1978). Extended freshwater residence in California streams has also been documented for age-1+ coho salmon (Bell and Duffy 2007, Ransom 2007). The proportion of a cohort that exhibited extended freshwater rearing ranged from 0 percent to almost 30 percent among Northern California streams and was linked most strongly to peak winter streamflow (Ransom 2007). Coho salmon also use non-natal streams for rearing, and redistribute into riverine ponds following fall rains (Peterson 1982, Ackerman and Cramer 2006, Soto et al. 2008, Hillemeier et al. 2009). For juvenile coho salmon that rear for at least a year in freshwater streams, this habitat offers the opportunity to grow prior to migration to larger rivers and the ocean. While rearing in such environments, coho salmon may grow slowly but experience a relatively low predation risk compared with downstream habitats (Quinn 2005).

Coho salmon fry may move upstream or downstream to rear after emergence. Coho salmon rearing areas include lakes, sloughs, side channels, estuaries, beaver ponds, low-gradient tributaries to large rivers, and large areas of slack water (PFMC 1999). During the rearing period, juveniles set up territories for feeding, especially in pool areas of streams (Hartman

1965). The abundance of coho salmon in streams is limited by the number of suitable territories available; streams with more complex habitat support larger numbers of fry (Scrivener and Andersen 1982, Larkin 1977).

During summer, juvenile coho salmon move into deep pools and areas with dense shade and large woody debris (LWD) for refuge from high water temperatures (Nickelson et al. 1992; Brown et al. 1994). A study of coho salmon occurrence in tributaries of the Mattole River suggested that a MWMT (maximum weekly maximum temperature) greater than 18.1 °C or a MWAT (highest average of mean daily temperature over any seven-day period) greater than 16.8 °C would preclude the occurrence of coho salmon. Lethal temperatures range from 24 to 30 ºC (McCullough 1999), but coho salmon can survive at high daily maximum temperatures if (1) high quality food is abundant, (2) thermal refugia are available, and (3) competitors or predators are few (NRC 2004).

In the winter, juvenile coho salmon avoid being washed out of their habitat by high flows by utilizing flow refugia including smaller tributary streams, intermittent streams, deeper pools, and large woody debris (Tripp and McCart 1983, Skeesick 1970, Narver 1978, Quinn and Peterson 1996, Solazzi et al. 2000). Ebersole et al. (2006 and 2009) found that coho salmon in a Washington stream moved into seasonally dry areas shortly after fall rains, and that these fish as well as those that moved into tributaries had higher survival than those that remained in the mainstem. In the Washington stream, off-channel ponds, large woody debris, and other floodplain habitat were scarce due to past land-use and geology, conditions shared across much of the SONCC coho salmon ESU. Ebersole et al. (2009) found that much of the variation in overwinter survival in this system was associated with winter discharge and the effects of high winter streamflows, emphasizing the need for high flow refugia. Large woody debris and other instream cover are heavily used by coho salmon in systems where these habitat features are more abundant (Nielsen 1992, Hardy et al. 2006), indicating the importance of access to cover while rearing.

The synchrony of arrival timing in coastal waters and the availability of food is especially critical for determining the survival rates of different cohorts (Walters et al. 1978). Many studies have shown that the timing of outmigration can have a large impact on the survival of coho salmon at sea (Pearcy 1992). Spence and Hall (2010) found patterns in outmigration of coho salmon smolts at 54 locations from central California to Kodiak Island, Alaska. They observed latitudinally-associated differences in duration, season, and variability in timing of migration across years, which they attributed to regional differences in the predictability and timing of favorable marine conditions. Spence and Dick (2014) examined short-term probability of migration of four coho salmon populations in the North Pacific (Canada and Oregon) that entered the ocean in different ocean production domains. Two factors, amount of daylight and water temperature, explained migration timing in the farthest northern location, while migration in Oregon sites was tied to numerous environmental factors [amount of daylight, water temperature (absolute and change), flow (absolute and change), and lunar phase] and migration in the southern Canadian site, was influenced by all these factors except lunar phase. There is likely selective pressure on coho salmon smolts to begin smoltification and to enter the ocean at times when ocean conditions will be most favorable, and there is latitudinal variability in how predictable these ocean conditions are due to different ocean production domains (Spence and Dick 2014). The southernmost populations, closest to the SONCC coho salmon ESU, responded to the most environmental cues, suggesting that the timing and predictability of ocean conditions in these areas was less predictable than in areas to the north.

Downstream migration of coho salmon in the SONCC coho salmon ESU begins in the spring sometime between April and May and continues into June. Most smolts measured between 90 and 115 mm fork length. Factors affecting the onset of emigration include the size of the fish, flow conditions, water temperature, dissolved oxygen (DO) levels, day length, and the availability of food (Shapovalov and Taft 1954). Smolt migration timing is affected by anthropogenic activities, including habitat degradation (Moring and Lantz 1975, Scrivener and Andersen 1984, Holtby and Scrivener 1989), and habitat restoration (Johnson et al. 1993, Rodgers et al. 1993). Beeman et al. (2012) documented a positive relationship between flow volume and travel time and survival of juvenile coho salmon in the mainstem Klamath River. The anthropogenic activities listed above may influence migration timing by affecting environmental factors such as temperature (Scrivener and Anderson 1984) and flow (Beeman et al. 2012).

A juvenile’s downstream migration to the ocean is accompanied by a series of internal changes in morphology, physiology, and behavior needed for a transition to saltwater. Travel rates to reach the ocean are determined by flow rates, date, and distance as well as individual based characteristics such as the extent of parr-smolt transformation. Travel rates increase with flow rates and travel distance. Fish migrating later in season also move faster than fish migrating earlier in the year (Dawley et al. 1986). Mortality from downstream migration is positively correlated to the distance traveled and has been linked to predation and hydropower operations in past studies (Quinn 2005).

Once juveniles reach the estuary, they will spend a variable amount of time completing the juvenile-to-smolt transformation. Estuarine residence is dependent on variety of factors, many of which remain unknown for this species of salmon. Growth rates in estuaries are generally higher than in freshwater habitats, and many juvenile coho salmon take advantage of feeding opportunities and time to transition to salt water while in the estuary. Depending on the opportunity and capacity of the estuary, coho salmon on the Oregon and California coast will spend a few days to a few weeks in the estuary (Miller and Sadro 2003, Clements et al. 2012, Pinnix et al. 2013, Jones et al. 2014).

Large smolts have higher ocean survival than small smolts (Bilton et al. 1982, Henderson and Cass 1991, Lum 2003, Quinn 2005, Jokikokko et al. 2006, Muir et al. 2006). In addition, larger smolts produce larger adults (Lum 2003, Henderson and Cass 1991), which have higher fecundity than smaller adults (Weitkamp et al. 1995, Fleming 1996, Heinimaa and Heinimaa 2004). The average size of outmigrating coho salmon is approximately 128 mm with the largest smolts originating from the Trinity River (mean 147 mm) and the smallest originating from Blue Creek on the Klamath River (mean 104 mm). The large sizes of Trinity River smolts likely results from hatchery operations in that basin, which produce larger than average smolts. The range of smolts sizes in the SONCC coho salmon ESU is between 90 and 200 mm (Weitkamp et al. 1995).

SONCC coho salmon have evolved multiple life-history strategies, which encompass a range in timing of outmigration and amount of time spent in the river or estuary by migrating smolts. The earliest outmigration in the SONCC coho salmon ESU occurs in Roach Creek on the Klamath River and Ten Mile Creek on the Eel River (March or earlier). The latest occur in the South Fork of the Eel River (mid-June or later). Because of this, the Eel River has the broadest range of outmigrant timing (March to August; Weitkamp et al. 1995).

1.9.3 Ocean Migration

Early ocean migration patterns of young coho salmon have been described in a number of studies (e.g., Weitkamp et al. 1995, Weitkamp et al. 2004, Van Doornik et al. 2007). By the beginning of their first winter at sea, coho salmon begin to move into feeding grounds. Studies using coded wire tags (CWT) have shown that this dispersal at sea is regionally specific, with coho salmon from northern California and Oregon south of Cape Blanco dispersing locally (Weitkamp and Neely 2002). These fish were recovered primarily in California (65 to 92 percent), with some recoveries in Oregon (7 to 34 percent) and almost none (<1 percent) further north. Compared with other coho salmon populations, the SONCC coho salmon ESU has a comparatively small marine distribution. Coho salmon occur in the upper part of the water column in the open ocean, at observed depths of from about 10 to 25 m (summarized by Quinn 2005).

One potential reason SONCC coho salmon do not move farther north is the productivity associated with upwelling areas off the coast of California, which provide high densities of food (Moyle 2002). When they first enter coastal areas, coho salmon feed primarily on marine invertebrates; as they grow larger, they shift to more piscivorous diets (Shapovalov and Taft 1954). Coho salmon feed opportunistically on a variety of prey including small pelagic fishes, shrimp, crab and crab larvae, and other pelagic invertebrates (Sandercock 1991). Growth associated with feeding opportunities at sea is rapid and most fish can double their length and increase their weight more than tenfold their first summer.

While there are many opportunities for growth at sea, coho salmon experience high predation pressures and steep mortality. Studies of smolt-to-adult survival place estimates between 1 percent and 10 percent with the greatest mortality during the first summer at sea. Factors such as size, physiological condition, migration date, and ocean conditions can all influence mortality, and under optimum conditions survival can be as high as 40 percent (Sandercock 1991). In addition to ocean entry timing as a factor influencing survival (as discussed above), size is also important in minimizing mortality since much of the predation that occurs at sea is size-selective (McGurk 1996, Shapovalov and Taft 1954). Generally, small fish have higher mortality rates than larger fish up until about 100 mm (Koenings et al. 1993). Predation is thought to be an important cause of mortality on smaller fish in their first year at sea and has less of an impact on adult populations.

1.9.4 Maturation

The growth and survival of adult coho salmon is closely linked to marine productivity, which is controlled by complex physical and biological processes that are highly dynamic and vary greatly over space and time. Shifts in salmon abundance due to climatic variation are known to be large and sudden (Beamish et al. 1999). Short and long-term cycles in climate [e.g., El Niño/La Niña and the Pacific Decadal Oscillation] are thought to affect adult coho salmon size, abundance, and distribution at sea, as does inherent year-to-year variation in environmental conditions not associated with climatic cycles. Several studies have related ocean conditions specifically to coho salmon production (Cole 2000), survival (Ryding and Skalski 1999, Koslow et al. 2002), and spatial and temporal patterns of survival and body size (Hobday and Boehlert 2001, Wells et al. 2006). The link between survival and climate could be operating via the availability of nutrients regulating the food supply and hence competition for food (Beamish and Mahnken 2001). For example, the 1983 El Niño event off the Pacific coast of North America resulted in increased adult mortality and decreased average size for Oregon's returning coho salmon. Juvenile coho salmon entering the ocean in the spring of 1983 also had low survival, resulting in low adult returns in 1984 (Johnson 1988). Larger-scale decadal to multi-decadal events also have been shown to affect ocean productivity and coho salmon (Hare and Francis 1995; Mantua et al. 1997; Beamish et al. 1997a; Beamish et al. 1999; Pearcy 1992; Lawson 1993). Although salmon evolved in this variable environment and are well suited to withstand climactic changes, the resiliency of the adult population has been reduced by the loss of life-history diversity, lower population abundance, cohort loss, and fragmentation of the spatial population structure. Changes in the freshwater environment (e.g., loss and degradation of habitat) have also weakened the ability of coho salmon to respond to the natural variability in ocean conditions.

The age composition and size of coho salmon at maturity is influenced by a number of factors including growth rate, sex, origin (either hatchery or wild and population), and genetic makeup (Quinn 2005). Due to variation in these factors, coho salmon exhibit a range of ages and sizes at maturation. The most common life-history strategy for coho salmon in the SONCC coho salmon ESU is a fairly strict 3-year life cycle, with most coho salmon spending approximately 18 months at sea before returning to their natal rearing grounds to spawn (Gilbert 1912, Briggs 1953, Shapovalov and Taft 1954, Loeffel and Wendler 1968, Weitkamp et al. 1995). The most recent data show that the average size of returning adults in Oregon and California is between 56.4 and 64.6 cm (average 62.7). Variations to this life-history do exist and some fish return after only 5 to 7 months at sea. These "jacks" that return early keep runs from being genetically isolated based on a strict 3-year return year. In general, coho salmon that migrate earlier than average and at a size larger than average are believed to produce a higher rate of jack returns (Bilton et al. 1984). Studies have shown highly variable numbers of returning jacks to Oregon and California streams, possibly due to the influence of hatchery fish. Jacks in the Klamath River made up to 97 percent of returns in one year between 1984 and 1987 (average 59 percent) (Hopelain 2001). Other studies have shown the jacking rate ranges from 7 percent to 34 percent (e.g., Murphy 1952).

The size of coho salmon when they reach maturity also exhibits spatial and temporal variability along with the age at maturity. Size is dependent on factors related to growth and genetic heritage with the sex, origin, age, and run timing all influencing the size of a fish when it reaches maturity. In general, coho salmon in later runs tend to be larger than those in earlier runs (Sandercock 1991), coho salmon from mainstem areas are often larger than those spawning in tributaries (Lister et al. 1981), males tend to be larger than females, and older fish are larger than younger fish. Of available data from southern Oregon and northern California streams and rivers, the smallest spawners tend to come from the Rogue River (average 56 cm between 1976 to 1986) and the largest tend to come from Redwood Creek (average 76.1 cm between 1950 to 1951). The range for this area is between 30 and 91 cm (Weitkamp et al. 1995).

One overall trend across the range of coho salmon is the observed decrease in size of mature fish over the past 50 years. Harvest practices, effects of fish culture, declining ocean productivity, and density-dependent effects in the marine and freshwater environments attributable to large numbers of hatchery releases are potential factors leading to this decline. Weitkamp et al. (1995) noted that the rate of this decline are population, or area, specific with the highest rates of decline in Oregon and California being observed in Rogue River spawners (Slope = -1.50). The CA and OR troll data on coho size also supports a regional decline in size (Slope = -0.05). In the few creeks within the SONCC coho salmon ESU with historical and current data for comparison, average declines averaged between 1.1 and 4.2 cm per decade. These declines in adult size have direct implications for individual reproductive success and population viability because smaller spawners have lower fecundity.

1.9.5 Homeward Migration and Spawning

Timing and location of reproduction are two of the most critical adaptations salmon populations make to their environment. Salmon are uniquely evolved in their ability to take advantage of feeding and growth opportunities at sea and optimal spawning conditions in freshwater streams and rivers. Once a salmon starts the process of maturation, it begins a homeward migration to the location in which it was spawned. Once adult coho salmon reach nearshore and estuarine waters they are able to use imprinted chemical cues to help guide them. Imprinting in fry occurs shortly after emergence and is based on stream-specific or population-specific characteristics of their natal stream.

About 95 to 99 percent of all salmon return to their natal stream using these imprinted cues, however a small percentage (the magnitude of which varies temporally and by population) are “strays,” meaning they spawn in streams they were not born in (Quinn 2005). Whether this characteristic of adult coho salmon is genetically, behaviorally, or environmentally influenced is unknown, but ultimately the occurrence of straying contributes to the persistence and distribution of populations and the entire ESU. As a general rule, straying is linked to the stability and degree of specialization of a population or its spawning habitat. Populations occupying “flashy” or steep, unstable coastal streams are more likely to exhibit non-natal rearing as are small coastal streams that require little or no specialization for spawning. Information on straying rates for coho salmon in California is sparse, but Shapovalov and Taft (1954) reported values between 15 percent and 27 percent for Scott and Waddell Creek. Other genetic studies of California coho salmon populations show differences among populations that suggest lower effective straying rates. Fish that do stray are most commonly found in spawning areas near their natal stream (Shapovalov and Taft 1954, Jacobs 1988, Labelle 1992).

Upriver migration of adults to spawning areas normally occurs from October to March for populations in the SONCC coho salmon ESU, with a peak between November and January. For most populations, the duration of spawning migration is at least three months or more. Coho salmon river entry timing is influenced by many environmental and genetic factors, the most important of which is river flow (Shapovalov and Taft 1954, Salo and Bayliff 1958, Sumner 1953, Eames et al. 1981, Lister et al. 1981). Coho salmon generally wait for freshets before entering rivers, so a delay in fall rains delays river entry and, potentially, spawn timing as well. Many of the small coastal streams in California are barred over by sand at their mouths, and coho salmon in these streams have to wait to ascend until the sand barriers are breached by high stream flows that follow heavy winter rains. Once a fish enters a river, if conditions in the stream are unsuitable for entry, fish will often wait (or "hold") in the vicinity of the stream mouth for conditions to change, usually marked by a decreasing temperature and increasing flow. This holding allows coho salmon to reach further into headwater streams where good spawning and rearing conditions may exist.

Because of the influence of environmental drivers, run timing shows considerable spatial and temporal variability. Large river systems are especially diverse in terms of coho salmon run timing. For example coho salmon runs in the Klamath River can last over four months with various populations entering the system from late August to mid-January (Washington Department of Fisheries (WDF) 1951, Leidy and Leidy 1984, WDF et al. 1993, Polos 1994). In terms of large-scale spatial patterns in run timing, Weitkamp et al. (1995) found some regional patterns that define the SONCC coho salmon ESU. Coho populations in southern Oregon and northern California tend to have later run timing than population to the north. There also appears to be a wider range of timing, with some runs starting in late August (Klamath) and most lasting into mid-February.

Once conditions are favorable, adult coho salmon migrate into spawning areas along the coast and in small tributaries of larger rivers. Coho salmon migrate further upstream than chum salmon but not usually as far as Chinook. In general, coho spawning grounds are within 240 km of the coast (Godfrey 1965). Large river systems like the Klamath, Trinity, Eel, and Rogue Rivers historically supported coho salmon in their upper tributaries (Williams et al. 2006). Once adult fish reach the spawning grounds, they can spend days, weeks, or months waiting to spawn. During this time salmon are subject to predation and disease prior to spawning.

2. Structure, Viability, and Status of the SONCC Coho Salmon ESU

The SONCC coho salmon ESU must meet the criteria described in Chapter 4 for NMFS to determine it has recovered to the extent that the protections of the Federal Endangered Species Act could be removed,. Chapter 2 describes the underpinnings of these population-related criteria. These criteria are based on guidance provided in two NOAA Technical Memoranda, which describe the historical population structure and biological viability criteria, respectively, for the SONCC coho salmon ESU (Williams et al. 2006, Williams et al. 2008).

2.1 Intrinsic Potential

2.1.1 Modeling Intrinsic Potential of Historical Habitats

Spawner abundance serves as an important indicator of viability and extinction risk, and for salmon it is heavily influenced by the extent and quality of available freshwater habitat. An estimate of historical habitat carrying capacity can serve as an indirect means of estimating the number of adults needed to reach viability. Because of degraded current freshwater habitat conditions, which often differ from historical conditions, recovery planners need a method that estimates the extent and capacity of watersheds to support coho salmon prior to the major anthropogenic impacts to habitat which began in the mid-1800s. Williams et al. (2006) characterized the historical extent and carrying capacity of SONCC coho salmon streams by using a GIS-based model. This "IP" model "…predicts the potential for a stream reach to exhibit habitat characteristics suitable for rearing juvenile coho salmon, as a function of the underlying geomorphic and hydrologic characteristics of the landscape (Williams et al. 2006)." The IP model provides recovery planners with a framework to develop a recovery strategy for the SONCC coho salmon ESU.

To account for differences in habitat suitability across the landscape, three habitat components were modeled to serve as predictors of historical habitat suitability (Figure 2-1): stream gradient, valley constraint, and average annual discharge (based on catchment area and localized precipitation data). For each stream reach (50-200 m) in the SONCC coho salmon ESU, each of the three attributes was scored from zero to one and the geometric mean of the scores was calculated. A score of one indicates reaches with the most intrinsic potential to support rearing juvenile coho salmon, and a score of zero indicates areas with no such potential. For example, a narrow and steep stream reach with little predicted flow has low potential to support quality rearing habitat and would likely score close to zero, while a low-gradient stream with a bigger floodplain and more predicted flow has more potential to support quality rearing habitat and would score closer to one. The IP score for each reach in a population area was multiplied by its respective reach length and the values for each reach in a population were added to identify the total integrated IP in kilometers (km) for that population (Figure 2-2). The number of IP-km in a population was used to classify each population (Williams et al. 2006) and to calculate spawner abundance targets (Williams et al. 2008).

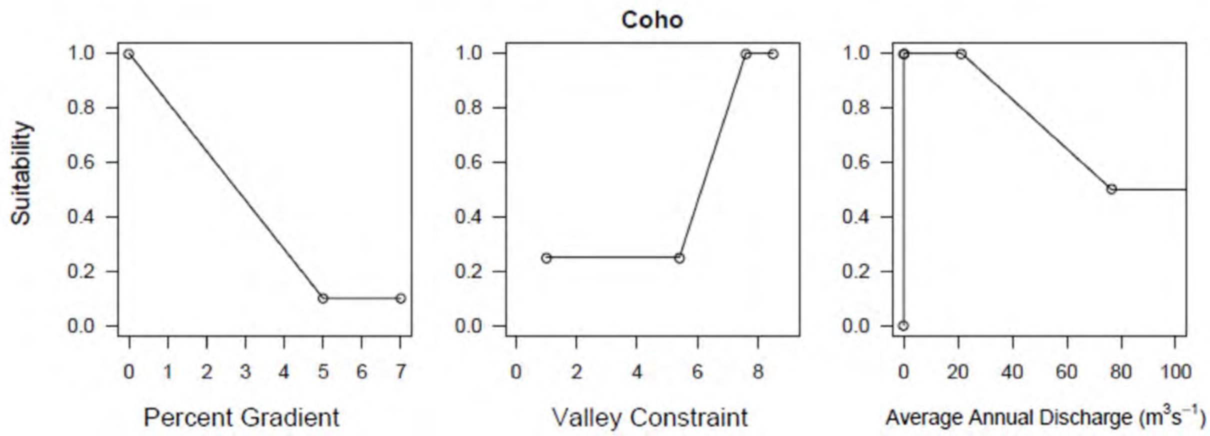

Figure 2-1. Suitability curves for each of the three IP components (Gradient, Valley Constraint, and Discharge). Source: Agrawal et al. 2005.

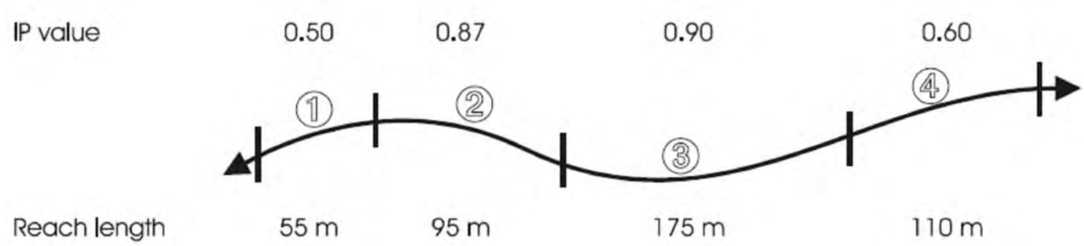

No.	Reach length (m)	IP value	Integrated IP (IP m)
1	55	0.50	27.5
2	95	0.87	82.65
3	175	0.90	157.50
4	110	0.60	66.00
Total	435	-	333.65

Figure 2-2. Calculation of integrated intrinsic potential (IP) from reach-specific IP values. Source: Williams et al. 2006.

Summer water temperatures in the interior portions of some large drainages in the ESU (i.e., Rogue, Klamath, Trinity, and Eel rivers) can approach or exceed the tolerable limits for juvenile coho salmon (Eaton et al. 1995). Where this occurs, temperature might preclude coho salmon from using areas that, based on geomorphic and hydrologic characteristics, would otherwise be suitable. Comprehensive data on water temperatures were not available for the ESU, and the available water temperature data was likely influenced by land-use practices that altered temperature regimes in comparison to historical conditions. Therefore, to identify areas where temperature might limit the distribution of coho salmon, Williams et al. (2006) combined information on the historical distribution of coho salmon and mean August air temperature to identify a threshold temperature above which juvenile coho salmon generally do not occur. This analysis found that coho salmon were rarely reported as present in watersheds where the lowest mean August air temperature in the basin exceeded 21.5 °C (Agrawal et al. 2005); this temperature is comparable to the maximum tolerable water temperature for coho salmon reported by Eaton et al. (1995). Therefore, a 21.5 °C threshold (i.e., temperature mask was used to modify results from the IP model by identifying IP-km in areas where coho salmon are likely to be excluded by warm temperature, and excluding these IP-kms from calculation of spawner targets.

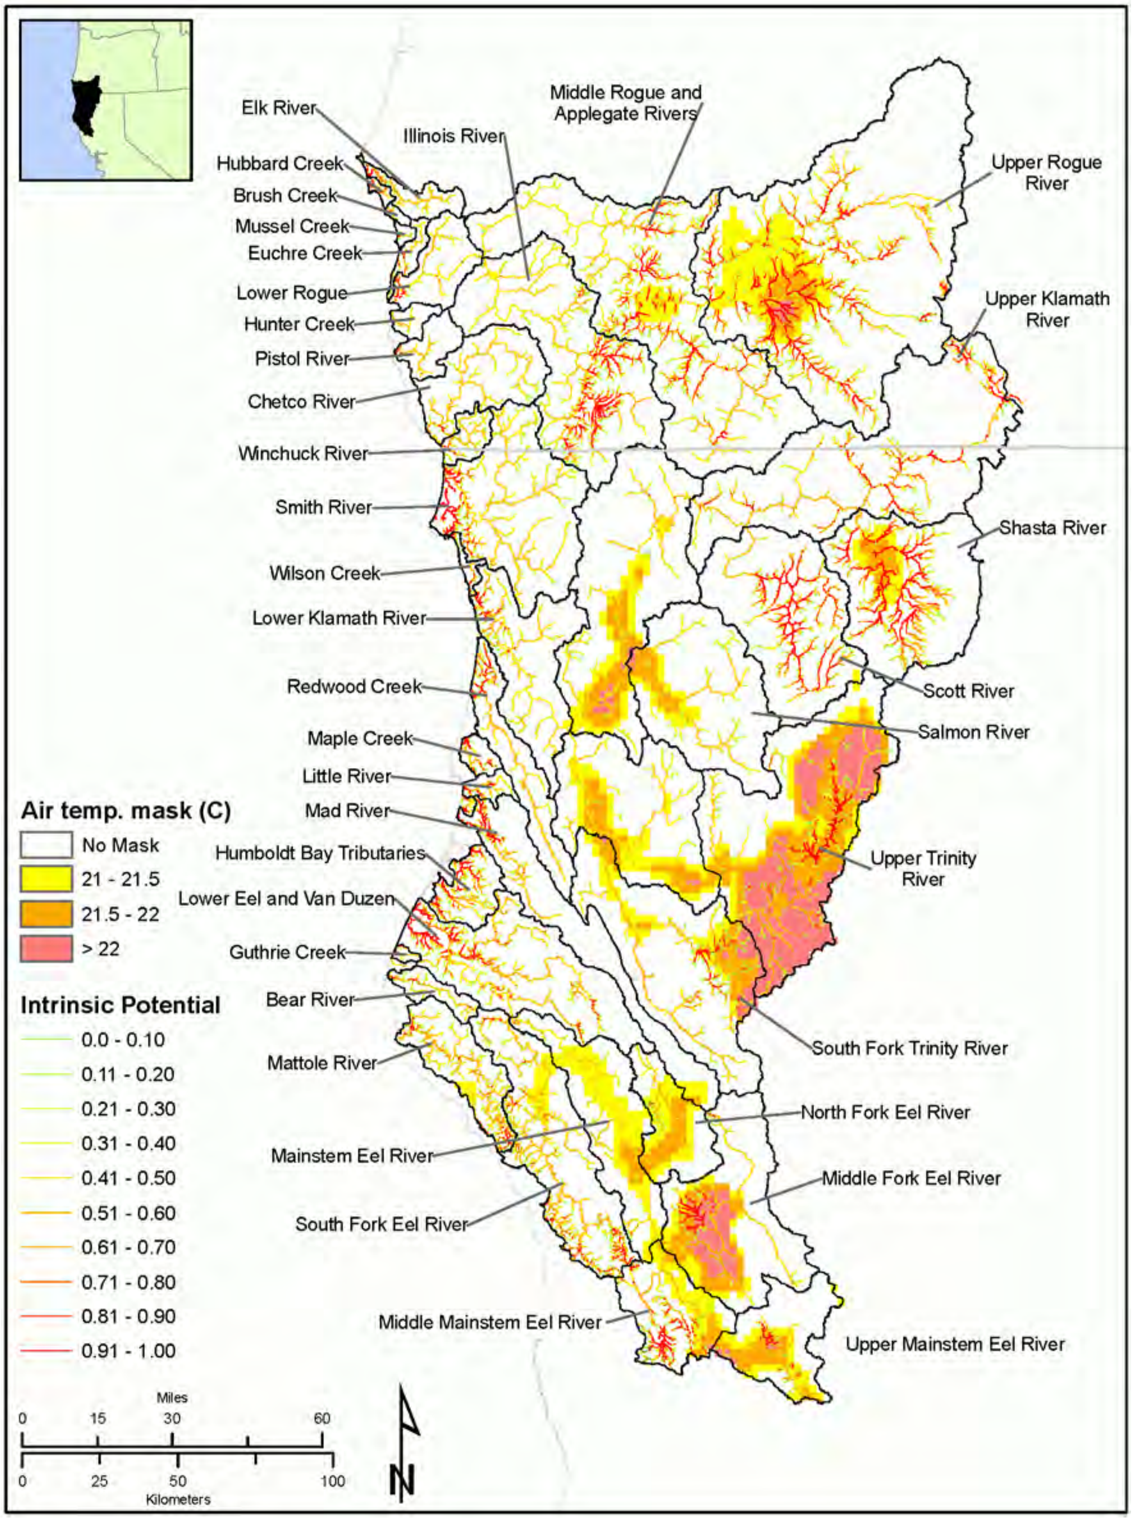

Figure 2-3. Intrinsic Potential for coho salmon across the SONCC Coho Salmon ESU, including areas where coho salmon are likely to be excluded by warm temperature indicated by temperature mask (from Williams et al. 2006).

2.1.2 IP Model Assumptions and Uncertainty

Williams et al.'s (2006) use of the IP model to identify potentially suitable coho salmon habitat rests on two assumptions. The first assumption is that the suitability curves (Figure 2-1), which translate geomorphic and hydrologic characteristics into IP, apply to watersheds in the SONCC Coho Salmon ESU as they do for the Oregon Coast Range where the model was originally developed. Williams et al. (2006) lacked local data from which to develop region-specific suitability curves and therefore "…assumed that either the suitability curves based on data from the Oregon Coast Range applied to watersheds in southern Oregon and northern California, or that the relationship between watershed characteristics and habitat potential throughout the SONCC Coho Salmon ESU differed from that observed in Oregon in a uniform and consistent way." An extensive literature search provided no basis for choosing alternative suitability curves for the SONCC coho salmon ESU (Agrawal et al. 2005).

The second assumption was that differences in geomorphic structure and processes between the Oregon Coast Range and the SONCC Coho Salmon ESU, although present, do not require modification of the IP components (gradient, discharge, valley-width constraint) (Williams et al. 2006). One of the most substantial differences among coastal watersheds in Oregon and California could be the amount and timing of precipitation, especially as one moves south along the coast (Williams et al. 2006). Williams et al. (2006) attempted to account for this variation by estimating regional models for mean annual discharge as a function of catchment area and mean annual precipitation (Agrawal et al. 2005). The relationships estimated for coastal watersheds north of Cape Mendocino were almost identical to that reported for coastal Oregon watersheds. Following an extensive literature search, Williams et al. (2006) found little to suggest the need to modify the IP components calculated for the Oregon Coast Range before using them for the SONCC Coho Salmon ESU.

NMFS is aware that the modeling approach used to estimate historical capacity of a stream reach may result in estimates that can be biased (i.e., can under- or over-estimate historical capacity). Recently updated coho salmon distribution datasets (Garwood 2012 and Bowers 2013) report documented coho salmon presence extending upstream of IP habitat in several populations. For example, coho salmon are distributed in the lower 8.4 miles of Bluff Creek in the Middle Klamath, none of which was identified as IP. Conversely, habitat believed to be unsuitable for coho salmon due to geologic conditions was modeled as IP habitat (and subsequently removed, see Appendix A) in the Big Springs Complex of the Shasta River (Appendix A). Recent research in Oregon (Steel et al. 2012, Flitcroft et al. 2013a) identified IP as a significant predictor of coho distribution for areas that support a large number of fish. The IP model as a whole provides the best available scientific information on the historical population structure of the ESU and on appropriate targets for a recovered SONCC coho salmon ESU.

IP-based viability criteria are ***not*** estimates of historical abundance. Rather, the criteria describe the number of spawners that are likely to lead to viable populations in terms of abundance and spatial structure. Comparisons of historical abundance estimates and IP model-driven density-based abundance targets for coastal watersheds in Oregon and the South Fork Eel River in California suggest that the methods used in Williams et al. (2006) do not overestimate the historical carrying capacities of coho salmon populations. In all instances, the target abundance is between 3% and 12% of the estimated historical abundance. As ESU- and population-specific research and monitoring occur, changes to the model and the resulting population thresholds could be warranted (Williams et al. 2008), and the recovery plan will be updated with the best available information.

NMFS acknowledges there is uncertainty regarding the IP model's ability to predict the potential of habitat to support rearing SONCC coho salmon. Several co-managers and members of the public have expressed concern that the IP model likely over-estimates the potential of particular streams, and that the use of the IP model to develop spawner targets in particular populations is not appropriate. The IP model and associated habitat suitability curves, temperature mask, and spawner density criteria provide an initial framework for recovery planners that can be adjusted or replaced as the best available information relevant to SONCC coho salmon habitat utilization and viability parameters improves over time. For example, if new research demonstrates SONCC coho salmon can tolerate higher temperatures than current information suggests, NMFS may update the temperature mask. Additionally, if new information suggests spatial structure and diversity needs of SONCC coho salmon can be realized at lower spawner densities than this Plan currently requires, NMFS may update the spawner density criteria.

IP habitat should not be confused or associated with modeled critical habitat. IP habitat is identified using a coarse-scale model which is one of many tools one can use to estimate the current or historical extent of anadromy. Although a useful tool to visualize the estimated historical range of SONCC coho salmon, other approaches can be used to provide greater insight into the possible presence of migration barriers. The IP model depends on appropriate and accurate Digital Elevation Models (DEM) which are subject to improvement (i.e., finer resolution) or refinement/corrections (e.g., a road crossing with culvert may appear as a natural barrier in DEM). Modeled IP habitat lacks the precision needed to determine whether a specific reach meets the description of designated critical habitat for the SONCC coho salmon ESU "to include all river reaches accessible to listed coho salmon between Cape Blanco, Oregon and Punta Gorda, California" (50 CFR 226.210(b)). Therefore, alterations to the extent of modeled IP habitat for use in this Plan, such as removal of IP habitat above a probable natural barrier, would not necessarily modify designated critical habitat for the SONCC coho salmon ESU.

Oregon Department of Fish and Wildlife concerns with recovery framework

The Oregon Department of Fish and Wildlife (ODFW) has concerns that the methods used to produce Williams et al. (2006) may overestimate the extent of historical coho production in the populations within the Northern Coastal and Interior Rogue diversity strata. Further, ODFW believes these methods may have led to inaccurate characterizations of historical populations as larger than they likely were. Finally, ODFW believes the low-risk targets for core populations may not need to be achieved if the other 3 VSP criteria are being met. This has been identified as a critical research need in Chapter 5 and NMFS intends to work with partners to reevaluate the population structure, and associated recovery criteria, within the Northern Coastal and Interior Rogue diversity strata as part of a conservation planning process. ODFW is in general agreement with NMFS on the recovery actions needed for Oregon populations, including a recovery action (present in all populations) that calls for refinement of the methods used to delineate populations and set population targets.

2.2 Historical Structure and Function of the ESU

2.2.1 Classifying Populations

Williams et al. (2006) describes the population structure of SONCC coho salmon based on the location and amount of potential coho salmon habitat and identifies all the populations in the ESU and their demographic characteristics. A population is defined as a group of fish of the same species that spawns in a particular location at a particular season and does not interbreed substantially with fish from any other group (McElhany et al. 2000). An integral element of determining the historical population structure for the ESU was estimating the distribution of potential juvenile rearing habitat within each basin. This was accomplished using both historical records and the IP model (Williams et al. 2008).

Watersheds across the ESU vary greatly in size. Large basins, such as the Klamath River watershed, support multiple populations because they contain several large rivers or streams which vary in terms of their environmental conditions and each support populations. Small watersheds probably did not historically support viable populations, but are not necessarily a part of a larger population. In the development of the historical population structure, Williams et al. (2006) recognized the full range of coho salmon habitat in the SONCC coho salmon ESU.

Williams et al. (2006) adopted a population classification system based on two factors: self-recruitment and viability-in-isolation. Self-recruitment reflects the proportion of a population's spawners that are native (not strays), and is a function of the size of the population, the size of potential donor populations, and the distance between populations. Viability-in-isolation is based on the probability of extinction for a population in complete isolation from all other populations. A population that has a low (<5%) probability of extinction over 100 years would be viable-in-isolation. Viability-in-isolation is assessed as a function of population size using IP-km as a proxy.

Williams et al. (2006) treated self-recruitment and viability-in-isolation as two axes, resulting in four types of historical populations depending on the estimated values of these two factors (Figure 2-4).

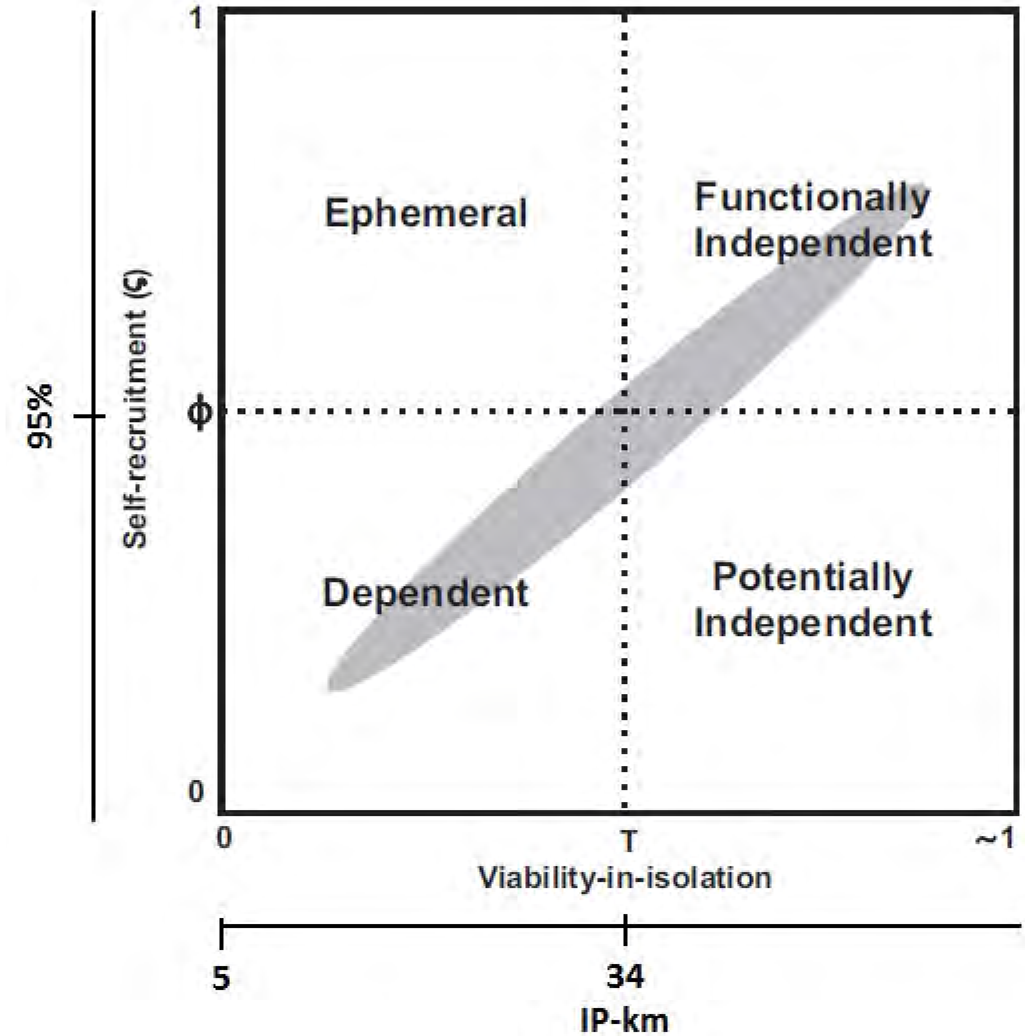

Figure 2-4. Population type as a function of viability-in-isolation and self-recruitment. Figure modified from Williams et al. (2006).

Those populations that are viable-in-isolation are potentially or functionally independent populations. Those which are not viable-in-isolation are either dependent or ephemeral. The boundary between independent and dependent populations is determined by the habitat capacity [estimated using IP-km]), below which there is a low likelihood of a population persisting without migrants from other populations. Populations that have at least 5 but less than 34 IP-km have relatively lower viability-in-isolation and are designated as dependent if they have less than 95 percent fidelity (0.95 self-recruitment) or ephemeral if they have more than 95 percent fidelity. Basins with less than 5 IP-km are not recognized as populations. Independent populations that have 95 percent fidelity (0.95 self-recruitment) are designated as functionally independent, while populations that have less than 95 percent fidelity are potentially independent. Williams et al. (2006) describes in detail the values assigned to each population.

Although Williams et al. (2006) recognized 45 populations in the ESU, due to subsequent modifications to the IP-km for several populations, and exclusion of populations that are too small to be dependent, this recovery plan considers 40 populations. Modifications to IP are described in Appendix A.

The type of each population is as follows:

Functionally Independent Populations are those with a high likelihood of persisting in isolation over a 100-year time scale and are not substantially altered by exchanges of individuals with other populations.

Potentially Independent Populations have a high likelihood of persisting in isolation over a 100-year time scale, but are too strongly influenced by immigration from other populations to exhibit independent dynamics.

Dependent Populations have a substantial likelihood of going extinct within a 100-year time period in isolation, yet receive sufficient immigration to alter their dynamics and extinction risk, and presumably increase persistence or occupancy.

Ephemeral Populations[3] do not have a high likelihood of sustaining themselves over a 100-year time period in isolation, and do not receive sufficient immigration to affect this likelihood. Habitats that support such populations are expected to be occupied only rarely. This type of population is not included in this recovery plan and is not considered further.

Dependent populations, although not expected to persist in the long-term (100 years) without strays from other populations, serve at least two roles within an ESU (Williams et al. 2006). If an independent population is extirpated, dependent populations can provide a nearby source of colonists to repopulate the area. Dependent populations are also critically important for bridging spatial gaps to allow dispersal of spawners between independent populations, and so increase connectivity.

2.2.2 Grouping Populations into Diversity Strata

Williams et al. (2006) separated populations into seven diversity strata. Populations in each diversity stratum likely exhibit genotypic and phenotypic similarity to each other due to exposure to similar environmental conditions, common evolutionary history, and location relative to each other (Table 2-1; Williams et al. 2006). Figure 2-5 shows the historical structure and function of the SONCC coho salmon ESU as described in Williams et al. (2006).

[3] Ephemeral populations were not considered when developing the recovery strategy for SONCC coho salmon described in this recovery plan and will not be discussed further.

Table 2-1. Arrangement of historical populations of the SONCC coho salmon ESU. Population types are functionally independent (F), potentially independent (P), and dependent (D).

Diversity Stratum	Population Type	Population Unit
Northern Coastal Basins	F	Elk River
	P	Lower Rogue River
	F	Chetco River
	P	Winchuck River
	D	Brush Creek
	D	Mussel Creek
	D	Hunter Creek
	D	Pistol River
Central Coastal Basins	F	Smith River
	F	Lower Klamath River
	F	Redwood Creek
	D	Maple Creek/Big Lagoon
	P	Little River
	F	Mad River
	D	Elk Creek
	D	Wilson Creek
	D	Strawberry Creek
	D	Norton/Widow White
Southern Coastal Basins	F	Humboldt Bay Tributaries
	F	Low. Eel/Van Duzen Rivers
	P	Bear River
	F	Mattole River
	D	Guthrie Creek
Interior Rogue River	F	Illinois River
	F	Mid. Rogue/Applegate Rivers
	F	Upper Rogue River
Interior Klamath River	P	Middle Klamath River
	F	Upper Klamath River
	P	Salmon River
	F	Scott River

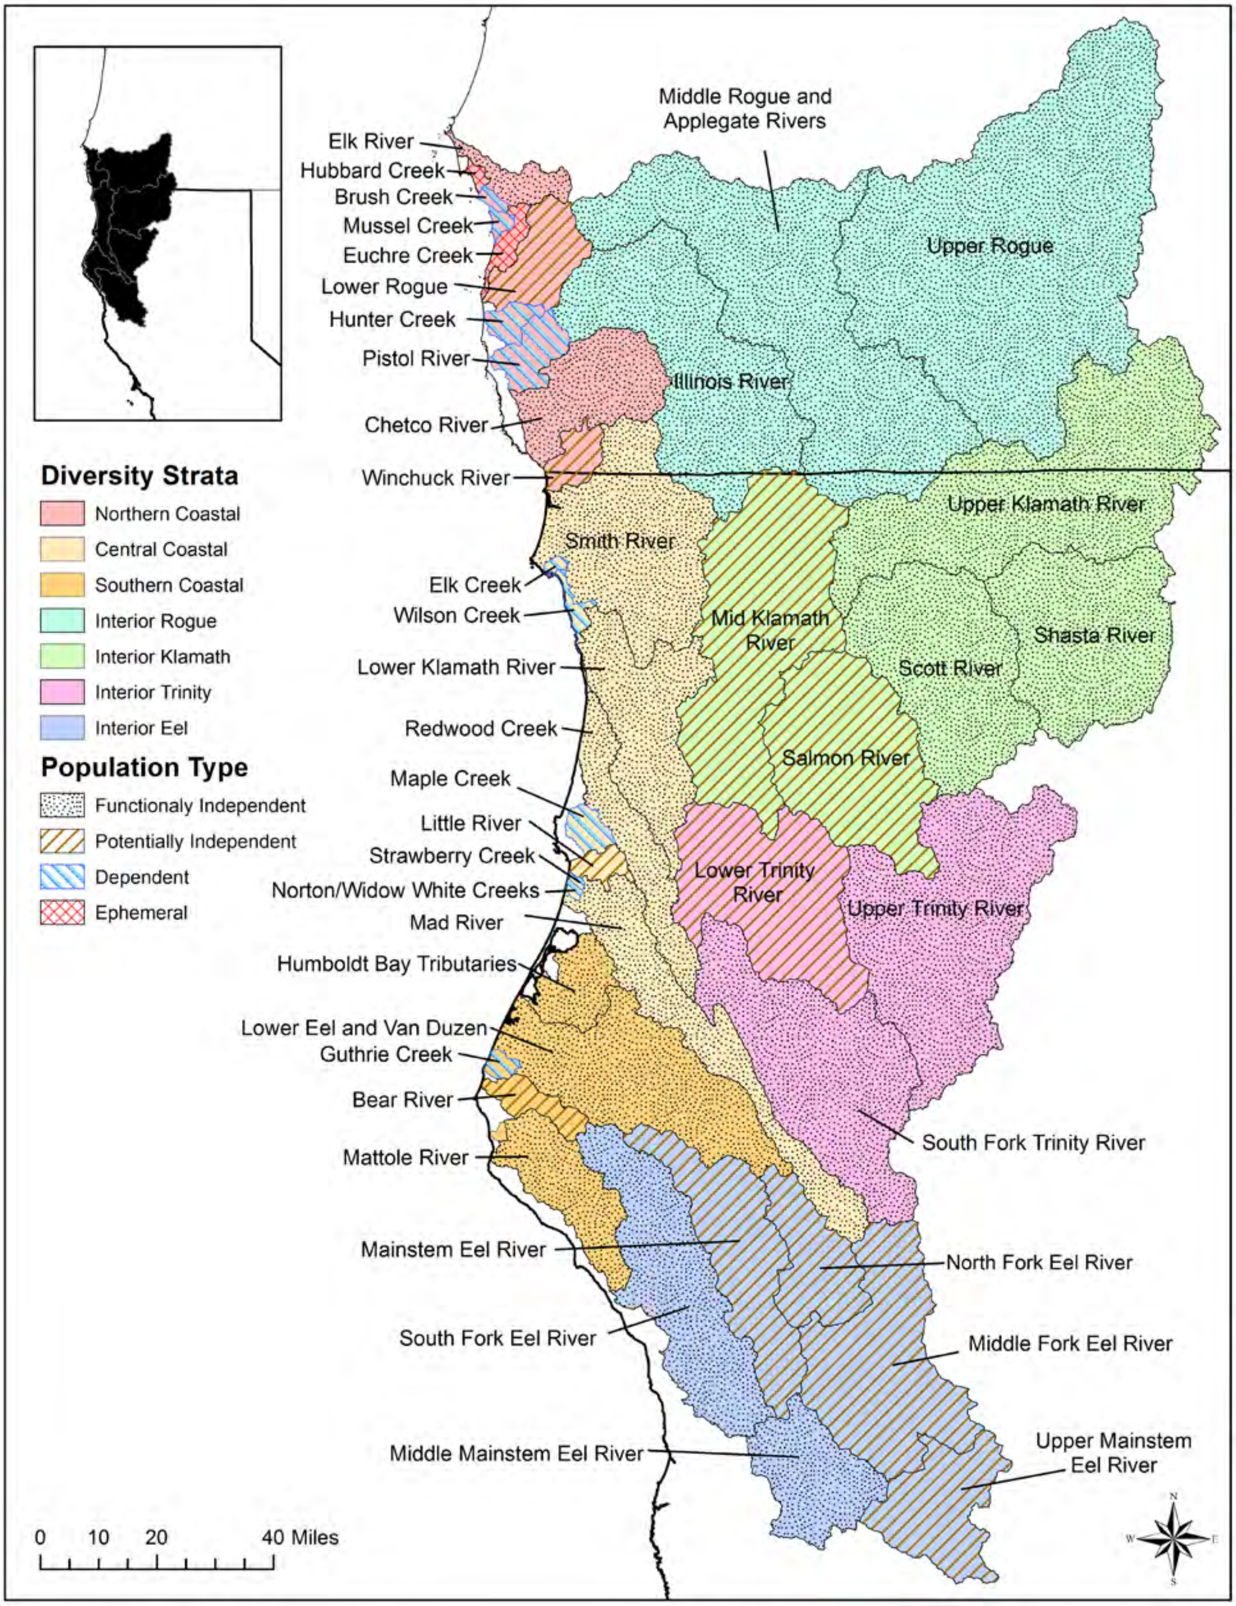

Figure 2-5. Historical population structure of the SONCC coho salmon ESU, as described in Williams et al. (2006).

2.3 Viability Criteria

Viability is the likelihood that a population will sustain itself over a 100-year time frame (McElhany et al. 2000). Viability criteria are the means by which a viable ESU is defined, and by which extinction risk is evaluated. Viability criteria are used to develop the delisting criteria described in Chapter 4.

2.3.1 ESU

The viability of an ESU depends on several factors, including the number and status of populations, spatial distribution of populations, the characteristics of large-scale catastrophic risk, and the collective diversity of the populations and their habitat (Lindley et al. 2007). In order for the SONCC coho salmon ESU to be viable, in each diversity stratum at least 50 percent of the independent populations (i.e., Functionally Independent or Potentially Independent) must be viable, and the abundance of these viable independent populations collectively must make up at least 50 percent of the total abundance modeled for all of the independent populations in that stratum (Williams et al. 2008). The independent populations that are chosen to meet the population viability criteria are called “core.” NMFS’ rationale for its choice of core populations is explained in Appendix C and is based on NMFS’ assessment of which populations are most likely to achieve those criteria most quickly. Many recovery scenarios with different core populations could result in a recovered ESU. Based on new information about population status or habitat conditions, NMFS’ designation of core and non-core populations may change to achieve recovery more quickly or efficiently. Although not all populations are required to be viable, the ESU viability criteria are intended to ensure representation of the diversity throughout the ESU, buffer the ESU against potential catastrophic risks, and provide sufficient connectivity among populations to maintain long-term demographic and genetic processes.

The ESU viability criteria incorporate the principles of representation, redundancy, and connectivity (Table 2-2). Representation relates to the genetic and life-history diversity of the ESU, which is needed to conserve its adaptive capacity. Redundancy addresses the need to have a sufficient number of populations so the ESU can withstand catastrophic events (Williams et al. 2008). Connectivity refers to the dispersal capacity of populations to maintain long-term demographic and genetic processes. The overarching goal of these rules was to determine an appropriate number and arrangement of populations that allow populations to track changes in environmental conditions (Williams et al. 2008).

Table 2-2. ESU viability criteria for SONCC coho salmon. Source: Williams et al. 2008.

ESU Viability Characteristic	Criteria
Representation	1. All diversity strata should be represented by viable populations
Redundancy and Connectivity	2. a) At least fifty percent of historically independent populations in each diversity stratum should be demonstrated to be at low risk of extinction according to the population viability criteria. AND 2. b) Total aggregate abundance of the populations selected to satisfy 2a must meet or exceed 50% of the aggregate viable population abundance predicted for the stratum based on the spawner density. 3. All dependent and independent populations not expected to meet low-risk threshold within a stratum should exhibit occupancy indicating sufficient immigration is occurring from the "core populations". 4. The distribution of extant populations, both dependent and independent, needs to maintain connectivity across the stratum as well as with adjacent strata.

Williams et al. (2008) writes about Criterion 3 (Table 2-2): "We propose that recovery planners place a high priority on populations that are remnants of historically independent populations **with a minimum standard that most historically independent populations should be at no greater than moderate risk of extinction (i.e., not at high risk) when evaluated as independent populations** [Emphasis added]". This recommendation would require a higher standard for occupancy than just presence of individuals. It should be recognized that these independent populations no longer fulfill their historical role within the ESU, but they can play a critical role in connectivity and have the potential for representing critical components of the evolutionary legacy of the ESU."

The depensation threshold is the number of spawning adults below which a population is subject to depensatory effects such as not being able to find a mate, or having all adults eaten by predators before they can reproduce. To meet Williams' recommendation above, most non-core independent populations would be at moderate (not high) risk of extinction in a recovered ESU and so would consistently have more spawners than the depensation threshold (Table 2-3). These populations are called "Non-Core 1". "Non-Core 2" populations were identified in response to the requirement that "most" (not all) independent populations should be at moderate risk of extinction, which allows that some independent populations do not need to be either at moderate risk or low risk. For some independent populations, there is little to no documentation of coho salmon presence in the last century, and prospects are low for the population to recover to numbers at least four spawners per IP-km. These populations are categorized as Non-Core 2 populations, and so have a lower threshold (juvenile occupancy) than if they were Non-Core 1 populations. This threshold is the same as for dependent populations: these populations should exhibit occupancy patterns that indicate sufficient emigration is occurring from the core populations, in order to maintain connectivity within and among diversity strata (Table 2-2).

2.3.2 Population

Williams et al. (2008) builds on the Viable Salmonid Population (VSP) concept (McElhany et al. 2000) to establish viability criteria at the population and ESU level. The population viability criteria represent an extension of an approach developed by Allendorf et al. (1997), and include metrics related to population abundance (effective population size), population decline, catastrophic decline, spawner density, hatchery influence, and population viability assessment. Populations that fail to satisfy several viability metrics are likely at greater risk than those that fail to satisfy a single metric. A viable population must have a low extinction risk for all the population metrics (Table 2-3). For a population to be at moderate risk of extinction, it must meet the moderate risk description for each of the criteria shown in Table 2-3. To align with the ESU viability criteria described in Table 2-2, NMFS identified four population categories with different targets based on their role in meeting these criteria. Core populations are those needed to meet Criteria 2a and 2b in Table 2-2. These populations must be at low risk of extinction, or viable, in order to delist. Non-Core 1 populations are those independent populations needed to meet Criterion 3, and should be at no greater than moderate risk of extinction for the ESU to be viable. Non-Core 2 populations are those independent populations that may be at higher than moderate risk of extinction in a recovered ESU, because there is no evidence they supported coho salmon, or because the amount of IP habitat in them is very low. Non-Core 2 and Dependent populations must meet Criterion 3 for the ESU to be viable. Non-Core 2 populations and dependent populations have no target extinction risk.

Table 2-3. Viability criteria used to assess extinction risk for SONCC coho salmon populations. For a given population, the highest risk score for any category determines the population's overall extinction risk. Source: Williams et al. 2006.

Criterion	Extinction risk		
	High	Moderate	Low
	- any One of -	- any One of -	- all of -
Effective population size[a]	$N_e \leq 50$	$50 < N_e < 500$	$N_e \geq 500$
- or -	*- or -*	*- or -*	*- or -*
Population size per generation[b]	Ng ≤250	$250 < N_g < 2500$	$N_g \geq 2500$
- or -	*- or -*	*- or -*	*- or -*
Population size per year[b]	*Average* $N_a \leq 83$	*83 < Average* $N_a < 830$	*Average* $N_a \geq 830$
Population decline[c]	Precipitous decline[d]	Chronic decline or depression[e]	No decline apparent or probable
Catastrophic decline	Order of magnitude decline within one generation	Smaller but significant decline[f]	Not apparent
Spawner density (adults/IP-km)	N_a/*IP-km* ≤ 1	1 < N_a/*IP-km* ≥ MRSD[g]	N_a/*IP-km* ≥ MRSD[g]
Hatchery influence			Hatchery fraction <5%
	-in addition to above-		
Extinction risk from PVA	≥20% within 20 years	≥5% within 100 years but <20% within 20 years	<5% within 100 years[h]

[a] The effective population size (N_e) is the number of breeding individuals in an idealized population that would give rise to the same variance in gene frequency under random genetic drift or the same rate of inbreeding as the population under consideration (Wright 1931).
[b] The generation time for coho salmon is approximately three years, therefore the number of spawners per generation $N_g = 3 N_a$ where N_a is the annual number of spawners.
[c] The population decline criteria require the calculation of two parameters, N_a and the population trend (*T*). Williams et al. (2008) recommends using the geometric mean of the most recent four generations (i.e., 12 years) to estimate annual population abundance, so N_a is equal to the geometric mean of 12 years of spawner abundance.
[d] Population has declined within the last two generations or is projected to decline within the next two generations (if current trends continue) to annual run size of $N_a \leq 500$ spawners (historically small but stable populations not included) or $N_a > 500$ but declining at a rate of ≥10% per year over the last two-to-four generations.[e] Annual spawner abundance N_a has declined to ≤500 spawners, but now stable **or** number of adult spawners (N_a) > 500 but continued downward trend is evident.
[f] Annual spawner abundance decline in one generation < 90% but biologically significant (e.g., loss of year class).
[g] MRSD, or minimum required spawner density, is the number adults divided by the amount of IP-km in a population. For high extinction risk, the MRSD is the same number as the depensation threshold.
[h] For populations to be considered at low-risk of extinction, all criteria must be satisfied (i.e., not just a PVA). A population viability analysis (PVA) can also be included for consideration, but must estimate an extinction risk <5% within 100 years *and* all other criteria must be met. If discrepancies exist between PVA results and other criteria, results need to be thoroughly examined and potential limitations of either approach carefully identified and examined.

The risks of small population size

Population size is extremely important to recovery of species because the time-to-extinction decreases as the population size decreases (Caughley 1994, Fagan and Holmes 2006). This longstanding theoretical prediction and empirically observed phenomenon of small populations (Fagan and Holmes 2006) highlights the importance of keeping currently healthy salmonid populations from reaching low abundance levels. In addition, it adds urgency to recovery efforts for those populations that are depressed. The effects of stochastic pressure due to small population size are discussed in the 2011 status review for SONCC coho salmon (Ly and Ruddy 2011).

Extinction is theorized to occur in stages. In the first phase of extinction, population instability occurs with population abundance fluctuating with a higher than normal amplitude. Anadromous salmonid populations are known to have large swings in abundance that are usually linked to variations in ocean productivity (Northcote and Atagi 1997; also see Chapter 3). This makes identifying the instability stage difficult for fisheries managers because they rarely have sufficient population abundance data with which to distinguish between population instability and natural population variability. In the decline phase there is a sustained period in which death rates exceed birth rates within one or more populations (Figure 2-6). Depending on the robustness of the data and length of the dataset, the decline in the phase may or may not be evident by examining the trend in abundance over time. The collapse phase is characterized by reductions in the number or extent of occurrence of a species. The extent of the occurrence of a species may erode from the edges (i.e., range contraction) or from gaps closer to the center of its range (i.e., fragmentation; Ewers and Didham 2005). In the terminal phase (Figure 2-6), a population is not likely to increase in abundance over any time interval before extinction (Fagan and Holmes 2006). Any increases in abundance are likely to be very short-lived (Fagan and Holmes 2006) and the reproductive success of the population depends on the success of a small number of individuals (Caughley 1994, Fagan and Holmes 2006). The longer a population stays in the small dynamics phase (Figure 2-6), the more likely it will go extinct.

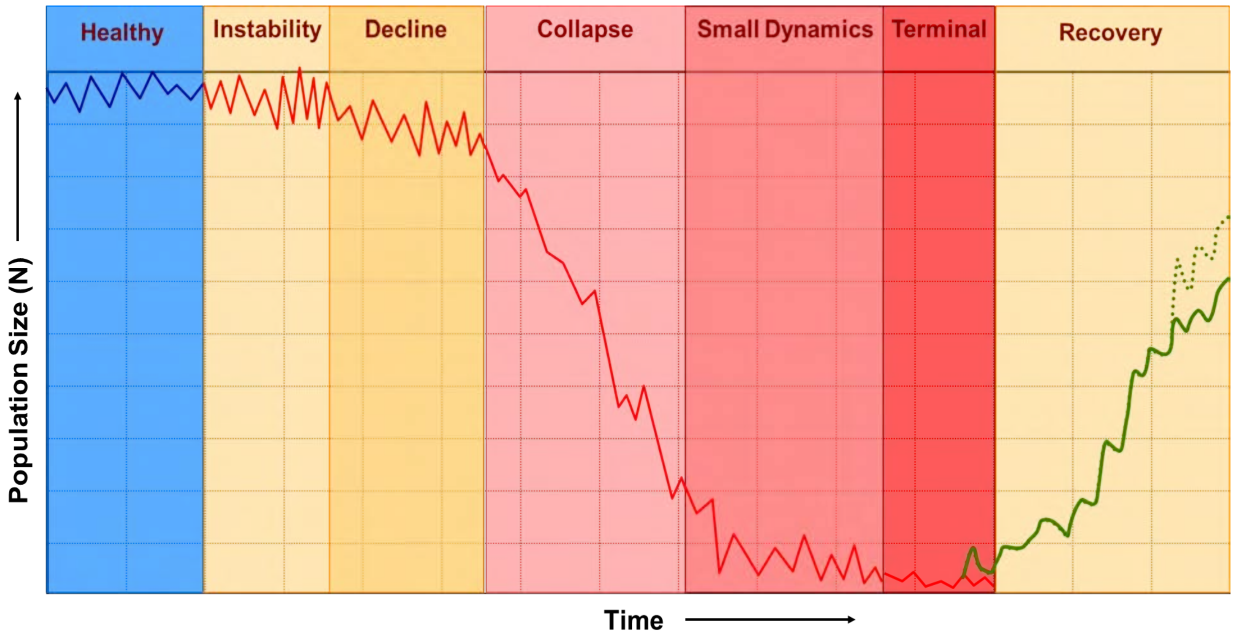

Figure 2-6. Conceptual diagram of the demographic extinction process. Diagram shows the size of a population over time through different stages. In the terminal phase, two possible trajectories for the population are extinction or recovery. Figure adapted from C. Johnson, pers. comm., 2010.

For Snake River coho salmon, which were monitored for 20 years preceding their extinction, the population size at which the final decline began (terminal phase) was 404 individuals (Fagan and Holmes 2006). After the population reached 233, there were no increases in the population in subsequent years, with a final population size preceding extinction of 6 individuals (Fagan and Holmes 2006).

In terms of recovery of small populations (those with fewer individuals than the depensation threshold) of anadromous salmonids, it is important to recognize that these populations are subject to random environmental and demographic changes. This is unlike large populations which are, in general, only subject to environmental stochasticity (Lande 1993). Because small populations can be affected by more than one form of stochasticity, they have a much greater probability of extinction than large populations (Lande 1993, Caughley 1994, Melbourne and Hastings 2008). Once a population enters the small population dynamics phase it is equally important, if not more so (Melbourne and Hastings 2008), to recognize and consider that the population is at a substantial risk of extinction resulting from the demographic factors originating from within the population.

Depensation Threshold

Population size provides an indication of the type of extinction risk that a population faces. For instance, smaller populations are at a greater risk of extinction than large populations because the processes that affect populations operate differently in small populations than in large populations (McElhany et al. 2000). One risk of low population size is the population effects of depensation. Depensatory effects occur when populations are reduced to very low densities and individual growth rates decrease as a result of a variety of mechanisms [e.g., failure to find mates and therefore reduced probability of fertilization and failure to saturate predator populations (Liermann and Hilborn 2001)]. Depensation, and its resultant effects, results in negative feedback that accelerates a decline toward extinction (Williams et al. 2008).

The depensation threshold is the number of spawners below which a population is subject to depensatory effects. Williams et al. (2008) defined the depensation threshold as 1 spawner per IP-km. A population below the depensation threshold is at high risk of extinction (Table 2-3). The depensation threshold for each independent population is shown in Table 2-6. In order for the ESU to be viable, all independent populations which aren't extirpated must not be at high risk of extinction, and so their spawner numbers must be greater than the depensation threshold.

2.4 Current Status of the ESU

In order to determine the current risk of extinction of the SONCC coho salmon ESU, NMFS utilized the population viability criteria (Table 2-3) and the concept of Viable Salmonid Populations (VSP) to evaluating populations described by McElhany et al. (2000). A viable salmonid population is defined as one that has a negligible risk of extinction over 100 years. Viable salmonid populations are described in terms of four parameters: abundance, population productivity, spatial structure, and diversity. These parameters are predictors of extinction risk, and reflect general biological and ecological processes that are critical to the growth and survival of salmon (McElhany et al. 2000). In a recovered ESU, viability criteria for all four parameters would be met.

The productivity of a population (i.e., production over the entire life cycle) can reflect conditions (e.g., environmental conditions) that influence the dynamics of a population and determine abundance. In turn, the productivity of a population allows an understanding of the performance of a population across the landscape and habitats in which it exists and its response to those habitats (McElhany et al. 2000). In general, declining productivity equates to declining population abundance.

Understanding the spatial structure of a population is important because the population structure can affect evolutionary processes and, therefore, alter the ability of a population to adapt to spatial or temporal changes in the species' environment (McElhany et al. 2000). Spatial structure and the distribution of appropriate amounts and types of habitat (and ecological processes) should be considered the foundation of population and ESU viability.

Diversity, both genetic and behavioral, is critical to success in a changing environment. Salmonids express variation in a suite of traits, such as anadromy, morphology, fecundity, run timing, spawn timing, juvenile behavior, age at smolting, age at maturity, egg size, developmental rate, ocean distribution patterns, male and female spawning behavior, and physiology and molecular genetic characteristics. The more diverse these traits (or the more these traits are not restricted), the more diverse a population is, and the more likely that individuals, and therefore the species, would survive and reproduce in the face of environmental variation (McElhany et al. 2000). However, when this diversity is reduced due to loss of entire life-history strategies or to loss of habitat used by fish exhibiting variation in life-history traits, the species is in all probability less able to survive and reproduce given environmental variation.

Because some of the parameters are related or overlap, the evaluation is at times necessarily repetitive. Viable ESUs are defined by some combination of multiple populations, at least some of which exceed “viable” thresholds, and that have appropriate geographic distribution, protection from catastrophic events, and diversity of life histories and other genetic expression. The following subsection provides the evaluation of the risk of extinction for SONCC coho salmon based the four VSP parameters. For more information on the status of specific populations, refer to Chapters 7 to 46. The upcoming status review for SONCC coho salmon may not consider all the time series data presented here, because at least 9 to 12 years of time series data are needed for rigorous application of the criteria described in Williams et al. (2008) in the status review (Williams et al. 2011).

2.4.1 Population Abundance

Quantitative population-level estimates of adult spawner abundance spanning more than 9 years are scarce for SONCC coho salmon. New data since publication of the previous status review (Williams et al. 2011) consists of continuation of a few time series of adult abundance, expansion of efforts in coastal basins of Oregon to include SONCC coho salmon populations, and continuation and addition of several “population unit” scale monitoring efforts in California. The following text summarizes the available data for adult coho salmon abundance in the SONCC coho salmon ESU. Although long-term data are scarce, the available monitoring data indicate that spawner abundance has generally declined for populations in this ESU.

Unless otherwise noted, Figure 2-7 to Figure 2-16 show the observed or estimated number wild adult coho salmon populations of the SONCC coho salmon ESU. The data from Redwood Creek, the Smith River, Freshwater Creek, and Bogus Creek do not reflect escapement to the entire watershed. In some cases, one year class appears to be stronger or weaker than the others (i.e., the Scott River, the Shasta River, and Redwood Creek’s Prairie Creek). The Huntley Park seine estimates provide the best overall assessment of naturally produced coho salmon spawner abundance in the Rogue River basin (Oregon Department of Fish and Wildlife [ODFW] 2005a). Four independent populations contribute to this count (Lower Rogue River, Illinois River, Middle Rogue and Applegate rivers, and Upper Rogue River).

For the high-risk threshold related to depensation, Williams et al. (2008)’s viability criteria are based on an estimate of average spawner density in the three consecutive years of lowest abundance within the last four generations (i.e., 12 years). For this analysis, the average spawner density was obtained by dividing the number of spawners by the amount of IP-km, as the depensation threshold is set at 1 spawner per IP-km. A ratio less than one indicates the population is at high risk of extinction for this parameter, while a ratio greater than one indicates the population is at moderate risk of extinction for this parameter. Among those locations described above, where the number of adults has been observed or estimated for a watershed, this ratio is less than one for the Little River (0.76, Figure 2-9) and the Shasta River (0.15, Figure 2-12). The ratio of the average abundance of the lowest three year classes over the amount of IP-km is greater than one for the Upper Rogue River (2.67, Figure 2-15), the Rogue River (from

Huntley Park; 1.36, Figure 2-16), Upper Trinity River (3.10, Figure 2-11), and Scott River (1.45, Figure 2-13).

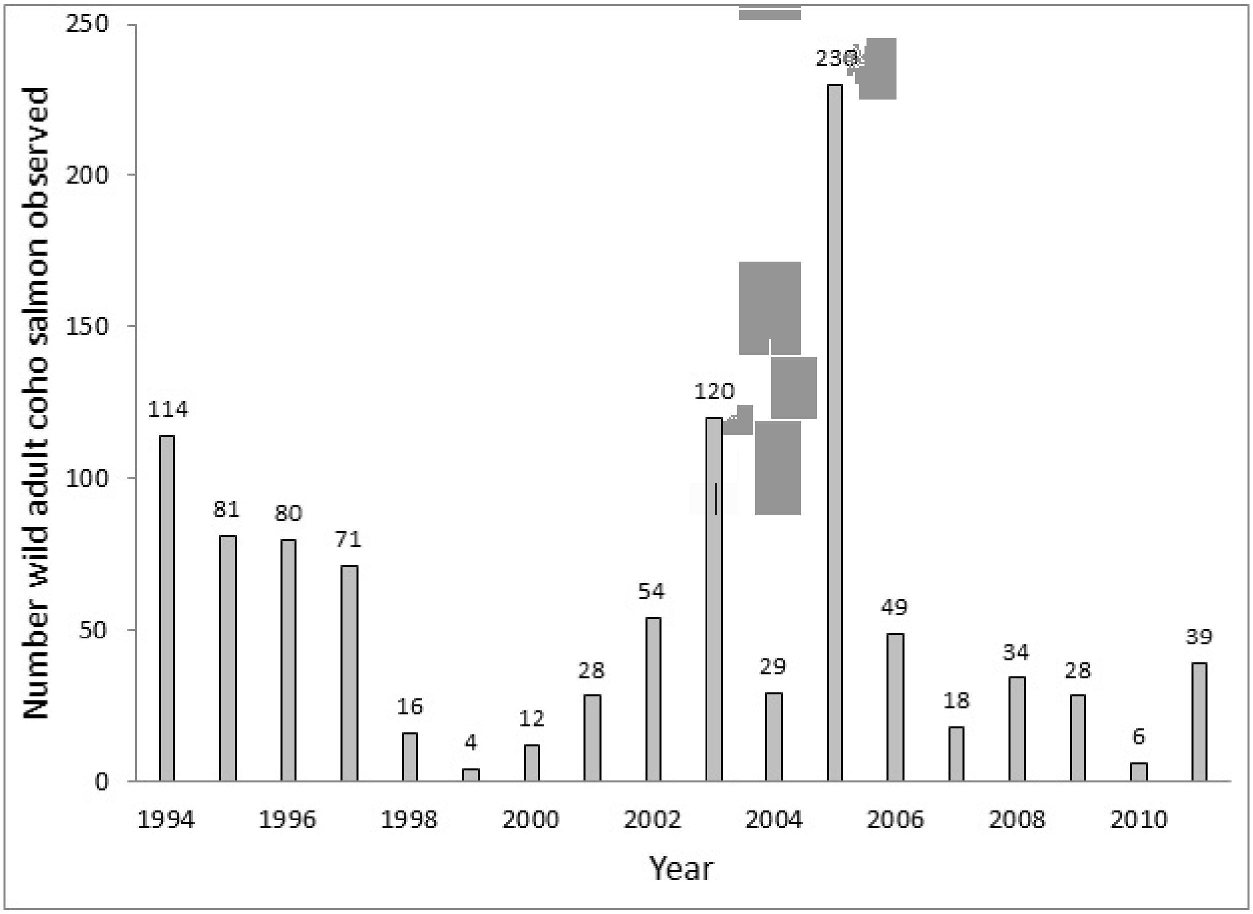

Figure 2-7. Number of wild adult coho salmon observed in Mill Creek, a tributary of the Smith River basin, 1994 through 2011. Slope of LN-transformed values = -0.046, 95% C.I = -0.148, 0.055 (Data source: Larson 2012).

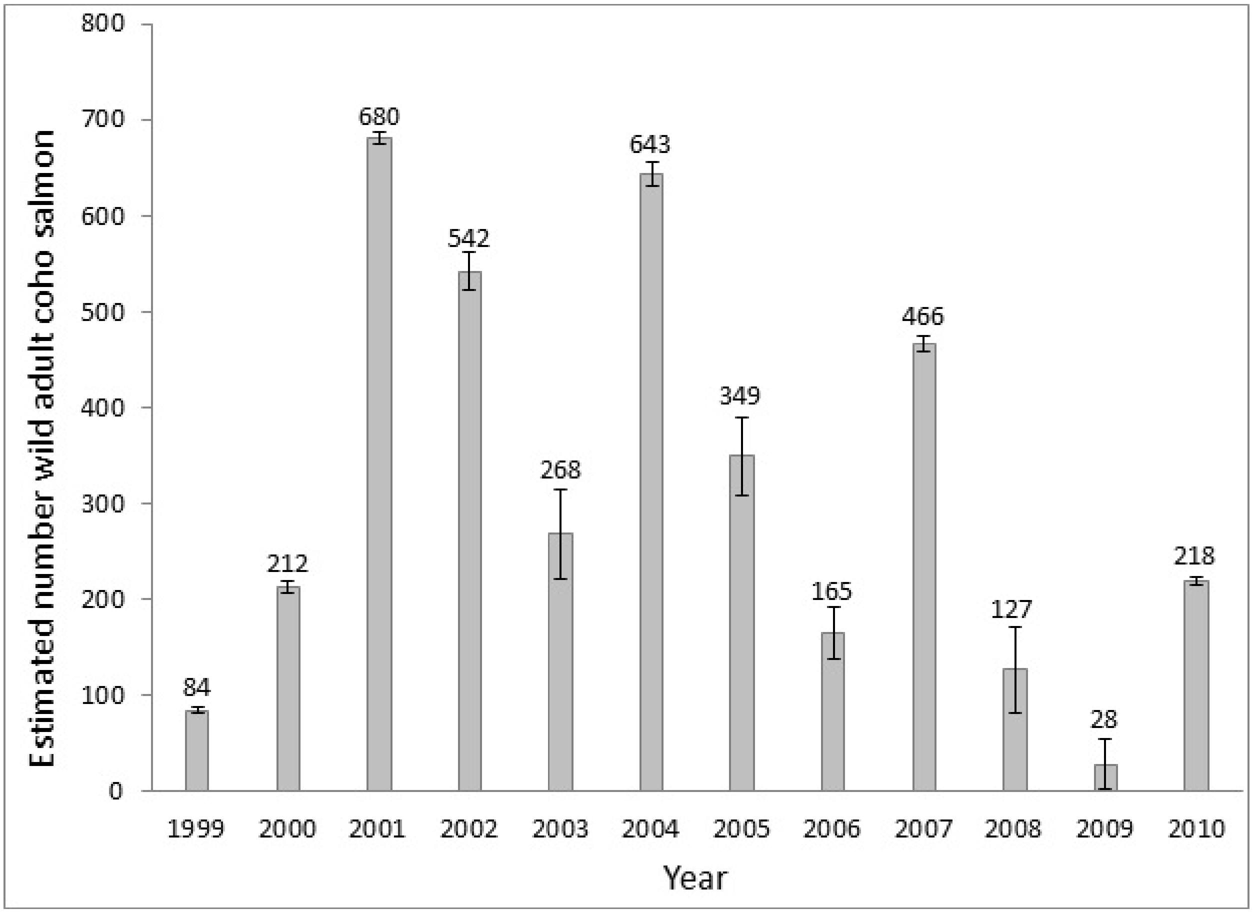

Figure 2-8. Estimated number adult coho salmon in Prairie Creek, a tributary to Redwood Creek (Humboldt County, California). Slope of LN-transformed values = -0.014, 95% C.I. = -0.181, 0.152 (Data source: Duffy 2011).

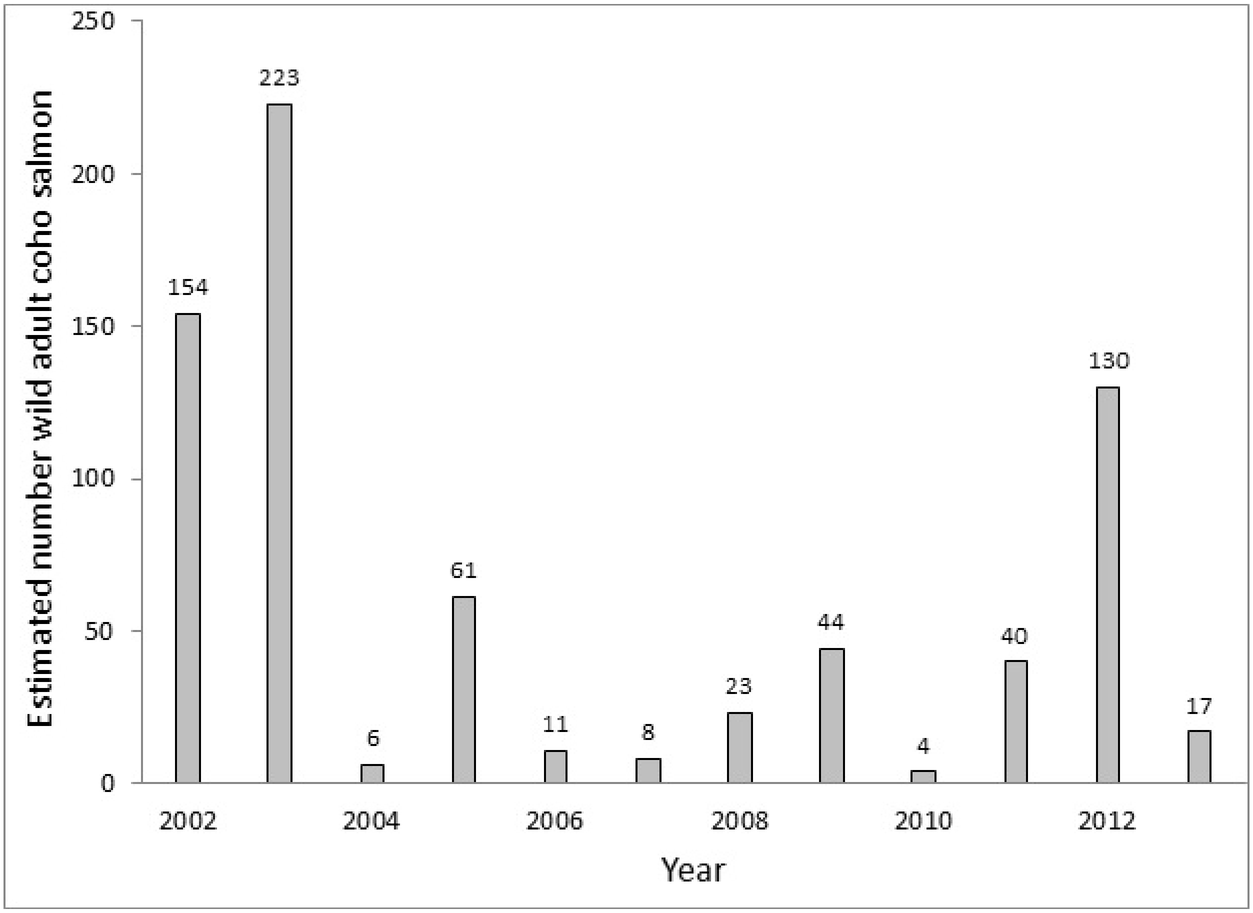

Figure 2-9. Estimated number wild adult coho salmon in the Little River. Slope of LN-transformed values = 0.44, 95% C.I. = -0.135, 0.223 (Data source: Bourque, R., pers. comm. 2013).

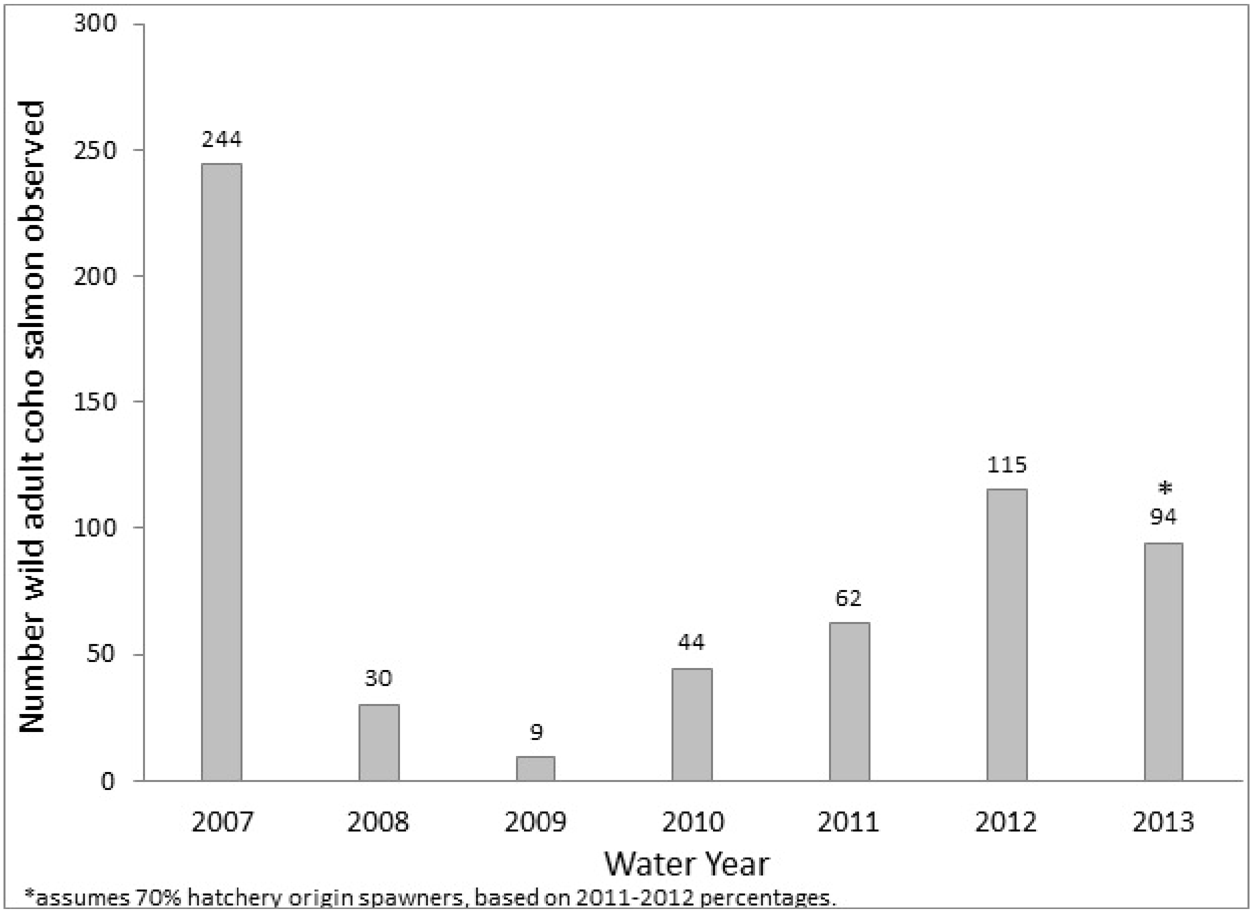

Figure 2-12. Estimated number wild coho salmon observed at video weir on the Shasta River Does not include hatchery origin fish on spawning grounds. Slope of LN-transformed values = 0.063, 95% C.I. = -0.542, 0.667. (Data source: 2007-2012 Chesney and Knechtle 2013a, 2013 Knechtle, M. pers. comm. 2014).

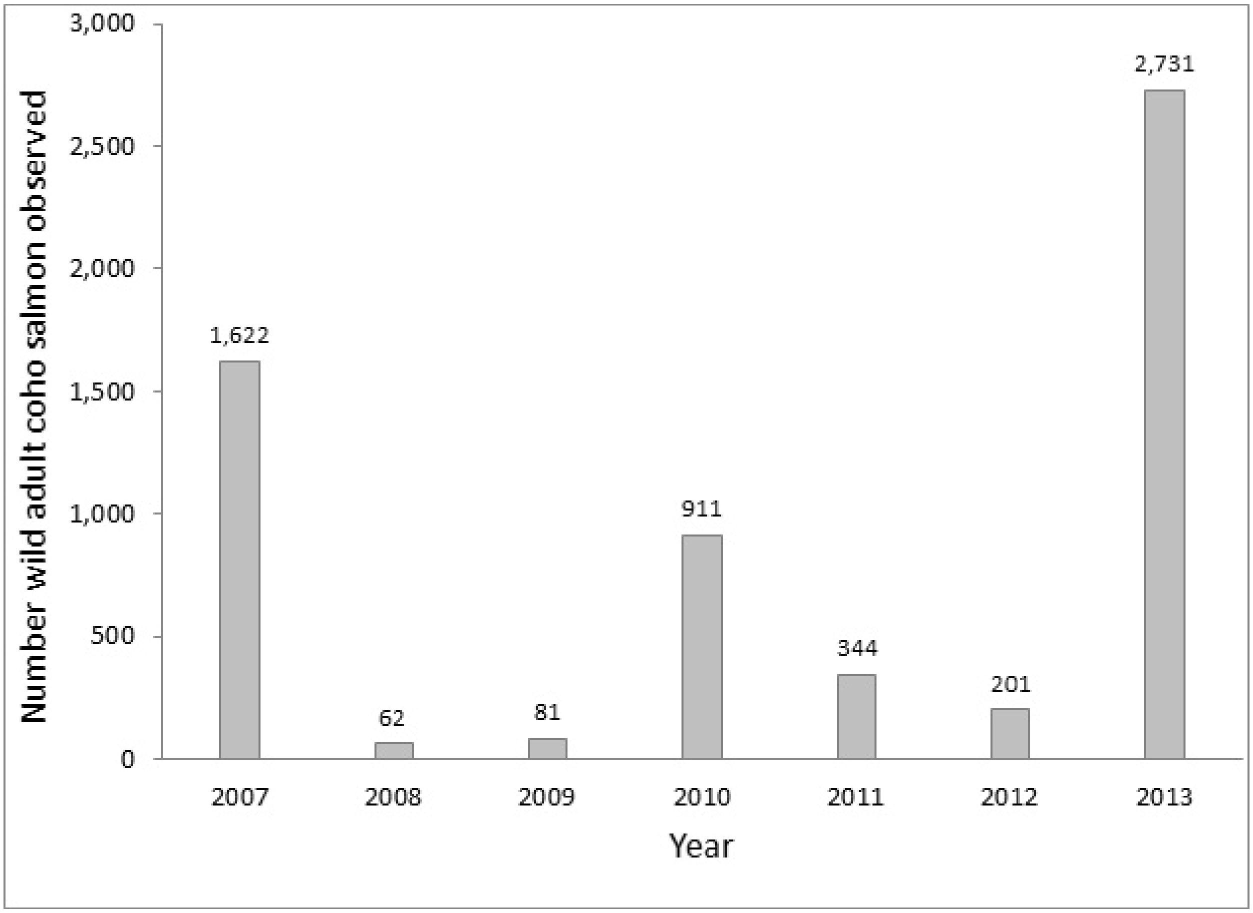

Figure 2-13. Number wild adult coho salmon observed at the Scott River fish counting facility at River Mile 18, 2007 to 2013. Does not include hatchery origin fish on spawning grounds. Slope of LN-transformed values = 0.191, 95% C.I. = -0.556, 0.939. (Data source: 2007-2012 data Knechtle and Chesney 2013a, 2013 data pers. comm. M. Knechtle, CDFW, 2014).

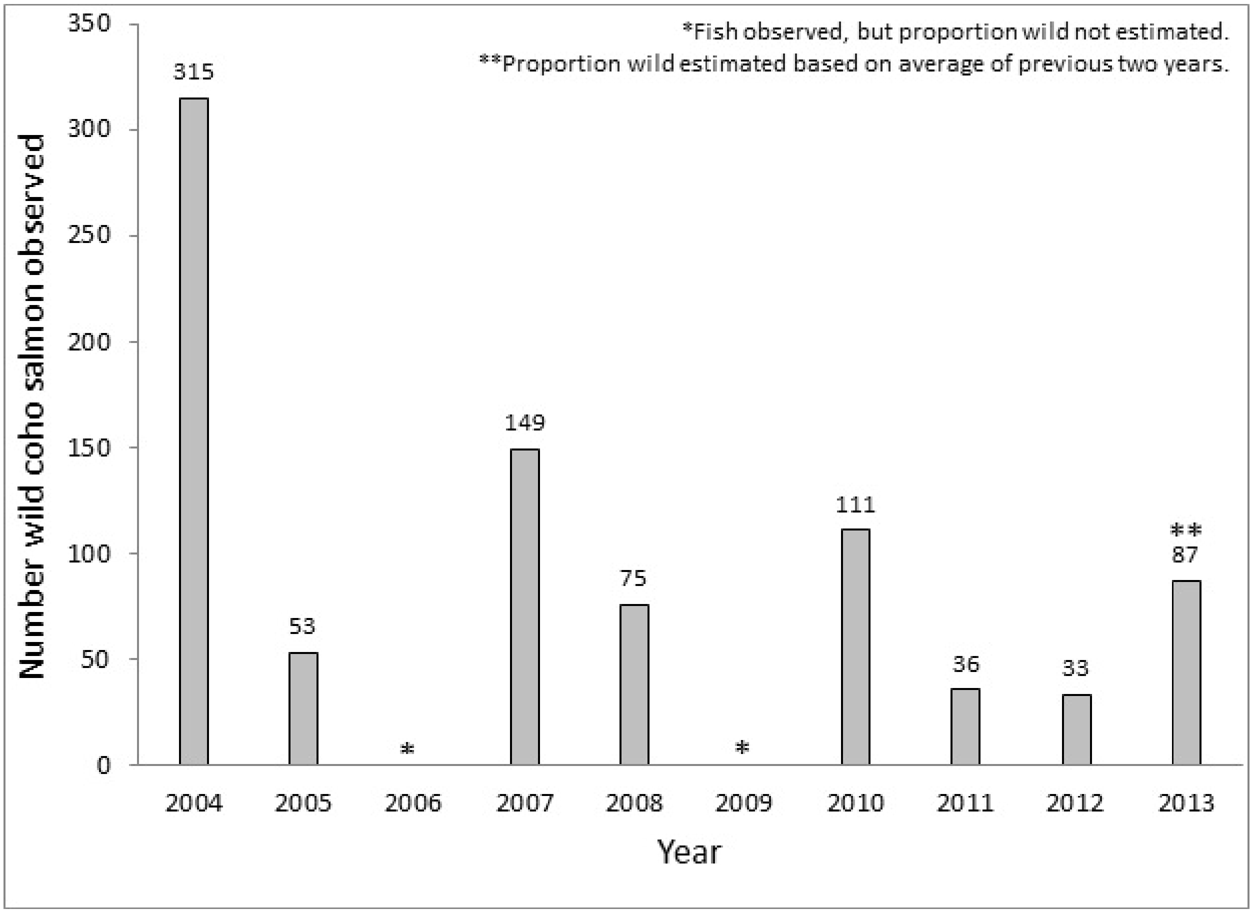

Figure 2-14. Number wild adult coho salmon observed in Bogus Creek, a tributary of the Upper Klamath River. Does not include hatchery origin fish on spawning grounds. Slope of LN-transformed values = -0.13, 95% C.I. = -0.329, 0.066. (Data source: 2007-2012 data Knechtle and Chesney 2013b, 2013 data pers. comm. M. Knechtle, CDFW, 2014).

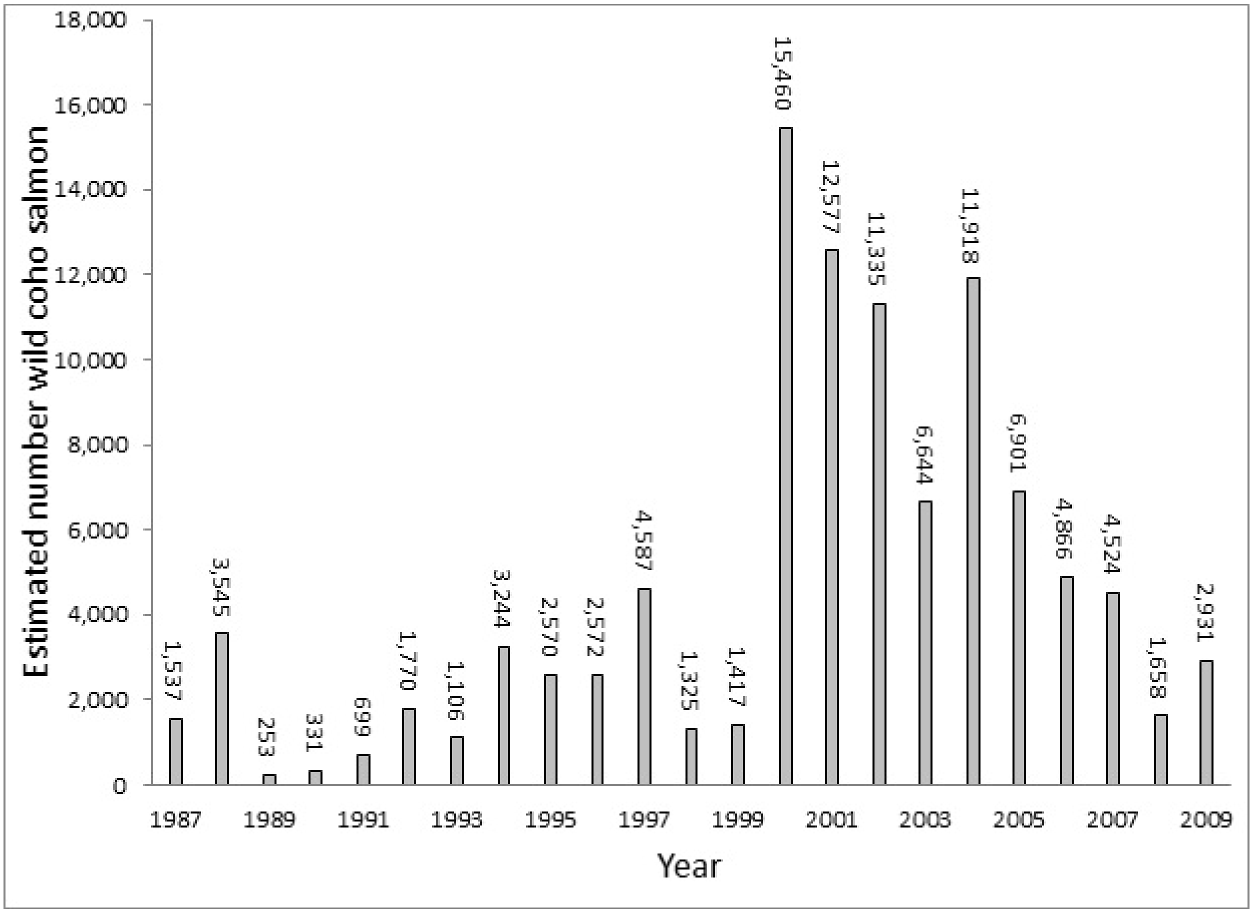

Figure 2-15. Number adult wild coho salmon observed at Gold Ray Dam on the Upper Rogue River. Slope of LN-transformed values = 0.094, 95% C.I. = 0.035, 0.154. Data source: ODFW 2010.

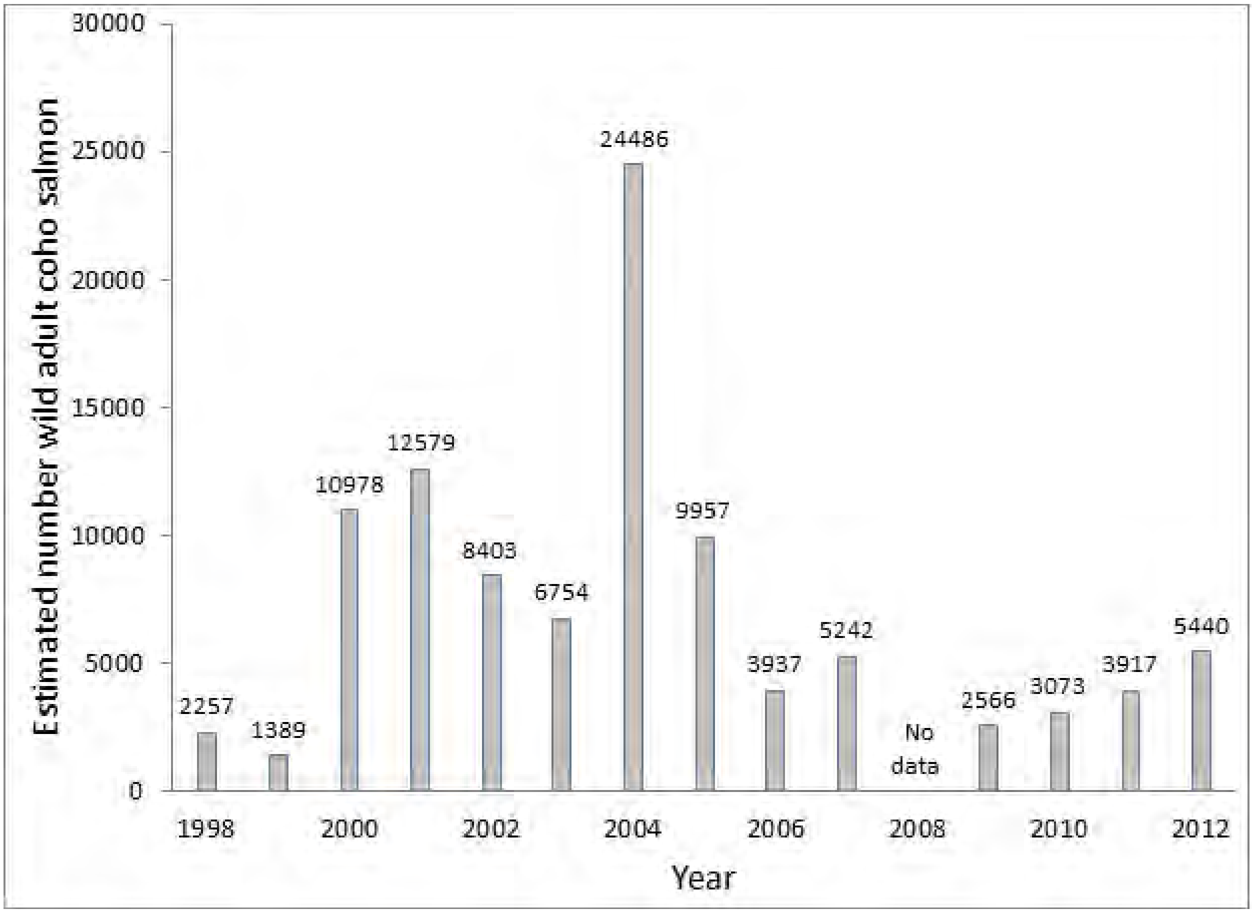

Figure 2-16. Estimated number of wild adult coho salmon in the Rogue River basin. (Huntley Park sampling), 1998 to 2012[4]. Slope of LN-transformed values = -0.023, 95% C.I. = -0.1469, 0.100 (Data source: ODFW 2012).

Though population-level estimates of abundance for most independent populations are lacking, the best available data indicate that none of the seven diversity strata appears to support a single viable population (one at low risk of extinction) as defined by in the viability criteria (Table 2-3). In fact, most of the 30 independent populations in the ESU are at high risk of extinction for abundance because they are below or likely below their depensation threshold (Table 2-6).

Populations that are below depensation have increased likelihood of being extirpated. Coho salmon spawners in the Eel River watershed, which historically supported significant spawners (e.g., 50,000 to 100,000 per year; Yoshiyama and Moyle 2010), have declined in number. Yoshiyama and Moyle (2010) concluded that coho salmon populations in the Eel River basin appear to be headed for extirpation by 2025. One of the four independent populations in this basin has already been extirpated (i.e., Middle Fork Eel River; Moyle et al. 2008, Yoshiyama and Moyle 2010) and one population contains critically low numbers (i.e., Upper Mainstem Eel

[4] 2008 data were excluded from consideration because the extremely low numbers were not consistent with that seen upstream at Gold Ray Dam, suggesting other reasons (sampling issues, data errors, etc.) for the dramatic drop in fish numbers from 2007 to 2008.

River, with only a total of seven adult coho salmon counted at the Van Arsdale Fish Station in over six decades; Jahn, J., pers. comm. 2010). Although long term spawner data are not available, both NMFS and CDFW believe the Lower Eel/Van Duzen River (Chapter 26), Middle Mainstem Eel River population (Chapter 44) and Mainstem Eel River population (Chapter 42) are very likely below the depensation threshold, and thus are at a high risk of extinction (rationale provided in referenced chapters). The only population in the Eel River basin that is likely to be above its depensation threshold is the South Fork Eel River (Chapter 41), which has also declined from historical numbers in the tens of thousands before 1950 (Taylor 1978; Figure 2-17).

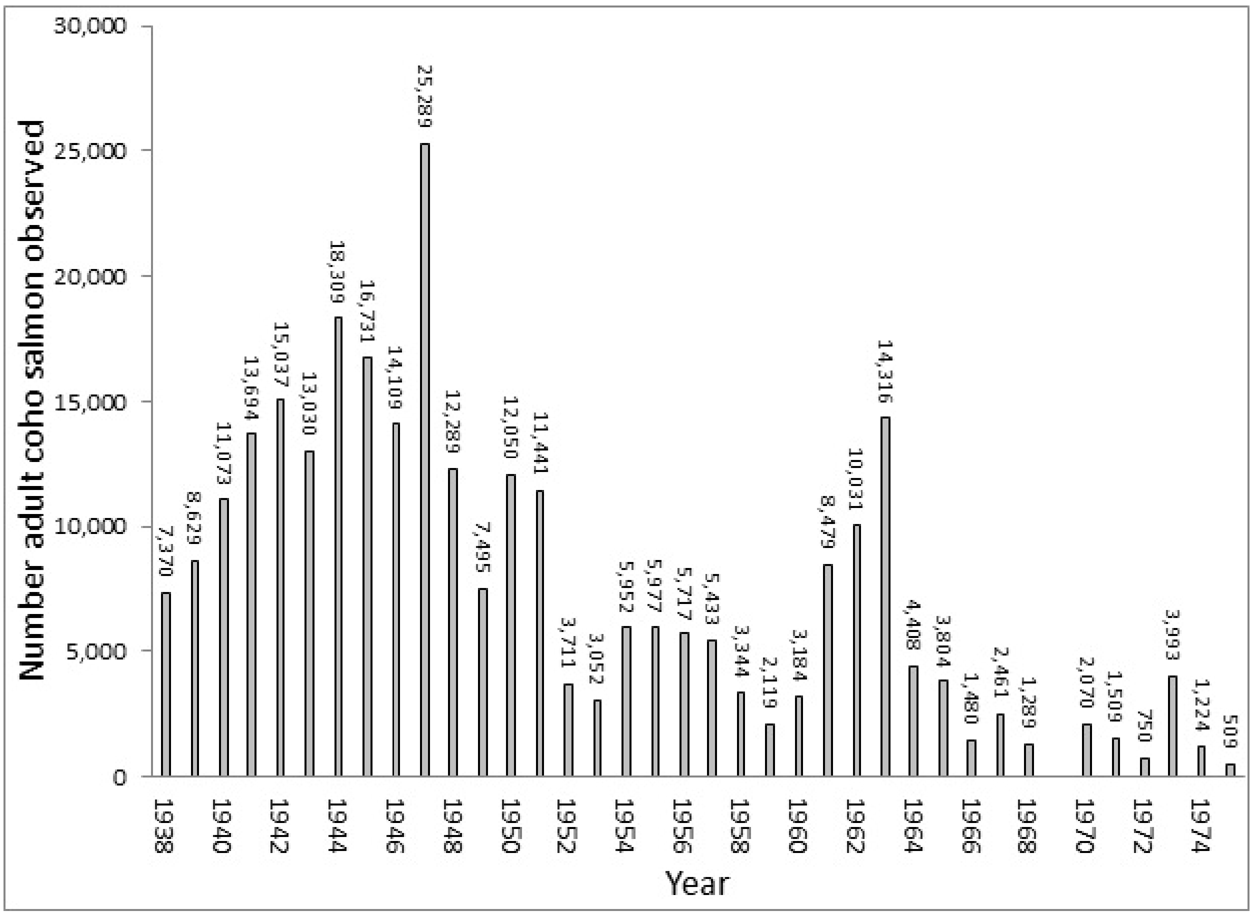

Figure 2-17. Fish counts at Benbow Fish Station, in the South Fork Eel River. Data are from 1938 to 1975 (excluding 1969). Counts may contain hatchery-origin fish. Data source: Taylor 1978.

In addition to the Eel River basin, two other independent populations south of the Eel River basin, the Bear River and Mattole River populations, have similar trajectories. The Bear River population is likely extirpated or severely depressed. Despite multiple surveys over years, no coho salmon have been found in the Bear River watershed (Bliesner et al. 2006, Ricker 2002). In 1996 and 2000, the California Department of Fish and Game (CDFG) surveyed most tributaries of the Bear River, and did not find any coho salmon (CDFG 2004a). In addition, CDFG sampled the mainstem and South Fork Bear River between 2001 and 2003 and found no coho salmon (Jong et al. 2008). In the Mattole River, surveys of live fish and carcasses since 1994 indicate the population is severely depressed and well below the depensation threshold of 250 spawners. Recent spawner surveys in the Mattole River resulted in only three and nine coho salmon for 2009 and 2010, respectively. These low numbers, along with a recent decline since 2005, indicate that the Mattole River population is at a high risk of extinction.

2.4.2 Productivity

The productivity of a population (i.e., production over the entire life cycle) can reflect conditions (e.g., environmental conditions) that influence the dynamics of a population and determine abundance. In turn, the productivity of a population allows an understanding of the performance of a population across the landscape, habitats in which it exists, and its response to those habitats (McElhany et al. 2000). In general, declining productivity equates to declining population abundance.

Available data show that the 95% confidence intervals for the slope of the regression line include zero for many populations (Figure 2-7 to Figure 2-16), indicating that whether the slope is negative or positive cannot be determined. However, there is 95% confidence that the slope of the regression line is negative, indicating a decreasing trend, for Mill Creek in the Smith River and Freshwater Creek in Humboldt Bay Tributaries. In contrast, there is 95% confidence that the slope of the regression line is positive, indicating an increasing trend, at Gold Ray Dam in the Upper Rogue River.

2.4.3 Spatial Structure

The viability report for the SONCC coho salmon ESU explicitly described spatial structure and concluded data were insufficient to set specific population spatial structure targets (Williams et al. 2008). In the absence of such targets, McElhany et al. (2000) suggested the following: "As a default, historical spatial processes should be preserved because we assume that the historical population structure was sustainable but we do not know whether a novel spatial structure will be", where "historical" means "before the recent or severe declines that have been observed in many populations (McElhany et al. 2000)."

An ESU persists in places where it is able to track environmental changes, and becomes extinct if it fails to keep up with the shifting distribution of suitable habitat (Thomas 1994, Williams et al. 2008). If freshwater habitat shrinks due to climate change (Battin et al. 2007) or habitat degradation, certain areas such as inland rivers and streams could become inhospitable to coho salmon, which would change the spatial structure of the SONCC coho salmon ESU, having implications for the risk of species extinction.

Available data are inadequate to determine whether the spatial distribution of SONCC coho salmon has changed since 2005. In 2005, Good et al. (2005) noted that they had strong indications that breeding groups have been lost from a significant percentage of streams within their historical range. Relatively low levels of observed presence in historically occupied coho salmon streams (32 to 56 percent from 1986 to 2000) indicate continued low abundance in the California portion of the SONCC coho salmon ESU. The relatively high occupancy rate of historical streams observed in brood year 2001 suggests that much habitat remains accessible to coho salmon (70 FR 37160, June 28, 2005). Brown et al. (1994) found survey information on 115 streams within the SONCC coho salmon ESU, of which 73 (64 percent) still supported coho salmon runs while 42 (36 percent) did not. The streams Brown et al. (1994) identified as lacking coho salmon runs were all tributaries of the Klamath River and Eel River basins. CDFG (2002b) reported a decline in SONCC coho salmon occupancy, with the percent reduction dependent on the data sets used. All the assessments based on fish presence described above were affected by the often poor hydrologic conditions present in the survey years.

Although there is considerable year-to-year variation in estimated occupancy rates, it appears that there has been no dramatic change in the percent of coho salmon streams occupied from the late 1980s and early 1990s to 2000 (Good et al. 2005). However, the number of streams and rivers currently supporting coho salmon in this ESU has been greatly reduced from historical levels, and watershed-specific extirpations of coho salmon have been documented (Brown et al. 1994, CDFG 2004a, Good et al. 2005, Moyle et al. 2008, Yoshiyama and Moyle 2010). In summary, recent information for SONCC coho salmon indicates that their distribution within the ESU has been reduced and fragmented, as evidenced by an increasing number of previously occupied streams from which they are now absent (NMFS 2001). However, extant populations can still be found in all major river basins within the ESU (70 FR 37160; June 28, 2005).

The spatial structure of each population was not quantified for this plan because data are insufficient. The current spatial structure of each population is described in Chapters 7 to 46.

2.4.4 Diversity

The primary factors affecting the genetic and life-history diversity of SONCC coho salmon appear to be low population abundance and the influence of hatcheries and out-of-basin introductions. Although the operation of a hatchery tends to increase the abundance of returning adults (70 FR 37160; June 28, 2005), the reproductive success of hatchery-born salmonids spawning in the wild can be less than that of naturally produced fish (Araki et al. 2007a). As a result, the higher the proportion of hatchery-born spawners, the lower the overall productivity of the population, as demonstrated by Chilcote (2003). Williams et al. (2008) considered a population to be at least at a moderate risk of extinction if the contribution of hatchery coho salmon spawning in the wild exceeds 5 percent. Populations have a lower risk of extinction if no or negligible ecological or genetic effects resulting from past or current hatchery operations can be demonstrated. Because the main stocks in the SONCC coho salmon ESU (i.e., Rogue River, Klamath River, and Trinity River) remain heavily influenced by hatcheries and have little natural production in mainstem rivers (Weitkamp et al. 1995; Good et al. 2005), some of these populations are at high risk of extinction relative to the genetic diversity parameter. The extent of hatcheries in the ESU, and a discussion of their effects, is described in Chapters 3 and 7 to 46. Table 2-4 shows those populations with hatchery stress and threat ranks of high (greater than 10 percent and less than 30 percent hatchery-origin adults) and very high (greater than 30 percent hatchery-origin adults).

Table 2-4. Populations with hatchery effects rated as a high or very high stress and threat. Table shows % hatchery spawners, and source.

Population	Stress and Threat Rank	Average Percentage Hatchery Origin Adults
Upper Klamath River	Very High	47% at Bogus Creek from 2004 to 2012, excluding 2006 and 2009; Knechtle and Chesney (2013b)
Shasta River	High	16% in 2001, 2003, 2004; Ackerman and Cramer (2006). 23% from 2001 to 2004; Ackerman et al. (2006). 43% from 2007 to 2012; Chesney and Knechtle (2013)
Lower Trinity River	Very High	85-97% from 1997 to 2002; Sinnen et al. 2009. 60-100% from 1998 to 1999; Dutra and Thomas (1999)
South Fork Trinity River	Very High	36% in 1985; Jong and Mills (1992)
Upper Trinity River	Very High	97%, USFWS and HVT (1999)

Some populations are extirpated or nearly extirpated (i.e., Middle Fork Eel, Bear River, Upper Mainstem Eel) and some brood years have low abundance or may be absent in some areas (e.g., Shasta River, Scott River, Mattole River, Mainstem Eel River), which further restricts the diversity present in the ESU. The ESU's current genetic variability and variation in life-history likely contribute significantly to long-term risk of extinction. Given the recent trends in abundance across the ESU, the genetic and life-history diversity of populations is likely very low and is inadequate to contribute to a viable ESU.

2.4.5 Oregon Assessment

The Oregon Department of Fish and Wildlife assessed the status of the Rogue Coho Species Management Unit (SMU), which includes the Upper Rogue, Middle Rogue, and Illinois River populations (ODFW 2005a) using five interim criteria defined in their Native Fish Conservation Policy. These criteria were designed to identify cases of significant near-term conservation risks. The Rogue Coho SMU was found Not At Risk because all three populations met all six criteria (Table 2-5). The criteria used by ODFW and NMFS to assess the status of the ESU were different, leading to different results. In addition, the NMFS assessment included all populations within the ESU, while the ODFW assessment was limited to the three interior Rogue populations within the Rogue Coho SMU.

Table 2-5. Interim criteria and standards. As defined in the Native Fish Conservation Policy risk assessment of Oregon salmon and steelhead SMUs (ODFW 2005a).

Attribute	Criteria
Existing populations	At least 80% of historical populations are still in existence (i.e., not extinct) *and* not at risk of extinction in the near future.
Habitat use distribution	Naturally produced members of a population occupy at least 50% of the historically-used (pre-development) habitat in at least three of the last five years for at least 80% of existing populations.
Abundance	Number of naturally-produced fish is greater than 25% of average levels in at least three of the last five years for at least 80% of existing populations.
Productivity	Population replacement rate for at least 80% of existing populations is at least 1.2 naturally-produced adult offspring per parent in three of the last five years when total abundance was less than average returns of naturally produced fish.
Reproductive independence	90% or more of spawners are naturally produced in at least three of the last five years for at least 80% of existing populations.
Hybridization	Hybridization with non-native species is rare or nonexistent in three of the last five years for at least 80% of existing populations.

2.4.6 Summary

Though population-level estimates of abundance for most independent populations are lacking, the best available data indicate that none of the seven diversity strata appears to support a single viable population as defined by the SONCC coho salmon technical recovery team's viability criteria (low extinction risk; Williams et al. 2008). Further, 24 out of 31 independent populations are at high risk of extinction and 6 are at moderate risk of extinction (Table 2-6).

Based on the above discussion of the population viability parameters, and qualitative viability criteria presented in Williams et al. (2008), NMFS concludes that the SONCC coho salmon ESU is currently not viable and is at high risk of extinction.

The decline in abundance from historical levels, and the poor status of population viability metrics in general, are the main factors behind the extinction risk faced by SONCC coho salmon. The primary causes of the decline are likely long-standing human-caused conditions (e.g., harvest and habitat degradation), which exacerbated the impacts of adverse environmental conditions (e.g., drought and poor ocean conditions) (60 FR 38011; July 25, 1995). The demographic response to impaired habitat has been a reduction in the number of fish and their range, which has made them less resilient to environmental stresses such as poor ocean conditions. The stresses and threats that contribute to the current status of SONCC coho salmon are described in Chapter 3.

Table 2-6. SONCC coho salmon ESU core and non-core 1 populations and their current risk of extinction.

Stratum	Population	Extinction Risk	Depensation Threshold (1*IP-km)	Extinction Risk Criteria Used[1]
Northern Coastal Basin	Elk River	High	63	Spawner density
	Lower Rogue River	High	81	Population decline
	Chetco River	High	135	Spawner density
	Winchuck River	High	57	Spawner density
Interior Rogue River	Illinois River	High	590	Population decline
	Middle Rogue/Applegate Rivers	High	603	Population decline
	Upper Rogue River	Moderate	689	Spawner density
Central Coastal Basin	Smith River	High	325	Spawner density
	Lower Klamath River	High	205	Spawner density
	Redwood Creek	High	151	Spawner density
	Little River	Moderate	34	Spawner density
	Mad River	High	136	Spawner density
Interior Klamath	Middle Klamath River	Moderate	113	Spawner density
	Upper Klamath River	High	425	Spawner density
	Shasta River	High	144	Spawner density
	Scott River	Moderate	250	Spawner density
	Salmon River	High	114	Spawner density
Interior Trinity	Lower Trinity River	High	112	Spawner density
	South Fork Trinity River	High	242	Spawner density
	Upper Trinity River	Moderate	365	Spawner density
South Coastal Basin	Humboldt Bay tributaries	Moderate	191	Spawner density
	Lower Eel/Van Duzen Rivers	High	394	Spawner density
	Mattole River	High	250	Spawner density
Interior Eel	Mainstem Eel River	High	68	Spawner density
	Middle Mainstem Eel River	High	232	Spawner density
	South Fork Eel River	Moderate	464	Spawner density

[1]As described in Williams et al. (2008) and Table 2-3.

3. Stresses and Threats

Stresses are the physical, biological, or chemical conditions and associated ecological processes that may be impeding SONCC coho salmon recovery. General categories of stresses include water quality, competition, disease, access to habitat, instream flows, insufficient quality and quantity of physical habitat, and predation. Threats are activities or impacts that cause or contribute to the stresses that limit recovery of the species, including: water diversions, hydropower impacts, land management, invasive species, fish harvest management, and hatchery management.

When the SONCC coho salmon ESU was listed under the Endangered Species Act (ESA) in 1997, NMFS identified the factors which led to the decline of the species (62 FR 24588, May 6, 1997), and the stresses and threats associated with those factors. These factors, called "listing factors", are described in Chapter 1. Table 3-1, Table 3-2, and Table 3-3 describe the stresses and threats associated with each listing factor. Each population's stresses and threats are assessed in the population profiles (Chapters 7 to 46). This chapter describes the stresses and threats associated with each listing factor, the causes of those stresses and threats, and what can be done to address them. In addition, this chapter describes the listing factor "Inadequacy of existing regulatory mechanisms", which contributes to all stresses and threats.

NMFS assessed the viability of individual populations within the SONCC coho salmon ESU and the current condition of their habitats using five steps: (1) identify conservation targets; (2) assess population viability; (3) identify potential threats and stresses; (4) compile available literature, data and best professional knowledge on the condition of the landscape; and (5) determine the severity and impact of stresses and threats affecting each population. This methodology is detailed in Appendix B.

The timeframe for assessment of stresses and threats is over the next ten years[5] under current circumstances and management (Appendix B). In addition to those stresses identified at the time of listing, additional stresses currently affecting SONCC coho salmon were identified and ranked using the Conservation Action Planning (CAP) workbook (explained in Appendix B) for each life stage of coho salmon.

[5] The effects of climate change are expected to take at least 50 years to manifest.

Table 3-1. Relationship between listing factors, stresses and threats for SONCC coho salmon.

Adverse Fishery and Collecting Related Effects											X		X

In addition to the CAP assessment process, NMFS used the best available science regarding the impacts of predicted shifts in climate, effects from fishing and collecting activities, and estuary and mainstem condition on the ability of the species' to recover. Additional categories (either stresses or threats) were created for Climate Change, Impaired Estuary/Mainstem Function, and Fishing and Collecting.

3.1 Stresses

In each population profile we summarize and rank the stresses and threats (Chapters 7 to 46). Each of these population profiles includes a summary table of the stress rankings by coho salmon life stage, the overall stress ranking, and a narrative discussing the effects on the population. In addition to the stresses identified during listing, we performed a stress ranking and assessment for Impaired Estuary/Mainstem Function and Adverse Fishery- and Collection-Related Activities. Whenever available, empirical data were used in the stress assessment. Where empirical information was not available, NMFS staff relied on best professional judgment to assign a severity ranking to each stress by life stage. Refer to Appendix B for more detailed information on the methodologies used to rank stresses. The stresses assessed in this plan are listed in Table 3-4.

In the following subsection we summarize the stresses existing within the SONCC coho salmon ESU, with a brief description of the effects to coho salmon and their habitat associated with each stress. In addition, each population profile (Chapters 7 to 46) provides a detailed description of each stress at the population level, and the recovery strategy and actions recommended to achieve viability by reducing the severity of each stress as needed.

Table 3-4. Summary of stress severity ranking by population. Stress ranking represent CAP results as follows: L = Low, M = Medium, H = High, VH = Very High. See Appendix B for definition of severity rankings. See Chapters 7 to 46 for detail about any particular population's ranking.

	Stresses										
Population	Adverse Hatchery Related Effects	Impaired Water Quality	Degraded Riparian Forest	Increased Disease/ Predation / Competition	Altered Sediment Supply	Lack of Floodplain and Channel Structure	Altered Hydrologic Function	Barriers	Impaired Estuary/ Mainstem Function	Adverse Fishery- and Collection-Related Effects	Total High or Very High

[1]Identified as a key limiting stress.

3.1.1 Adverse Hatchery-Related Effects

Three artificial propagation programs are part of the SONCC coho salmon ESU: the Cole Rivers Hatchery (Rogue River), Trinity River Hatchery ,and Iron Gate Hatchery (Klamath River) coho salmon programs (70 FR 37160, June 28, 2005). Annual coho salmon production goals at these hatcheries are 200,000, 500,000, and 75,000 respectively. These hatcheries produce not only coho salmon, but also Chinook salmon and steelhead for release into the wild. Together, these hatcheries release approximately 14,215,000 hatchery salmonids into SONCC coho salmon ESU rivers annually. In addition to the three hatcheries, the Mad River and Rowdy Creek hatcheries in California and the Elk River Hatchery in Oregon are located within the ESU and produce steelhead and Chinook salmon that can prey on or compete with natural SONCC ESU coho salmon.

Table 3-5. Production levels at hatcheries throughout the SONCC coho salmon ESU.

State	Hatchery	Coho Salmon Production	Chinook Salmon Production	Steelhead Production
Oregon	Cole Rivers[1]	200,000 (released into Rogue River)	1.6 million (spring-run released into Rogue River)	220,000 (summer- run released into Rogue River)
				132,000 (winter-run released into Rogue River)
				132,000 (winter-run released into Applegate River)
	Elk River[2]	Not Applicable	325,000 fall-run smolts into Elk River	50,000 (winter-run smolts into Chetco River
			200,000 fall-run smolts into Chetco River	
California	Iron Gate[3]	79,710	6,280,978	104,324
	Trinity River[3]	502,617	4,434,995	800,000
	Mad River[4]	Not Applicable	Not Applicable	172,000
	Rowdy Creek	Not Applicable	105,000	100,000

[1] Data from ODFW 2014a
[2] Data from ODFW 2014b
[3] Data from ICF/Jones and Stokes 2010
[4] Data from CDFW 2013

Hatchery fish can affect natural salmon populations through a variety of ecological mechanisms, such as increased competition (Nickelson et al. 1986, NRC 1996, McMichael et al. 1997), predation (Sholes and Hallock 1979, HSRG 2004), genetic dilution (NRC 1996), and disease transmission (Goede 1986, NRC 1996, Coutant 1998, Moffitt et al. 1998). These interactions can occur immediately after release (presmolt or smolt stage) or after most hatchery smolts have emigrated. Effects from these stresses may include, on a population level: decreased spawning and reproductive success, decreased productivity, decreased abundance, changes in diversity and spatial structure, and mortality (Chilcote et al. 1986, Leider et al. 1990, Berejikian 1995, Fleming et al. 1997, McLean et al. 2003, HSRG 2004, Araki et al. 2009, Araki and Schmidt 2010, Williamson et al. 2010, Thériault et al. 2011, Whitcomb et al. 2014). In a recent literature review, 12 studies found negative effects of hatchery rearing on the fitness of hatchery fish, 8 studies found decreased reproductive success of hatchery origin fish, and 4 additional studies reported a decrease in the survival rate of hatchery fish as compared to wild fish (Araki and Schmidt 2010).

Competition

If hatchery fish are released in large numbers relative to natural-origin juveniles in a limiting environment, natural-origin fish may be affected through competition (Nielsen 1994). Competition occurs when the demand for a resource by two or more organisms exceeds the available supply (McMichael et al. 1999). Adverse competitive effects of hatchery salmonids on natural-origin salmonids may include food resource competition, competition for spawning sites, and redd superimposition (NMFS 2002a). Several studies have shown that wild fish may be displaced from preferred feeding and hiding locations by hatchery fish (Abbott et al. 1985, McMichael et al. 1997), which can lead to increased vulnerability to predation and decreased forage ability (McMichael et al. 1999). Ruggerone and Nielsen (2004) found evidence that intraspecific and interspecific competition with hatchery-origin juveniles and smolts in estuaries decreased the survival and growth rate of wild juveniles.

Adverse effects of competition may result from direct interactions, whereby a hatchery-origin fish interferes with natural-origin fish's access to limited resources, or through indirect means, such as the use of a limited resource by hatchery fish, which reduces the amount of resources available for natural-origin fish (SIWG 1984). Newly released hatchery smolts may compete with natural-origin smolts for food and space in areas where they interact during downstream migration (HSRG 2004). Interactions with juvenile hatchery-origin salmonids may lead to behavioral changes in natural-origin salmonids that are detrimental to productivity and survival (Pearsons et al. 1994). Many studies have suggested that hatchery-origin fish are competitively superior (when they are released at a larger size than the natural fish) and can displace natural-origin fish (Nickelson et al. 1986). Natural-origin fish may be competitively displaced by hatchery fish early in life, especially in cases when hatchery fish are more numerous, are of equal or greater size as wild fish, or are released as non-migrants and have taken up residency before natural-origin fry emerge from redds (Nielsen 1994, Pearsons et al. 1994).

Adverse effects from these interactions are dependent on the exposure time between populations, and the quantity and quality of habitat and resources available. The relative size of affected natural-origin fish when compared to hatchery fish, as well as the abundance of hatchery fish encountered, also will determine the degree to which natural-origin fish are displaced (Steward and Bjornn 1990). Large hatchery releases may cause displacement of rearing natural-origin juvenile salmonids from occupied stream areas, leading to abandonment of advantageous feeding stations or premature out-migration (Pearsons et al. 1994). Hatchery origin fish may also alter natural-origin salmonid migratory responses or movement patterns, leading to a decrease in foraging success (Hillman and Mullan 1989, Steward and Bjornn 1990).

In a review of 270 references on ecological effects of hatchery salmonids on natural salmonids, Flagg et al. (2000) found that, except in situations of low wild fish density, increasing release numbers of hatchery fish can negatively impact naturally produced fish. Evident from the review is that competition of hatchery fish with naturally produced fish almost always has the potential to displace wild fish from portions of their habitat (Flagg et al. 2000). Additional data on competition varies, and effects have been shown to be neutral to negative depending on the situation (NMFS 2002a). Any competitive interactions likely diminish as hatchery-produced fish disperse, but resource competition may continue to occur at some unknown, but lower level as natural-origin juvenile salmon and any commingled hatchery juveniles emigrate seaward (USFWS 1994).

Predation

Release of large numbers of hatchery salmonids in freshwater and estuarine areas brings risks to wild salmonids attributable to direct predation (direct consumption) or indirect predation (increases in predation by other predator species due to enhanced attraction) (NMFS 2002a). Studies have shown that hatchery fish can prey on smaller wild fish in some situations (Sholes and Hallock 1979, Hawkins and Tipping 1999, Pearsons et al. 2007, Naman and Sharpe 2010). The spatial and temporal overlap of predator and prey is one of the most influential factors in determining the extent of effects from predation (Naman and Sharpe 2010).

Hatchery-origin fish may prey upon wild juvenile salmonids at several stages of their life stage: when the smolts are newly released, when they have residualized prior to smolting (NMFS 2002a), or in estuarine and marine areas HSRG 2004). In general, natural-origin salmonid populations are most vulnerable to predation when natural-origin populations are depressed and predator abundance is high; in small streams, where migration distances are long; and when environmental conditions favor high visibility (SIWG 1984). Predation by hatchery fish on natural-origin smolts or sub-adults is less likely to occur than predation on fry. Naman and Sharpe (2010) found that there is at minimum a low level of predation occurring in all systems where yearling salmonids are released and overlap with smaller fish.

The potential for adverse effects on natural coho salmon populations is highest in late spring when lower flows and higher water temperatures may increase competition for suitable rearing habitat (CDFG and NMFS 2001). In the Trinity River, predation rates as high as 0.53 percent have been documented (Naman 2008). Naman (2008) found that when hatchery steelhead are released in March and April, natural-origin salmonids are very small, increasing the potential for predation. This study also found that hatchery-origin steelhead were able to consume prey that were up to 45 percent of their body length, and that hatchery-origin steelhead did not appear to be gape limited, meaning their prey was not too big to fit into their mouths (Naman 2008). Although the level of predation may not be as high in other SONCC coho salmon ESU basins with hatcheries, predation of natural coho salmon by hatchery steelhead is likely occurring at some level. Given the small number of wild-born juvenile coho salmon, predation at any level may be having an adverse effect on coho salmon.

Genetic Diversity

Gene flow occurs naturally among salmon and steelhead populations, a process referred to as straying (Quinn 1993, Quinn 1997). Straying occurs when an adult spawns in a stream other than the one it was born in. Natural straying serves a valuable function in preserving diversity through genetic drift and in re-colonization of vacant habitat. However, straying may be considered a risk when it occurs at unnatural levels or from unnatural sources, such as hatchery fish. Hatchery fish may be a threat to natural population productivity, diversity, and natural gene flow when they interbreed with natural-origin fish. Hatchery fish straying is considered a risk if it results in additional and potentially harmful gene-flow.

Hatchery activities can threaten the natural genetic diversity among salmon populations in several different ways. Many hatcheries have historically bred and released salmon that were not native to the drainage into which they were released. When these fish stray and breed with native salmon, the unique genetic attributes of the local salmon populations can be degraded or lost through dilution by the genetic attributes of the out-of-basin fish (Reisenbichler and Rubin 1999, Ford 2002). In addition, the transferring of genes from hatchery fish to wild fish can be problematic because hatchery programs have the potential to significantly alter phenotypic traits (Hard et al. 2000; Kostow 2004) and behavior (Berejikian et al. 1996) of reared fish. Genetic interactions between hatchery and naturally produced stocks can decrease the amount of genetic and phenotypic diversity of a species by homogenizing once disparate traits of hatchery and natural fish. The result can be progeny with lower survival (McGinnity et al. 2003, Kostow 2004) and ultimately, a reduction in the reproductive success of the natural stock (Reisenbichler and McIntyre 1977, Chilcote 2003, Araki et al. 2007b, Williamson et al. 2010, Chilcote et al. 2011, Thériault et al. 2011, Whitcomb et al. 2014), potentially compromising the viability of natural stocks via out breeding depression (Reisenbichler and Rubin 1999, HSRG 2004). Araki et al. (2009) found wild-born descendants of hatchery fish showed significant decreases in reproductive success, and that reproductive success can decrease as rapidly as 40 percent per captive reared generation. Hatchery fish may exhibit reduced homing fidelity relative to natural-origin fish (Grant 1997, Quinn 1997, Jonsson et al. 2003, Goodman 2005), resulting in unnatural levels of gene flow into recipient populations.

Natural populations in the Klamath and Trinity basins are heavily influenced by hatcheries (Weitkamp et al. 1995; Good et al. 2005) through genetic and ecological interactions. Genetic risks associated with out-of-basin and out-of-ESU stock transfers have largely been eliminated because such transfers rarely occur. However, two significant genetic concerns remain: 1) the potential for domestication selection in hatchery populations such as the Trinity River, where there is little or no infusion of wild genes, and 2) straying by large numbers of hatchery coho salmon either in basin or out-of-basin. Spawning by hatchery salmonids in rivers and streams is often not controlled (Independent Scientific Advisory Board 2002) and hatchery fish stray into rivers and streams, transferring genes from hatchery populations into naturally spawning populations (Pearse et al. 2007).

Because most of the main stocks in the SONCC coho salmon ESU (i.e., Rogue River, Klamath River, and Trinity River) remain heavily influenced by hatcheries and have little natural production in mainstem rivers (Weitkamp et al. 1995; Good et al. 2005), many of these populations have reduced genetic diversity. The genetic and life-history diversity of the Shasta

River population unit has been significantly impaired by the straying of hatchery-born coho salmon from Iron Gate Hatchery. Straying of adult hatchery coho salmon into the Shasta River has been estimated at 2, 73, 20, and 25 percent of the spawning population from 2007-2010, respectively (Chesney and Knechtle 2011b). Hatchery-origin coho salmon make up most of the spawning run to the Trinity River each year. On average, only three percent of in-river spawners in the Upper Trinity River were not reared in a hatchery (USFWS and HVT 1999). Between 1997 and 2002, hatchery coho salmon constituted between 85 percent and 97 percent of the coho salmon (adults plus jacks) returning to the Willow Creek weir in the Lower Trinity River (CDFG 2009). Most of these fish likely migrate upstream and interact with naturally-produced coho salmon in the Upper Trinity River. Spawning surveys in 1998-99 found a high proportion of hatchery strays (60-100 percent) in all Lower Trinity River streams where coho salmon were found (Dutra and Thomas 1999). Jong and Mills (1992) found that 35.8 percent of returning adults to the South Fork Trinity River in 1985 were of hatchery origin. Because adult coho salmon returns to Trinity Hatchery have been in excess of 25,000 fish during some years, it is likely that the stray rate of hatchery coho salmon to the South Fork Trinity River has continued to be high (>35 percent). Although the actual proportion of hatchery fish in the river changes from year to year and depends largely on natural returns, these data indicate that straying of hatchery coho salmon does occur in important tributaries of the Klamath River basin.

Not all effects of hatchery fish on natural origin fish are negative. In populations experiencing very low abundance, such as the Shasta River population, the presence of hatchery fish can help maintain a population until abundance increases or habitat improves. The addition of hatchery-origin fish to a population that is experiencing reduced abundance can assist in continuing the retention of a full set of genes and genetic characteristics that may only exist in the hatchery-origin population (Brannon et al. 2004). Using hatchery fish to improve genetic diversity may assist the population in the long run when abundance and productivity increase, allowing the complete life-history diversity and genetic traits of the population to exist for future generations (Brannon et al. 2004). Since hatchery fish retain genes from their originating population, increasing the breeding population size of an extant population by adding hatchery fish can provide a benefit by contributing genetic variation to the existing wild population, variation that is necessary to adapt to changing conditions over time (Brannon et al. 2004).

Disease

Natural-origin coho salmon may be exposed to diseases from hatchery-born coho salmon through hatchery effluent, which can contain fish pathogens. Interactions between hatchery fish and natural fish in the environment may also result in the transmission of pathogens if either the hatchery or natural fish are harboring fish disease and the two types of fish interact (NMFS 2002a). Under natural, low-density conditions, most pathogens do not lead to a disease outbreak. When fish disease outbreaks do occur, they are often triggered by stressful hatchery rearing conditions, or by a deleterious change in the environment (Saunders 1991). Hatchery-origin fish may have an increased risk of carrying fish disease pathogens because of relatively high rearing densities that increase stress and can lead to greater manifestation and spread of disease within the hatchery population.

3.1.2 Impaired Water Quality

One of the most important ecological requirements of coho salmon is cold, clean, well-oxygenated water. Impaired water quality parameters in the SONCC coho salmon ESU include increased water temperature, changes in pH above or below optimum levels, reduced dissolved oxygen, increased nutrient loading, and increased extent or duration of turbidity. Human activities that impair water quality include water diversions, in-channel construction, riparian vegetation reduction, agriculture, alteration of the streambed and banks, components of timber management, and the introduction of point- and non-point source pollution from urbanization and industrialization. NMFS concluded that impaired water quality is either a high or very high stress in 27 out of 40 populations in the SONCC coho salmon ESU, primarily due to increased water temperature, decreased dissolved oxygen, and increased turbidity (Table 3-4; Chapters 7 to 46).

Increased water temperature is one of the most widespread (and greatest) stresses in the SONCC coho salmon ESU. Water temperature influences coho salmon growth and feeding rates (partly through increased metabolism) and development of embryos and alevins (McCullough 1999), as well as timing of life-history events such as freshwater rearing, seaward migration (Holtby and Scrivener 1989), upstream migration and spawning (Spence et al. 1996). Increased water temperature can be detrimental to the survival of most life stages of coho salmon, but in the SONCC coho salmon ESU summer-rearing juveniles are the most likely to be affected by elevated water temperatures. Elevated water temperature can result in increased levels of stress hormones in coho salmon, often resulting in mortality (Ligon et al. 1999). Increased water temperature, even at sub-lethal levels can inhibit migration, reduce growth, stress fish, reduce reproductive success, inhibit smoltification, contribute to outbreaks of disease, and alter competitive dominance (Elliott 1981). Increases in water temperature may result from changes in the quantity and quality of riparian vegetation, the presence of dams, water diversions, other anthropogenic activities, and have also been correlated to large-scale (or localized) climate change and precipitation. Additionally, threats including timber harvest, urbanization, roads, and other land use activities affect water temperatures within the SONCC coho ESU.

In addition to appropriate water temperatures, salmonids need adequate concentrations of dissolved oxygen for the survival of all life stages (Spence et al. 1996). Reduced levels of dissolved oxygen can impair the growth (Herrmann et al. 1962) and developmental (Silver et al. 1963) processes of various life stages of salmon, including eggs and fry. Low dissolved oxygen can also decrease the swimming (Davis et al. 1963), feeding and reproductive ability of juveniles and adults (Bjornn and Reiser 1991). Such impacts can affect fitness and survival by altering embryo incubation periods, decreasing the size of fry, increasing the likelihood of predation, and decreasing feeding activity (Carter 2005). Under extreme conditions, low dissolved oxygen concentrations can be lethal to salmonids (Bjornn and Reiser 1991).

Nutrient contributions from sources such as fertilizer run-off, livestock, and septic systems may foster algae blooms that can contribute to elevated pH levels, increased ammonia toxicity, and depressed dissolved oxygen levels. Algae and other aquatic plants create diel 24 hour cycles in which photosynthesis causes high pH during daylight hours and respiration causes low dissolved oxygen at night (Nimick et al. 2011), both of which may be stressful or lethal to salmonids. Additional water quality impairments may be caused when large algae blooms begin to decay and increase the biological oxygen demand (Lathrop et al. 1998, Landsberg 2002). These water quality problems may be exacerbated by reduced flows.

Both acidic (pH <6.5) or alkaline conditions (pH >8.5) can cause salmonid stress (Spence et al. 1996). Adverse effects from low pH can occur at levels that are not lethal to adult fish, but which can impair reproduction and other processes. Reproductive impairments include altered spawning behavior, reduced egg viability, decreased emergence success and reduced survival of the early life stages which are known to be the most vulnerable to low pH (Jordahl and Benson 1987). Conversely, chronic high pH levels in freshwater streams can also decrease activity levels of juvenile salmonids, induce stress responses, decrease or stop feeding, and induce a loss of equilibrium (Murray and Ziebell 1984). Prolonged exposure to pH levels of 8.5 or greater may exhaust the ion exchange capacity at gill membranes and lead to increased alkalinity in the bloodstream of salmonids (Wilkie and Wood 1995). If water temperatures are high (e.g. 25 °C), high pH may also cause conversion of ammonium ions to highly toxic dissolved ammonia (Goldman and Horne 1983).

Historically, populations of adult Pacific salmon and steelhead released mass quantities of nutrients, energy, and other essential biomolecules into their natal watersheds through the process of reproduction. These salmon-derived materials (marine-derived nutrients) support the productivity of freshwater and riparian food webs through release of eggs and carcass decomposition. The salmon-nutrients promote both primary and secondary productivity and ultimately juvenile salmonid growth (Bilby et al. 1996, Schindler et al. 2003, Kiffney et al. 2014). However, salmon spawning populations are severely reduced across much of their native range (CA, OR, WA, ID); population reductions of over 90% in some rivers are likely contributing to widespread resource limitation for salmonid-rearing food webs (Gresh et al. 2000). For example, a recent study in the Cedar River, Washington documented that observed food limitation in juvenile coho salmon can be remedied by providing access to salmon analogs (pasteurized pellets formed from adult Chinook salmon); specifically coho body size was 50% greater at the end of a 45-d experiment in which salmon analogs were added at a biomass density of 0.6 kg/m^2 (Kiffney et al. 2014). Similar juvenile salmonid growth responses have been observed in a variety of field and experimental studies (Bilby et al. 1996, Wipfli et al. 2004, Guyette et al. 2013).

A number of studies have suggested that restoration of food web processes, including restoring the resources provided from spawning salmon, may serve as an effective strategy in addressing food-limitation in salmonid-rearing food webs thereby contributing to population recovery of listed salmon populations (Wipfli and Baxter 2010). There are four possible approaches to addressing resource limitation of salmonid-rearing food webs, including additions of inorganic nutrients, salmon carcass analogs, natural salmon carcasses and increased adult escapement. Resource additions of salmon carcass tissue have promoted food web productivity, including juvenile salmonid growth, across a range of loading rates (~0.1 – 1.0 kg/m^2 wet mass of salmon tissue or analogs; Claeson et al. 2006, Janetski et al. 2009, Kohler et al. 2012, Kiffney et al. 2014).

The four approaches to restoring inputs of marine-derived nutrients have a number of advantages and disadvantages; which method is most effective and practical depends on a variety of conditions including time of year, ambient nutrient levels, spawning biomass densities, and logistical constraints (e.g., remoteness, costs, access to disease-free carcasses, staff, see Kiffney et al. 2005 and Compton et al. 2006). For example, the ecological effects of live adult salmon exceed those of carcasses (Tiegs et al. 2011) and resource additions in summer likely exceed those in late fall or winter (Kiffney et al. 2014). All nutrient addition projects, regardless of the method of enhancement, should be coupled with monitoring programs to ensure objectives and targets are met and that unintended consequences are avoided. What to monitor depends on technical and logistical constraints but could include nutrient concentrations in water (total and dissolved nitrogen and phosphorus); periphyton and invertebrate productivity; salmonid growth, biomass and smolt production; and the stable isotopes of carbon and nitrogen, which provide a tracer for salmon-derived nutrients (Bilby et al. 2001, Kiffney et al. 2005, Compton et al. 2006).

Water Quality Programs

Federal and state programs exist to maintain and improve water quality conditions throughout the SONCC coho salmon ESU. Both California and Oregon have statewide water quality programs aimed at improving current water quality conditions, and the U.S. Environmental Protection Agency (USEPA) works closely with both states to identify and improve conditions in impaired watersheds.

In 1969, the California Legislature enacted the Porter-Cologne Water Quality Control Act (the Act) to preserve, enhance and restore the quality of the State's water resources. The Porter-Cologne Act is the principal law governing water quality in California. Unlike the Clean Water Act, Porter-Cologne applies to both surface water and ground water. Beyond establishment of the state framework, this act has been revised to comply with the federal Clean Water Act.

The Act established the State Water Resources Control Board (SWRCB) and nine Regional Water Quality Control Boards (RWQCBs) as the principal state agencies with the responsibility for controlling water quality in California. Under the Act, water quality policy is established, water quality standards are enforced for both surface and ground water, and discharges of pollutants from point and non-point sources are regulated. The Act authorizes the SWRCB to establish water quality principles and guidelines for long range resource planning including ground water and surface water management programs and control and use of recycled water. The California Coastal Act of 1976 extended the California Coastal Commission’s authority indefinitely. The California Coastal Commission was established by a voter initiative in 1972, and provides oversight for projects that impact water resources along the California coast. The California Coastal Commission has joint responsibility with the State Board and Regional Boards for implementation of the state’s Nonpoint Source Program (see section 319 of the Clean Water Act, section 309 of the Coastal Zone Management Act of 1972, and section 6217 of the Coastal Zone Act Reauthorization Amendments of 1990).

The Oregon Department of Environmental Quality (ODEQ) is the state agency responsible for protecting Oregon’s surface waters and groundwater. ODEQ’s Water Quality Program develops water quality standards for Oregon’s waters, monitors water quality in designated river basins, regulates point source discharges, regulates injection systems by issuing permits to protect groundwater, and controls nonpoint sources of pollution through statewide management plans. Oregon has established both numeric and narrative water quality criteria, but does not have streamflow criteria to protect streamflow. Anti-degradation rules exist in areas around the state and help to maintain water beneficial uses of water. ODEQ is the state agency tasked with developing and implementing TMDLs.

Using the Oregon Water Quality Index to monitor trends in water quality, ODEQ regularly collects water samples at over 150 sites on more than 50 rivers and streams across the state. ODEQ visits most sites six times annually and tests a number of water quality variables at each visit. The state has monitored some sites routinely since the late 1940s (available at http://www.deq.state.or.us/lab/wqm/docs/09-LAB-004.pdf). The data are used to determine whether there is too much pollution in a water body, and to set limits on how much pollution a water body can receive. The ODEQ also maintains a volunteer water quality monitoring program around the state, providing equipment and assistance to volunteers and groups wanting to assist in water quality data collection (available at: http://www.deq.state.or.us/lab/wqm/docs/08-LAB-015.pdf). Oregon's Water Quality Nonpoint Source Control Program Plan (ODEQ 2000) identified the pollution management programs, strategies, and resources that were currently in place or that were needed to minimize nonpoint source pollution effects. The plan integrates a variety of other state and federal initiatives, and the state is currently completed the process of re-evaluating the program.

The Clean Water Act (CWA; 33 USC § 1251 et seq.) is a federal law aimed at improving and protecting water resources around the United States. The CWA was adopted "to restore and maintain the chemical, physical and biological integrity of the Nation's waters" (33 U.S.C. § 1251(a)). Under section 303(d) of the CWA (33 USC 1313(d)), States are required to identify those waters that are not meeting water quality standards. These waters are placed on the State's list of impaired waters, which is submitted to the U.S. Environmental Protection Agency (USEPA) for review and approval. States must develop total maximum daily loads (TMDLs) for these impaired waters. TMDLs are a calculation of the maximum amount of a pollutant that a water body can receive and still safely meet water quality standards. If the USEPA disapproves of the State's list of impaired waters and TMDLs, then the USEPA establishes the list and TMDLs.

Since the initial listing of SONCC coho salmon many TMDLs have been completed (Table 3-6), and California and Oregon are working to manage excessive pollutants and other water quality impediments. TMDLs in California are developed by RWQCBs. These TMDLs are designed as Basin Plan amendments and include implementation provisions. The beneficial use of salmonid fishes is most often affected by non-point source sediment and temperature impairments, so development of non-point source TMDLs is important. The ability of these TMDLs to protect coho salmon in Oregon and California is expected to be significant in the long term. Ultimately their efficacy in protecting coho salmon habitat will depend on how well the protective measures are implemented, monitored, and enforced.

Table 3-6. List of total maximum daily loads (TMDLs) and their status. Data from the North Coast Regional Water Control Board and the Oregon Department of Environmental Quality websites.

Watershed	Pollutant(s)	TMDL Status	Watershed	Pollutant(s)	TMDL Status
Mattole River	Sediment and Temperature	Completed - 2004	Klamath River	Sediment	In Progress
Lower Eel River	Sediment and Temperature	Completed - 2007	Salmon River	Temperature	Completed - 2006
Lower Eel River	Low Dissolved Oxygen	In Progress	Scott River	Sediment and Temperature	Completed - 2006
Van Duzen River	Sediment	Completed - 1999	Shasta River	Organic enrichment, Low DO, Temperature	Completed - 2007
Middle Fork Eel River	Sediment and Temperature	Completed - 2003	Upper Trinity River	Sediment	Completed - 2001
Middle Mainstem Eel River	Sediment and Temperature	Completed - 2004	Upper Trinity River	Mercury	In Progress
North Fork Eel River	Sediment and Temperature	Completed - 2002	South Fork Trinity River	Sediment	Completed - 2001
South Fork Eel River	Sediment and Temperature	Completed - 1999	South Fork Trinity River	Temperature	In Progress
Upper Mainstem Eel River	Sediment and Temperature	Completed - 2004	Upper Rogue River	Bacteria, DO, pH, Sediment, Temperature	Completed - 2008
Elk River	Sediment	Completed-2011	Middle Rogue River	Bacteria, Sediment, Temperature	Completed - 2008
Freshwater Creek	Sediment	Completed-2011	Lower Rogue River	Bacteria, Temperature	Completed - 2008
Humboldt Bay	PCBs	In Progress	Lobster Creek (Rogue River)	Temperature	Completed - 2002
Jacoby Creek	Sediment	In Progress	Bear Creek (Rogue River)	Temperature, Bacteria	Completed - 2008
Mad River	Sediment, Turbidity, Temperature	Completed - 2007	Lower Sucker Cr (Illinois River)	Temperature	Completed - 2002
Redwood Creek	Sediment	Completed - 1998	Illinois River	Temperature	Completed - 2008
Redwood Creek	Temperature	In Progress	Chetco River	Bacteria, DO, pH, Temperature	Initiated
Klamath River	Nutrients, Bacteria, Temperature, Low DO	Completed - 2010	Applegate River	Temperature, DO	Completed - 2004

Under CWA section 518(e) (33 U.S.C. § 1377(e)), tribes may apply to the USEPA to be treated as a State for purposes of various listed sections of the CWA, and USEPA-approved tribal water quality standards apply to surface waters within tribal lands. The Hoopa Valley, Yurok, and Karuk tribes have all developed water quality control plans (Hoopa Valley Tribe Environmental Protection Agency 2008, Yurok Tribal Environmental Program 2004, Karuk Tribe of California 2002) and the Quartz Valley and Resighini Rancherias have developed water quality programs (Quartz Valley Indian Reservation 2009, Resighini Rancheria Environmental Department 2006).

3.1.3 Degraded Riparian Forest Conditions

Riparian forests provide significant benefits to freshwater aquatic systems and the biota that live within and around them (Welsch 1991). Riparian forests influence the water table, moderate discharge during high flow events, regulate microclimates, provide shade to control temperature, protect stream banks from erosion (Bisson and Wondzell 2009), intercept sediment (Mellina and Hinch 2009), and help maintain instream water quality by filtering nutrient runoff (Welsch 1991). In addition, riparian forests are the source of instream large wood, which is important in creating and maintaining the habitat complexity necessary for high quality coho salmon rearing habitat (Crispin et al. 1993, Gallagher et al. 2012) and providing breeding sites for some amphibians and invertebrates (Moseley et al. 1998). Though all riparian forests supply wood to streams, old growth and late seral forests tend to be dominated by large conifers, which are uniquely capable of shaping instream and floodplain conditions as dead wood (Naiman et al. 2010).

Riparian dead wood provides numerous ecological functions, which vary somewhat depending on whether they remain standing or fall onto the forest floor or into water bodies such as streams, wetlands or ponds (Pollock and Beechie 2014). Thinning riparian conifer forests generally reduces the production of ecologically functional riparian dead wood (e.g., >30 cm or > 50 cm diameter) in both the short and long term, in correlation with the intensity of the thin (Pollock et al. 2012, Pollock and Beechie 2014). Optimal thinning conditions in moist Douglas-fir forests are in young (<40 years), densely planted (>300 trees per acre) stands where the primary management goal is to produce very large diameter live trees or very large diameter dead wood (Beechie et al. 2000, Pollock and Beechie 2014). For example, in Beechie et al. (2000), moderate thinning adjacent to large (15 m wide) streams increased "pool forming" wood production, whereas such thinning next to smaller streams reduced pool-forming wood production (See table 2 and figure 6 of Beechie et al. 2000). Riparian area structure and composition throughout the ESU has changed due to irrigation diversions, timber harvest, farming, grazing, wildfire, and urbanization, which all contribute to a high or very high ranking of degraded riparian forest conditions in 33 populations in the ESU (Table 3-4; Chapters 7 to 46). Of these, timber harvest has been the primary source of human disturbance in riparian areas (Villarin et al. 2009). In California, harvest of riparian redwood forests began in the middle of the 19th century but was then reduced after 1973 when the California Forest Practices Act set limits to harvest in riparian zones (Russell 2009). Historically, riparian forests were frequently harvested to the edge of the water and logs were dragged through the water to splash dams and haul roads (Richardson et al. 2012). Historic timber practices often significantly altered riparian forest composition to favor early successional stages dominated by deciduous species such as red alder and willow (Sedell et al. 1988, Russell 2009, Villarin et al. 2009). As a consequence, many stream banks have smaller trees of fewer species resulting in smaller, shorter-lived instream large wood (Sedell et al. 1988), even 100 years after harvest (Russell 2009).

Agriculture and livestock grazing have also degraded riparian forests. Geographic Information System (GIS) analyses of land use and ownership in coastal Oregon indicate that much of the larger low gradient, low elevation river valleys that historically supported coho salmon are privately owned and their riparian forests have been cleared for agricultural and developed uses (Burnett et al. 2007, Firman et al. 2011), a condition that also exists within coastal California. The conversion of forest to agriculture is associated with many negative effects on stream ecosystems, including lower densities of coho salmon, a lack of conifers, and a scarcity of large wood (Burnett et al. 2007, Firman et al. 2011). Livestock grazing affects riparian zones by compacting soil, removing vegetation, preventing woody seedling growth, and physically impacting stream morphology by breaking down banks, often resulting in wide, shallow channels (Belsky et al. 1999, Poff et al. 2011). Major bank erosion and mass wasting is much more prevalent on non-vegetated stream banks, resulting in increased sediment loads and channel widening (Naiman and Decamps 1997).

Riparian ecosystems are complex and the various threats to them should be viewed collectively (Poff et al. 2011). For example, episodic flooding plays a major role in structuring riparian vegetation in a natural ecosystem (Hawkins et al. 1997, Villarin et al. 2009), but after human alterations to riparian areas, the overall effects of floods are exaggerated (Hawkins et al. 1997). Disruption to natural landscapes, such as timber harvest (and associated road building), livestock grazing, and urbanization can promote rapid runoff (Hawkins et al. 1997, Beechie et al. 2012) and magnify the destructive power of peak flows to stream banks left unprotected by overgrazing or over-harvesting (Hawkins et al. 1997). Major floods occurring in the years 1955, 1964, 1974, 1986, 1997, and 2006 likely caused significant damage to riparian areas throughout the ESU. In general, eliminating or decreasing riparian areas may result in stream channelizing and straightening, channel widening, channel aggradation, and lowering of the water table (Belsky et al. 1999). The effects of degraded riparian conditions on fish habitat include reduction of streamside shade and cover, decreased large wood recruitment, increases in stream temperature, changes in water quality and stream morphology, and the addition of sediment through bank degradation and off-site soil erosion (Forest Ecosystem Management Team [FEMAT] 1993, Spence et al. 1996, Cohen 1997, Mellina and Hinch 2009).

3.1.4 Increased Disease/Predation/Competition

Disease and predation are locally significant throughout the ESU, and are likely limiting the recovery of some SONCC coho salmon populations. Currently, disease and predation are listed as a high or very high stress to 13 populations in the ESU (Table 3-4). Impacts from diseases are likely exacerbated by human-induced environmental impacts and activities, such as alteration of hydrologic function through dams and diversions, impaired water quality conditions, hatchery practices, habitat alterations, and changing climatic conditions. Coho salmon are exposed to numerous bacterial, protozoan, and parasitic pathogens throughout their lives, and have evolved with exposure to these and other organisms (Stocking and Bartholomew 2004). Susceptibility of fish to disease changes according to environmental condition and overall health. When water quality deteriorates, diminished flows cause crowding and stress, or when parasite spore loads are extremely high, then lethal disease outbreaks can occur (Foott 1995, Spence et al. 1996, Guillen 2003, CDFG 2004b, Yurok Tribal Environmental Program 2004, Nichols and Foott 2005). Disease issues arise when the interaction between host and pathogen is altered and when natural resistance levels become impaired by stressful environmental conditions or decreased fitness levels. Within the last few decades, the prevalence of diseases in wild stocks has been an increasing concern, and has become a factor in the continuing survival and viability of wild stocks of coho salmon (CDFG 2002a).

Diseases can affect coho salmon in almost any life stage where exposure occurs. Some diseases infect returning adults as they enter bays and estuaries, while other diseases attack or kill juveniles rearing upstream. Many pathogens may remain dormant in juveniles or when conditions are not stressful, and then appear symptomatically when fish return to freshwater and conditions become stressful. Different life stages have different susceptibilities, making it difficult to discern time of infection or disease infection rates and causes. Known diseases and disease agents that can cause significant losses to adults include: bacterial kidney disease (*Renibacterium salmoninarum*), furunculosis (*Aeromonas salmonicida*), columnaris (*Flexibacter columnaris*), *pseudomonas/aeromonas*, and *ichthyopthirius* or "Ich" (*Ichthyopthirius multifilis*). Juvenile salmonids are primarily affected by furunculosis, columnaris (*Flavobacterium columnare*), coldwater disease (*Flexibacter psychrophilis*), *Nanophyetus salmonicola*, Aeromonid bacteria, pseudomonas/aeromonas, ichthyopthirius, the kidney myxosporean *Parvicapsula minibicornis*, and ceratomyxosis (*Ceratonova shasta*) (CDFG 2002a, Federal Energy Regulatory Commission [FERC] 2007).

Diseases proliferate when fish are stressed by high water temperatures, crowding, environmental contaminants, or decreased oxygen (Warren 1991). In addition, adequate water quantity and quality during the late summer months are critical in controlling or triggering disease epidemics, and degraded condition of these variables may trigger the onset of epidemics in fish that are carrying the infectious agents (Holt et al. 1975, Wood 1979, Matthews et al. 1986, Maule et al. 1988). Problems remain in identifying the proximate and ultimate causes of death due to epidemic disease outbreaks, and the subsequent effect that these are having on population survival numbers. The lack of data continues to hamper the efforts of managers to understand the full effect that disease is having on coho salmon populations.

Although not emphasized in the original listing document, ceratomyxosis, which is caused by *C. shasta*, is one of the most significant diseases affecting juvenile coho salmon due to its prevalence and impacts in the Klamath Basin (Nichols et al. 2003). Bartholomew et al. (2006) believes that the recent increases in air temperature may be compounding the disease potential in the Klamath Basin. High water temperature, low dissolved oxygen, high pH (alkalinity) and possibly unionized ammonia in the mainstem Klamath River create stressful conditions for all ages and types of salmonids. These conditions can then increase disease transmission to coho salmon. Severe infection of juvenile coho salmon by *C. shasta* may be contributing to declining adult coho salmon returns in the Klamath basin (Foott et al. 2010). *C. shasta* has been responsible for most of the mortality of Klamath River juvenile salmonids in recent years. Mortality rates from temporary and longer term exposures at various locations in the Klamath River vary based on location, time of year, year, and water temperature, but are consistently high (10 to 90 percent) (Bartholomew 2008).

In addition, parasitic infections by *P. minibicornis* were detected in 65 percent of young of the year and 71 percent of yearling coho salmon in the mainstem Klamath River in 2007 (Nichols et al. 2008). Additionally, the Klamath River below Iron Gate Dam supports large populations of the intermediate host (a polychaete worm) of *C. shasta* due to an abundant food supply (particulate organic matter) and ample amounts of its two favored substrates (fine particulate organic matter that settles on the bottom of the river bed and mats of the attached algal species *Cladophora* that are stimulated by high nutrient levels).

Adults in the Klamath basin are also impacted by other diseases, primarily from the common pathogens *Ichthyopthirius multifilis* (Ich) and *Flavobacterium columnare* (columnaris) (NRC 2004). These pathogens were partially responsible for the 2002 adult fish kill on the Klamath River (USFWS 2003, Lynch and Risely 2003, Belchik et al. 2004, CDFG 2004b). During this event, over 300 coho salmon and 34,000 Chinook salmon were killed by a disease epizootic from Ich and columnaris, which was exacerbated by stressful conditions in the Klamath River (USFWS 2003, Belchik et al. 2004, CDFG 2004b). Conditions favoring massive growth of Ich and columnaris were created that year due to high densities of returning Chinook salmon, low September flows and warm water temperatures (USFWS 2003, Belchik et al. 2004, CDFG 2004b) that likely delayed and inhibited migration of adult fish further upstream (USFWS 2003). Adult mortality from Ich and columnaris are not as common as juvenile mortality from *C. shasta* or *P. minibicornis* (Bartholomew et al. 2003). In summary, disease effects are likely to negatively impact all of the VSP parameters for the SONCC coho salmon ESU, especially in the Klamath River Basin, because both adults and juveniles can experience high mortality in some years.

At the time of listing, predation was listed as a factor contributing to the decline and listing of coho salmon in the SONCC ESU, but more recent data suggests that it is a bigger problem than originally thought. Notable predators include non-native Sacramento Pikeminnow (*Ptychocheilus grandis*) and hatchery fish, as well as predation by other non-native species in some areas. These impacts are exacerbated by habitat modification, impaired water quality, hatchery practices, and other anthropogenic activities (Marine and Cech 2004).

In some watersheds, the rapid expansion of invasive predator populations was facilitated by alterations in habitat conditions (particularly increased water temperatures) that favor these species (Brown et al. 1994). Non-native fishes such as Sacramento pikeminnow, smallmouth bass (*Micropterus dolomieu*), brown trout (*Salmo trutta morpha fario*) and channel catfish (*Ictalurus punctatus*) can consume significant numbers of juvenile salmon (NMFS 1998). Sacramento pikeminnow have been observed throughout the Eel River basin and are a predator likely limiting juvenile coho salmon survival (CDFG 1994, 2004; NMFS 1996). In the Trinity River, brown trout are abundant enough to make up a substantial proportion of observations by biologists collecting juvenile salmonid habitat utilization data (Martin, A., pers. comm. 2009) and they likely consume naturally produced fry and juvenile coho salmon. Without adequate avoidance habitat (deep pools and undercut banks), and adequate flows for migration and rearing, predation can have a significant negative effect on juvenile salmonid growth (Quinn and Peterson 1996, Schlosser 1987, Bugert and Bjornn 1991, Bjornn and Reiser 1991, Brown 1999).

In addition to non-native species, hatchery fish can exert predation pressure on juvenile coho salmon. Native fishes in coastal streams and rivers have generally coevolved with native salmon and steelhead, which are also used for hatchery stocks. Under natural conditions native fishes may subsist with minimal, if any, negative interactions with salmon and steelhead in rivers and streams. The addition of large numbers of hatchery fish at one time and location, such as that occurring under salmon and steelhead stocking programs, may potentially result in locally elevated rates of predation and competition (ICF/Jones & Stokes 2010). The potential for predation and competition between hatchery‒reared and naturally produced salmonids depends on the degree of spatial and temporal overlap, differences in size and feeding habitats, migration rate and duration of freshwater residence, and the distribution, habitat use, and densities of hatchery and natural juveniles (Mobrand et al. 2005). Recently, concern has been expressed about the potential for hatchery‒reared salmon and steelhead to prey on or compete with wild juvenile Pacific salmonids (*Oncorhynchus* spp.) and the impact this may have on threatened or endangered salmonid populations (Naman 2008, Kostow 2009). Released at larger sizes and in great quantity, hatchery-reared salmonids prey on naturally-produced juvenile coho salmon (Kostow 2009). For example, predation by hatchery fish may result in the loss of tens of thousands of naturally produced coho salmon fry annually in some areas of the Trinity River (Naman 2008). Nickelson (2003) demonstrated that the productivity of wild coho salmon in 14 Oregon coastal basins was negatively correlated to the average number of hatchery smolts released into these basins, suggesting strong ecological interactions between hatchery and wild fish. Nickelson (2003) also reviewed evidence for the role of behavior and concluded that large numbers of hatchery fish likely increase mortality of wild fish by attracting predators and/or increasing their exposure to predators.

Predation by marine mammals (principally seals and sea lions) is a concern in areas experiencing dwindling run sizes of salmon (69 FR 33102, June 14, 2004). However, salmonids appear to be a minor component of the diet of marine mammals and therefore this type of predation is likely not contributing significantly to further decreases in run sizes (Scheffer and Sperry 1931, Jameson and Kenyon 1977, Graybill 1981, Brown and Mate 1983, Roffe and Mate 1984, Hanson 1993, Goley and Gemmer 2000, Williamson and Hillemeier 2001). Among other mammalian predators that can impact salmonid populations in freshwater areas, mink (*Mustela vison*) and otter (*Lutra canadensis*) can take significant numbers of overwintering coho salmon juveniles and migrating smolts, although this is dependent upon conditions favorable to predators and the availability of other prey (Sandercock 1991).

3.1.5 Altered Sediment Supply

The complex riverine habitat that coho salmon thrive in depends upon a balance of instream structure, transport capacity, and sediment supply (Yarnell et al. 2006). The alteration in the quantity and composition of the sediment supply into streams and rivers is a stress created through a variety of human induced threats. Increases in turbidity, changes in the quantity and quality of suspended sediment, and associated decreases in water quality can be caused by a variety of activities including timber harvest, grazing, agriculture, mining, road building, urbanization, and construction (Bash et al. 2001). These activities, when performed in excess or without proper management, have been shown to have the ability to contribute to periodic pulses or chronic levels of suspended sediment in streams (Bash et al. 2001) and likely have a wide range of effects on all life stages of salmonids. Impacts caused by these activities include changes to the size and composition of sediment entering the stream (Opperman et al. 2005, Kaufmann et al. 2009), changes to the quantity of sediment (Reid et al. 2010), and alterations in the timing of sediment entering stream channels (Cordone and Kelley 1961). Altered sediment supply is a high or very high stress in 31 populations in the SONCC coho salmon ESU (Table 3-4).

Many of the historical and ongoing anthropogenic activities in the ESU have caused changes to the amount and timing of sediment delivery to streams, most often evident as an increased amount of fine sediment. Increased sedimentation has been shown to have direct negative effects on coho salmon by interfering with their physiological and biological processes, and indirect effects through degradation of their habitat (Cordone and Kelley 1961, Koski 1966, Kondolf 2000). Accelerated rates of erosion and increased sediment delivery to streams after timber harvest and road construction are common occurrences in the mountainous, forested watersheds that are common in the ESU (Sidle et al. 1985, Montgomery et al. 2000). Impacts may result directly from increased sediment in suspension or through the deposition of fine sediment on or within the stream bed (Collins et al. 2011). High concentrations of suspended sediment can increase turbidity, decrease water clarity, and impair foraging efficiency thereby reducing growth and feeding rates of fish (Newcombe and McDonald 1991, Arauho 2011, Collins et al. 2011). Turbidity can reduce the amount of light available for photosynthesis and hence decrease primary production by algae and plants (Ryan 1991); however, there is also some evidence that these biota can adapt to maintain productivity at elevated sediment levels (Parkhill and Gulliver 2002, Izagirre et al. 2009). High suspended sediment loads can also clog or abrade sensitive fish gills and other soft tissues (Newcombe and Jensen 1996). The most common behavioral alteration associated with increased turbidity is reduced juvenile salmonid feeding behavior. There is an inverse relationship between turbidity and feeding efficiency or prey ingestion (Berg 1982, Berg and Northcote 1985, Sweka and Hartman 2001). Salmonids are visual predators that feed largely on drifting invertebrates, and changes in efficiency can be correlated to a decrease in their reactive distance to prey as turbidity increases. Feeding efficiency of juvenile coho salmon may drop by 45 percent at a turbidity level of 100 Nephelometric Turbidity Units (NTU) (Berg 1982), and turbidity as low as 70 NTU reduced salmonid foraging effectiveness and delayed their response to food (Bisson and Bilby 1982).

Increased sediment load can dramatically alter channel morphology. Pools may be filled, channels widened (Lisle 1982), riparian vegetation buried, streambank heights raised, and floodplain and flood prone areas disconnected (Kelsey 1980, Lisle 1982, Roberts and Church 1986, Knighton 1991). These alterations in geomorphology (i.e. excess sediment buildup, changes in proportion of fines) can increases the frequency and magnitude of localized flood events, which has occurred in Elk River, an important coho-bearing tributary to Humboldt Bay (Patenaude 2004). It may take decades before channels impacted by large aggradation events can fully recover (Madej et al. 2009). Lowland river systems are particularly susceptible to adverse effects of excess sedimentation owing to their low energy and limited ability to recover to their natural form (Kemp et al. 2011).

In spawning gravels, deposited fine sediment fills interstitial spaces between particles, reducing intergravel flow and inhibiting alevin movement, thereby decreasing survival rates (Kondolf 2000, Sparkman 2003, Greig et al. 2005). Excess fine sediment smothers habitat used by benthic organisms, decreasing the production of algae and macroinvertebrates that are an important food source for fry, juveniles, and smolts (Suttle et al. 2004, Cover et al. 2008). It can also decrease habitat availability and cover thereby increasing predation risks.

The quantity and timing of coarse sediment delivery to streams has also been altered by human activities throughout the SONCC ESU. Coarse sediment is an essential component of geo-fluvial mechanisms, such as gravel bar development (Ock and Kondolf 2012), and of spawning and rearing habitat for coho salmon (Lorenz and Eiler 1989). Reduced sediment supply can limit the availability of spawning substrate, alter availability of velocity refugia and macroinvertebrate habitat, and cause large scale changes in the morphology of downstream reaches (Cordone and Kelley 1961). Dams and other man-made barriers trap coarse sediment (Kondolf 1997) as well as decrease the frequency and magnitude of flows that mobilize these large particles thereby altering channel bed morphology, and impacting instream habitat (Ock and Kondolf 2012). Within the SONCC ESU, major dams on the Eel, Klamath, Applegate, Rogue, Shasta and Trinity rivers are of particular concern because they impede coarse sediment transport downstream into areas inhabited by coho salmon. Gravel mining also results in the removal of coarse sediment, which can significantly alter physical habitat characteristics and fluvial mechanisms, such as causing increased river depth, bank erosion, and head-cutting (Freedman et al. 2013). When upstream sediment sources are disturbed by dams or mining, high flows tend to transport only the finer fraction of the stream bed, leaving the coarser particles behind, causing channel incision and eventually an immobile channel (Kondolf 1997). These changes can create a significant stress on coho salmon, which rely on the natural dynamic structure of a river for instream cover, deep pools, appropriately sized spawning substrate and off-channel habitats, all of which cease to be created when the channel bed becomes immobile. These changes can last long after the dam or other structures are removed, and work to restore these areas may take years and even decades.

3.1.6 Lack of Floodplain and Channel Structure

Unconstrained reaches of low gradient rivers provide complex slow water habitats, including side-channels, lakes, backwaters, alcoves, sloughs, and beaver ponds (Independent Multidisciplinary Science Team [IMST] 2002, Branton 2011), that are essential for juvenile salmonid survival and rearing success. However, these reaches are highly susceptible to anthropogenic land use changes and alterations in channel morphology. Activities such as agriculture, timber harvest, mining and gravel extraction, flood control, road building, and urbanization and development of riparian areas can result in changes to floodplain and channel structure including channel straightening and reduced hydrological connectivity to off-channel and side channel habitat (Burnett et al. 2007 (timber harvest), Brown et al 1998 (mining and gravel extraction), Branton 2011 (flood control)). The lack of floodplain and channel structure is ranked as a high or very high stress in 39 of 40 populations of SONCC coho salmon (Table 3-4).

When stream channels are straightened, diked, and leveed, coho salmon suffer harmful effects through decreases of natural pool, winter rearing, and spawning habitats. Channel simplification also causes indirect changes in the timing of peak flows, increases in the frequency of scour events, and changes in the movement of sediment through the system (IMST 2002). Reduced hydrological connectivity may render these areas disproportionately susceptible to inter-annual variations in winter and summer stream flows (Sommer et al. 2005). When floodplains and off-channel habitats become disconnected from the main channel, juvenile fish can be displaced downstream during high flow events, encounter mortality from physical damage caused during high flows, and experience a decrease in the ability to survive through the winter from decreases in prey resources and slow water rearing and holding areas (Pess et al. 2002, Kock et al. 2012).

A lack of slow water, over-winter habitat has been shown to be a limiting factor to coho salmon populations. Solazzi et al (2000) showed that adding wood, alcoves, and dammed pools to a stream can significantly increase the over-winter survival of juvenile coho salmon.

A significant contributor to lack of floodplain and channel structure in the SONCC coho salmon ESU is a paucity of instream large wood. Coho salmon juveniles favor pools that contain shelter provided by large wood (Reeves et al. 1989). Research from across the Pacific Northwest has shown that streams with more large wood have more pools because large wood provides scour-forcing obstructions that create pools (Buffington et al. 2002, Montgomery et al. 2003, Rosenfeld and Huato 2003). Larger pieces of wood are more stable than smaller pieces of wood, and ratio of log length to channel width can be used as a gauge of stability (Montgomery et al. 2003). Past and current timber harvest practices have degraded riparian forests across the SONCC coho salmon ESU, decreasing the number of large conifers in riparian zones and reducing the potential for recruitment of long-lasting large wood (Sedell et al. 1988, Benda and Bigelow 2014). Hardwood trees like alder and willow are now the most abundant species in many riparian zones (Roni et al. 2002). These hardwood species do not provide long lasting large wood for channel forming processes (Cederholm et al. 1997) and their maximum potential size, and therefore stability, is much smaller than conifers. Early accounts of Pacific Northwest streams described prolific accumulations of wood in rivers and streams that settlers then cleared to facilitate movement of boats and logs during the late 1800s and early 1900s (Collins and Montgomery 2002). Then, during the 1950s, 1960s, and into the 1970s, fishery managers and biologists further removed large wood from streams, fearing it restricted fish passage and led to log jams and bank erosion (Sedell et al. 1988, Gallagher et al. 2012). As a result, the amount of large wood in streams is currently far lower than historical levels, resulting in a reduced capacity of stream habitats to support coho salmon.

The historical decline in beaver (*Castor canadensis*) populations has also contributed to lack of floodplain and channel structure. Beaver ponds provide high quality winter and summer rearing habitat for coho salmon (Reeves et al. 1989, Pollock et al. 2004). Beavers were highly valued for their fur pelts, and from the 1780s to 1840s, trappers swept through the Pacific Northwest, reducing the formerly robust beaver population to remnant levels (ODFW 2005b). The effect of decreased beaver abundance on coho salmon populations was likely very significant. For example, a study of the Stillaguamish River Basin in Washington compared current conditions with estimated historical conditions and concluded that the loss of beaver ponds accounted for most of the estimated 86 percent reduction in smolt production potential (SPP) of winter habitat and most of the 61 percent reduction of SPP for summer habitat (Pollock et al. 2004). Although still much reduced from pre-trapping levels, beaver populations have rebounded somewhat since the end of the era of intensive trapping. Recent studies in the Lower Klamath, Middle Klamath and Shasta sub-basins confirm that beaver ponds provide high quality summer and winter rearing habitat for coho salmon (Chesney et al. 2009, Silloway 2010). Information regarding the distribution and abundance of beavers within the SONCC coho salmon ESU is relatively limited (Lanman et al. 2013). In Oregon, ODFW fish habitat surveys detected beaver dams in the Rogue River basin but not in the Brush Creek, Mussel Creek, Hunter Creek, Pistol River, or Chetco River basins (although only a small portion of the Chetco basin was surveyed); there are no survey data available for the Elk River or Winchuck River. In California, beavers are present in the Smith River, Klamath River, Redwood Creek, Little River, Widow White Creek, Strawberry Creek, and Mad River basins. Beavers are absent in Humboldt Bay, Bear River, Mattole River, and most of the Eel River basin with the exception of Outlet Creek, mainstem Eel River in the vicinity of Cape Horn Dam, and a single sighting on Ten Mile Creek in the upper South Fork Eel sub-basin (Lanman et al. 2013, Riverbend Sciences 2014).

Using beaver as a salmon habitat restoration tool has proven to be effective and cost efficient (Pollock et al. 2007; DeVries 2012, Andonaegui 2000). In addition to creating off channel habitat for juvenile coho, beaver ponds can raise the water table, store spring runoff for late season release into streams (Parker 1986) and cool the water downstream of the beaver dams (Pollock et al 2003). Beaver ponds have been shown to expand riparian forests (Pollock et al 2007) and decrease erosive perturbation (Parker 1986). Beaver ponds slow high velocity stream flows and trap sediment behind their dams, which speeds up the recovery rate of down-cut stream channels and reduces turbidity downstream (Naiman et al 1988). Beavers are classified as a predatory species in Oregon and current regulations allow private landowners to destroy beavers and their habitat without notification to state agencies. In California, CDFW issues depredation permits to private landowners to destroy problematic beavers, and allows recreational trapping of beavers (no bag or possession limit) in Del Norte, Humboldt, Siskiyou, and Trinity counties. The coast of California south of Little River had previously been considered outside the historical range of beavers (Tappe 1942), but a recent review of historical evidence indicates that beavers were in fact native to the entire California coast (Lanman et al. 2013).

3.1.7 Altered Hydrologic Function

Water is the most essential component of fish habitat. The alteration of hydrology can create both environmental and physical changes that affect coho salmon. Environmental changes include altered timing and magnitude of high and low flows, alteration of temperature and dissolved oxygen levels, and changed cues for seasonal migration. Physical changes include aggradation or incision of the stream channel, scouring of the stream bed, disconnection of channel and floodplains, and damage to riparian vegetation from flooding events. Altered hydrologic function is ranked as a high or very high stress in 21 of the 40 populations in the ESU (Table 3-1, Chapters 7 to 46).

While every life stage of coho salmon requires adequate stream flow, summer rearing juveniles are most vulnerable because stream flows within the SONCC coho salmon ESU typically reach annual lows during the late summer or early fall due to lack of precipitation. Human water withdrawals for irrigation of agricultural crops and landscapes are highest during this period of lowest stream flow, resulting in the potential for significant flow reductions. Reduced summer flows can reduce growth and survival of coho salmon juveniles through several pathways, including: stream dewatering, increased water temperature, reduced habitat volume and quality, reduced food availability, and increased vulnerability to predation.

The most extreme case of reduced flow is stream dewatering, causing immediate mortality of any coho salmon rearing in the dry reach. While loss of surface flow can occur for prolonged durations, such as months, loss of surface flow can also occur on much shorter time scales such as hours or minutes. Small streams with multiple adjacent water diversions that operate simultaneously are particularly susceptible to running dry (Lancaster 2013) or experiencing rapid flow decreases (Deitch et al. 2009).

An additional stress to low-flow conditions is the emergence of marijuana cultivation in many areas of the SONCC coho salmon recovery domain. Although the number of plants grown each year is unknown, the water diversion required to support these plants is placing a high demand on a limited supply of water (Bauer, S., pers. comm. 2013a). Most diversions for marijuana cultivation occur at headwater springs and streams, thereby removing the coldest, cleanest water at the most stressful time of the year for coho salmon (Bauer, S., pers. comm. 2013b). Based on an estimate from the medical marijuana industry, each marijuana plant may consume 900 gallons of water per growing season (Humboldt Growers Association [HGA] 2010).

Juvenile coho salmon spend summer in freshwater and are sensitive to high summer water temperatures. Water temperatures can be strongly affected by the quantity of water in a stream, with effects varying by location and season according to site-specific factors. For example, computer simulations predict that a 50% reduction in flow would cause peak summer water temperature to increase as much as 2-3˚C in Bull Creek, a tributary to the South Fork Eel River, while a 50% increase in flow would decrease temperatures by a slightly lesser amount (Allen 2008). Similarly, another model predicts that a 50% decrease in groundwater accretions would increase peak summer water temperatures in mainstem Scott River by 2-3˚C, whereas a 50% increase would reduce water temperatures by as much as 2˚C (NCRWQCB 2005).

As flow decreases, so do the depth, volume, and complexity of pools where coho salmon juveniles over-summer (May and Lee 2004). Another potential result of low summer flow is loss of hydraulic connectivity in riffles (Magoulick and Kobza 2003). In such cases, pools become isolated from each other and drift of aquatic macroinvertebrates from riffles into pools is eliminated, reducing food availability for juvenile salmonids and hence reducing growth rates (Stillwater Sciences and Dietrich 2002, McBain and Trush 2012). Field experiments in a small Humboldt Bay stream found that even when hydraulic connectivity was maintained, reduced flow resulted in less invertebrate drift that reduced growth of rainbow trout (Harvey et al. 2006). With loss of connectivity, fish movement is restricted to single habitat units and they become more vulnerable to predation (Magoulick and Kobza 2003). Studies in a Washington stream found that juvenile coho that moved between habitat units grew faster than those who did not move (Kahler et al. 2001).

Increased flow (either total annual, spring or summer) results in increased smolt migration (Berggren and Filardo 1993, McCormick et al. 1998) and survival (Mathews and Olson 1980, Scarnecchia 1981, Giorgi 1993, Čada et al. 1994, Lawson et al. 2004). Berggren and Filardo (1993) found a significant correlation between average flow and smolt migration time in the Columbia River. Scarnecchia (1981) found a highly significant positive relationship between total stream flows and the rate of survival to the adult life stage for coho salmon in five Oregon rivers. Mathews and Olson (1980) documented a positive correlation between summer stream flow and adult coho salmon abundance. Coho salmon smolt production was positively correlated with summer flows in a coastal Washington stream (Beecher et al. 2010) and spring flows on the Oregon Coast (Lawson et al. 2004). Summer flow is an important explanatory variable of juvenile steelhead survival in tributaries of the Russian River (Grantham et al. 2012).

In addition to the relationship between flows and juvenile salmonid survival, flows can also affect juvenile salmonid growth. In studies on brook trout and juvenile Atlantic salmon, Davidson et al. (2010) and Xu et al. (2010) found that increased flow was generally associated with higher growth rates. Juvenile salmonids had 24 to 50 percent size reductions under low flow conditions (Davidson et al. 2010, Xu et al. 2010, Nislow and Armstrong 2012).

NMFS analyzed stream flow, precipitation, reservoir storage, and Geographic Information Systems (GIS) data to calculate a series of quantitative indicators, which were then used in conjunction with other information to inform NMFS' professional judgments, of the magnitude of the stress of altered hydrologic function for each coho salmon population and life stage (Asarian 2014). Altered hydrologic function is a high or very high stress in 18 of 39 populations throughout the ESU (Table 3-4).

As discussed in the following paragraphs, hydrologic function has been altered throughout the ESU by several mechanisms, including: 1) alteration of vegetation, which affects evapotranspiration and interception of precipitation; 2) landscape, channel, and floodplain alterations that increase storm flow, reduce infiltration, and reduce exchange between surface water and groundwater; and 3) water withdrawals reduce stream flow while dams impound water and shift the timing of stream flow.

The structure and species composition of vegetation in a watershed has a large effect on interception (i.e., precipitation that is caught by vegetation before it reaches the ground) and evapotranspiration. Timber harvest reduces the amount of precipitation intercepted by vegetation, resulting in increased peak flows during storm events (Reid and Lewis 2009), although this effect dissipates over time as vegetation re-grows (Grant et al. 2008). Reduced interception also elevates summer base flows for an initial number of years following harvest; as trees grow back, this effect diminishes with time and then reverses (Cafferata and Reid 2013, Surfleet and Skaugset 2013). Long-term studies in Oregon experimental forests showed that clearcut or thinning treatments, which replaced mature or old (100 to 250-yr-old) forest with young (i.e., 30 to 50-yr-old) forest reduced summer stream flow by 20-80% (Perry 2007), consistent with other studies showing higher evapotranspiration by young compared to old tree stands (Moore et al. 2004, Jassal et al. 2009, Wharton el al. 2009). In the Andrews Experimental Forest in Oregon, water use by riparian trees in a 40-year old stand was estimated to be 3.27 times greater than in a 450-year old stand, due to a combination of greater sapwood area, species composition (more alder and less Douglas fir and western hemlock), and younger trees in the 40-year old stand (Moore et al. 2004). Scaling sap flow measurements to the stand scale and using a forest growth model to predict future conditions, Stubblefield et al. (2011) concluded that stand-level water use by trees in the Mattole River watershed is likely to decline in future decades as the number of young (< 5 cm diameter at breast height) trees decreases due to canopy closure and stem suppression. A century of fire suppression has also altered vegetation communities, including the conversion of vast acreages of meadows (Mattole River and Range Partnership 2009) and oak woodlands (Engber et al. 2011) into dense stands of Douglas fir, which likely have higher evapotranspiration than the communities they replaced.

A variety of human activities reduce infiltration and groundwater recharge, resulting in increased storm flow and reduced base flow. By compacting soil and short-circuiting shallow subsurface flow paths, roads affect the timing and magnitude of peak flows (Grant et al. 2008). Other impervious surfaces such as parking lots and roofs have a similar effect (Spence et al. 1996, Booth and Jackson 1997). Filling of wetlands, channelization, and diking reduces floodplain connectivity and results in decreased groundwater recharge. In addition, trapping has greatly reduced the distribution and abundance of beavers (ODFW 2005b), resulting in fewer beaver dams available to recharge groundwater and promote floodplain connectivity (Pollack et al. 2007). The resulting channel incision can disconnect stream channels from their floodplains, causing a loss of riparian vegetation due to reduced groundwater levels and floodplain desiccation (Beechie et al. 2010). Salmon habitat can be severely altered by floods, sometimes requiring decades to recover. During flood events, land disturbances resulting from timber harvest, road construction, mining, urbanization, livestock grazing, agriculture, fire, and other uses may contribute sediment directly to streams or exacerbate sedimentation from natural erosive processes (California Advisory Committee on Salmon and Steelhead Trout 1988; California State Lands Commission 1993; FEMAT 1993). In some California streams, the pool-riffle sequence and pool quality still have not fully recovered from the 1964 regional flood. In fact, Lisle (1982) and Weaver and Hagans (1996) found that many Pacific coast streams continue to show signs of harboring debris flows from the 1964 flood, remaining shallow, wide, warm, and unstable.

By changing the flow of water, sediment, nutrients, energy, and biota, dams and water diversions interrupt and alter most of a river's important ecological processes, and therefore most aquatic organisms living in the river. There are numerous dams and diversions that occur throughout the SONCC coho salmon ESU, causing stress to coho salmon through a multitude of direct and indirect effects. More information on the effects of altered hydrologic function is included where applicable in other parts of Chapter 3, including section 3.2.9 (Dams and Diversions).

3.1.8 Barriers

Fish passage barriers in some way restrict the amount of available stream habitat on virtually all SONCC coho salmon rivers and are listed as a high or very high threat in 13 out of 41 populations (Table 3-4). The most common types of barriers include road-stream crossings (e.g., culverts), dams, tidegates, and agricultural diversions (Chapters 7 to 46). Unscreened diversions in particular were mentioned at the time of listing as a threat to SONCC coho salmon and are still a concern today (CDFG 2004a). Barriers can be inhibit salmonids through the physical blocking of stream reaches (e.g., dams, sediment buildup, changes in gradient at tributary mouths, etc.) or through water temperatures that increase to such an extent that salmonids cannot pass through the area during a portion of the year (Richter and Kolmes 2003, McElhany et al. 2000). These thermal barriers can be created by the removal of riparian vegetation, the simplification of stream channels, or from climate change, while physical alterations are mostly created by anthropogenic changes in land use.

While many road-stream crossing structures and diversions have been upgraded with structures that are designed to accommodate fish passage, several hundred road-related barriers and unscreened diversions still exist throughout the ESU, blocking access to hundreds of miles of freshwater habitat (CalFish 2009, ODFW 2008a). Efforts are currently underway to improve or remove fish passage barriers in as many places as feasible. Large dams used for water storage or hydroelectric purposes (such as the Trinity Dam, the Potter Valley Project dams in the Eel River basin, William L. Jess Dam on the Rogue River, and Matthews Dam on the Mad River) have blocked access to high quality habitat that was once accessible to coho salmon, in addition to changing the hydrologic function of their respective rivers. Efforts are being made around the ESU to remove or retrofit these structures, and return accessibility to previously blocked historical salmonid habitat. Dry stream reaches resulting from changes in stream flow, diversions, or channel aggradation can also present seasonal barriers to migration. The current lack of high quality habitat available within many populations has made the issue of barriers even more significant, because many barriers block some of the highest quality habitat and remaining refugia within key watersheds.

Approximately 450 manmade barriers remain throughout the California portion of the ESU (Koller 2010), which block access to historical spawning and rearing areas. Several significant fish passage improvements have occurred throughout the ESU. In the Rogue River, three dams were recently removed (Savage Rapids Dam in 2009, Gold Hill Dam in 2008, and Gold Ray Dam in 2010) and one was notched (Elk Creek Dam in 2008) to restore natural flow and fish passage. William L. Jess dam, the current upstream extent of the Rogue River, impounds Lost Creek Lake and is used for hydropower and flood control. Since 2005, in California 661 miles of stream have been opened to fish passage by removing 440 barriers (available at: http://www.dfg.ca.gov/fish/Administration/Grants/FRGP/index.asp). Overall, coho salmon passage has improved over the last five years, but barriers remain a major threat because many are still unaddressed and continue to block passage. More information regarding the direct and indirect effects of barriers can be found in the description of the effects of dams and diversions (Section3.2.9) and the description of altered hydrologic function (3.1.7). Geographically-specific information about barriers in need of remediation can be found in each population profile (Chapters 7 to 46) where applicable.

3.1.9 Impaired Estuary/Mainstem Function

Estuaries are semi-enclosed coastal water bodies where ocean and freshwater streams mix and include marshes, forested swamps, eelgrass beds, mudflats, tidal channels and backwater sloughs (Bottom et al. 2005, Gleason et al. 2011). Juvenile salmon use estuaries to acclimate to saltwater and to gather olfactory information for successful homing (Dittman et al. 1996, Bottom et al. 2005). During their freshwater to saltwater transition, juvenile coho salmon also depend on slow, backwater estuarine habitat, such as forested wetlands (Eaton 2010), to provide protection from predators and increased growth rates due to a highly productive macrodetrital food web based on accumulated organic matter (Sibert et al. 1977, Bottom et al. 2005). Examples within the SONCC coho salmon ESU include the Lower Klamath River, where coho salmon juveniles thrive in mainstem side channels, off-channel ponds, and backwaters where tributaries join the mainstem (Soto et al. 2008, Hillemeier et al. 2009). The typical coho salmon life cycle comprises one or more years of juvenile rearing in freshwater and then a relatively short but critical migration through the estuary on their way to the ocean (Shapovalov and Taft 1954, Thorpe 1994). However, coho salmon juveniles can rear extensively in estuaries (Miller and Sadro 2003, Lestelle 2007, Koski 2009, Craig 2010, Gleason et al. 2011, Jones et al. 2014), or move to the estuary for a season and then return to freshwater (Weybright 2011). For example, coho salmon smolts in Humboldt Bay, California spent an average of 9 to 12 days in tidal main channel floodplain and off-channel habitat and 15 to 21 days in the Humboldt Bay and the lower estuary (Pinnix et al. 2013). These diverse life-history strategies likely provide the species with resilience to detrimental conditions (Koski 2009, Bottom et al. 2009, Craig 2010).

Estuaries are found along the coastal shoreline, which is also home to a majority of the human population of the Pacific Northwest (Koski 2009, Gleason et al. 2011). In order to accommodate human development, many estuaries and associated low gradient stream reaches have been physically altered and degraded by diking, draining, and filling (Koski 2009). Anthropogenic activities have caused decreases in the quantity and quality of estuary habitat, decreases in water quality from timber harvest, road construction, riparian vegetation removal, and non-point source pollution (Gleason et al. 2011), as well as changes in estuary productivity from alterations in nutrient levels. In many watersheds, hydrologic connectivity and habitat have been reduced in estuaries and low gradient reaches by dikes, levees, tidegates, and culverts, which constrain and alter the natural hydrology, change instream channel morphology, and disconnect the channel from the surrounding floodplain (Koski 2009, Gleason et al. 2011). Estuarine habitat can be improved and expanded by removing or modifying tidegates (Roegner et al. 2010) or excavating new channels and ponds, as occurred recently in Salmon Creek (Love 2012) and Wood Creek (Anderson 2008, Hauer 2013) along Humboldt Bay.

More than half of Pacific Northwest wetlands have been lost due to anthropogenic activities, much of it in the stream-estuary zone commonly used by rearing coho salmon (Miller and Sadro 2003, Pinnix et al. 2013, Jones et al. 2014). For example, Redwood Creek is flanked for the first 3.4 miles by flood control levees that confine the channel to a 250-foot-wide channel migration zone, which bisects the estuary and has resulted in extensive loss of estuarine area and decreased habitat value (Cannata et al. 2006). Tideland reclamation and the construction of dikes and levees for agricultural purposes have considerably altered the natural function of the Eel River estuary, reducing estuarine habitat by 60% (Yoshiyama and Moyle 2010). Slough and creek channels that once meandered throughout the Eel River delta are now confined by levees that slow flow to a point that many have become filled with sediment (Yoshiyama and Moyle 2010). Levees occur in many populations within the ESU. Impaired estuary/mainstem function results in a high to very high impact in 28 out of 40 SONCC coho salmon populations (Table 3-4).

Estuaries and the salmonids that depend on them will be impacted by global warming in numerous ways (Katz et al. 2012). An acceleration of current rates of sea level rise will cause a shift in the extent and diversity of the coastal marshes, swamps, beaches, and other estuarine habitats in many areas of the Pacific Northwest (Galbraith 2005). Many low lying coastal and intertidal areas are expected to be inundated causing loss of freshwater marshes, swamps, and tidal flats and conversions to salt marshes and transitional marshes (National Wildlife Federation (NWF) 2007). Estuarine beaches will likely suffer losses due to inundation and significant erosion (NWF 2007). Under a conservative scenario of 2ºC warming within the next century, the Humboldt Bay estuary could lose 29% of its tidal flats, although salt marshes would expand (Galbraith 2005). Since marshes play a critical role in the regulation of nutrients and filtering of pollutants, net losses to coastal marsh habitat will likely cause declining water quality (NWF 2007). Habitat changes that result from sea level rise will be determined by local topography and estuaries in some populations, such as Elk River, are predicted to expand significantly with sea level rise (Flitcroft et al. 2013b). Climate change will alter precipitation and runoff patterns, which could increase estuarine salinity and in turn magnify the toxicity to fish of several pesticides often found in estuaries draining agricultural watersheds (Schlenk and Lavado 2011).

3.1.10 Adverse Fishery and Collection-Related Effects

Historical Fishing Impacts

In the final rule to list SONCC coho salmon (62 FR 24588, May 6, 1997) overfishing was recognized as a contributing factor in the compromised escapement levels seen between 1950 and 1990. Fishing regulations were changed to be more protective of coho salmon beginning in 1994, when the retention of coho salmon in ocean commercial and recreational fisheries was prohibited from Cape Falcon, Oregon (south of the Columbia River) to the U.S./Mexico border. In recent years, there has been some limited commercial fishing for coho salmon in the area from Cape Falcon, Oregon to Humbug Mountain, Oregon, but these fisheries have operated within the ESA-related limits for the Lower Columbia River, Oregon Coast, and SONCC coho salmon ESUs. California waters were open to coho salmon retention prior to 1998. Currently, coho salmon retention is limited to the mark-selective recreational hatchery coho salmon fishery in Oregon waters, and tribal harvest under federal reserved fishing rights in the Klamath River basin.

On average, only two percent of coho salmon eggs survive to the smolt stage, and only 10% of those smolts survive to adulthood (Quinn 2005). Fishing affects SONCC coho salmon recovery because it targets these adult fish. Adult fish have demonstrated the ability to survive the stresses and threats affecting egg, fry, juvenile, and smolt life stage and will soon reproduce, and their capture before reproduction prevents successful reproduction.

Federally Managed Fisheries

Salmonid fisheries

SONCC coho salmon are managed as part of the Oregon Coast Natural (OCN) stock aggregate, which includes coho salmon produced from all Oregon river and lake systems south of the Columbia River and contributes primarily to ocean fisheries off Oregon and California (Pacific Fishery Management Council [PFMC] 1999). OCN coho salmon are part of a larger aggregate of natural and hatchery production south of Leadbetter Point, Washington known as the Oregon Production Index (OPI) (Sharr et al. 2000). SONCC coho salmon are vulnerable to incidental mortality due to hooking and handling in the commercial and recreational ocean fisheries that primarily target Chinook salmon.

Amendment 13 to the PFMC Pacific Coast Salmon Plan, which was adopted in 1997, was designed to ensure that fishery-related impacts do not act as a significant impediment to the recovery of depressed OCN coho salmon stocks (Sharr et al. 2000). In contrast to previous management approaches, fishery management under Amendment 13 is based upon exploitation (i.e., mortality) rates, not escapement targets. These exploitation rates are based upon estimates of habitat production potential that incorporate effects of both freshwater and marine environments and are derived from habitat-based assessment and modeling of OCN coho salmon production (Sharr et al. 2000). Amendment 13 considers recovery of OCN stocks by ensuring sufficient spawner escapement to seed spawning habitat. A review of the effectiveness of Amendment 13 proposed more conservative allowable exploitation rates at very low levels of spawner abundance and marine survival, and slightly higher rates when conditions of spawner abundance and marine survival are favorable (Sharr et al. 2000). This proposal was adopted by the PFMC (L. Kruzic, NMFS, pers. comm. 2011). Two recent amendments to the Pacific Coast Salmon Plan are relevant to SONCC coho salmon. Amendment 14 (PFMC 2000b) redefines optimal yield, and both Amendment 14 and Amendment 16 (PFMC 2011a and NMFS 2011) provide new criteria to prevent or end overfishing of non-ESA listed species.

Ocean exploitation rates for SONCC coho salmon are based on the exploitation rate on Rogue/Klamath (R/K) hatchery stocks (NMFS 1999a). NMFS issued a biological opinion requiring that the overall annual ocean exploitation rate for R/K hatchery coho salmon remain less than 13% (NMFS 1999a). In 2001, the PFMC adopted management measures for Federal ocean waters under which all key coho salmon management objectives, based on the 1999 NMFS biological opinion, the Pacific Coast Salmon Plan, and the OCN Coho Salmon Work Group recommendations, were met. The major salmonid fishery affecting SONCC coho salmon is for Chinook salmon. Current regulations on Chinook salmon fisheries include time and area closures, seasonal quotas, minimum sizes, gear restrictions, and allowable take. Since 1999 the estimated exploitation rates on R/K hatchery coho salmon have been considerably lower than 13 percent (Figure 3-1). Due to a lack of life cycle monitoring stations and fishery monitoring effort, the effect of the fishery on particular populations within the SONCC coho salmon ESU is unknown. The viability criteria presented in this recovery plan were not considered in the biological opinion (NMFS 1999a), as they were not yet available when that opinion was prepared.

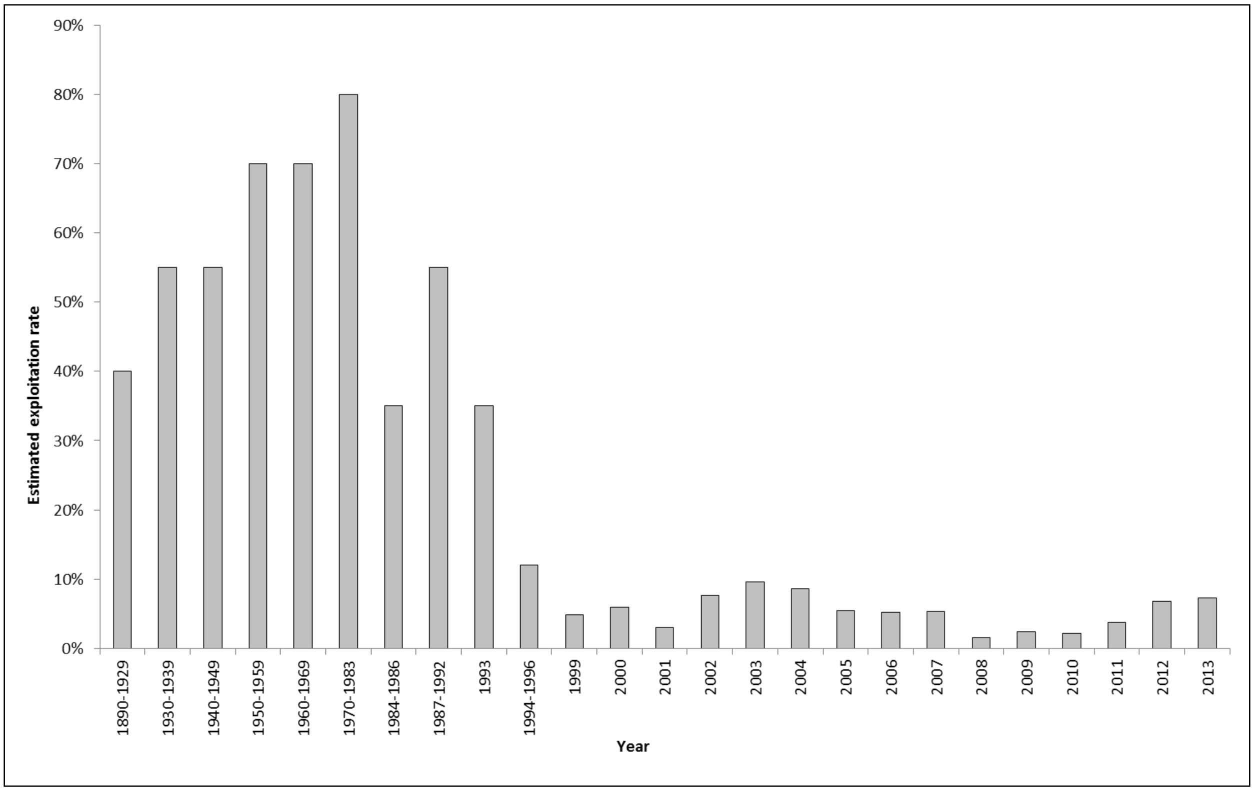

Figure 3-1. Estimated exploitation rate of coho salmon in southern Oregon and northern California. 1890 to 1996 rates are Oregon coast natural (OCN) stock aggregate estimates from ODFW (1997); 1998 rate is a preseason estimate for the OCN stock aggregate (PFMC 1999); 1999 to 2012 rates are post-season estimates for Rogue/Klamath (R/K) coho salmon (PFMC 2000 to 2004, 2005a, and 2006 to 2013, respectively); and the 2013 rate is a preliminary post-season estimate for R/K coho salmon (PFMC 2013a).

Non-salmonid fisheries

Groundfish

The groundfish fishery management plan includes 82 species, nearly all of which live on or near the ocean floor. Major types of fishes included in this group include rockfishes, flatfishes, roundfishes, sharks, and skates (NMFS 2003a). Most groundfish are harvested using trawls, pots, and hook-and-line gear. Mid-water and bottom trawls have been known to catch salmon (NMFS 1999b). NMFS has evaluated the impact of this fishery on listed salmon and steelhead and concluded it is not likely to adversely affect salmon or adversely modify critical habitat (NMFS 1999b and NMFS 2006). The Biological Opinion limits allowable bycatch of Chinook salmon in the trawl fisheries, but does not limit bycatch of other salmon or steelhead. The rationale is as follows: "Coho, chum, sockeye are caught in relatively low numbers in both the midwater trawl whiting fishery and the bottom trawl fishery with average catch per year coastwide in the tens to a few hundred of fish, and in the bottom trawl fishery in the tens of fish. Therefore, it is unlikely that listed ESUs of coho, chum, or sockeye will be significantly affected by the groundfish fishery" (NMFS 1999b)". Al-Humaidhi et al. (2012) summarized the observed and estimated total bycatch of salmon in West Coast fisheries, including groundfish, between 2002 and 2010. It is unknown what proportion of coho salmon observed in these fisheries originated in the SONCC coho salmon range. Bycatch of coho salmon in the coastwide non-hake groundfish sectors varied, but remained below 100 fish (Al-Humaidhi et al. 2012). In the Pacific hake sectors, coastwide bycatch peaked in 2007 at 475 coho salmon, and the bycatch in each of the next three years was below 100 (Al-Humaidhi et al. 2012). Based on the NMFS (1999b) and NMFS (2006) consultations, the threat posed by the groundfish fishery to SONCC coho salmon is low.

Coastal Pelagics

Coastal pelagic species (CPS) include northern anchovy, market squid, Pacific sardine, Pacific (chub or blue) mackerel, and jack (Spanish) mackerel. Anchovy and sardine are known as important forage species for all predators including salmon and steelhead. All the species in this group are extremely important to the ecosystem used by SONCC coho salmon. As explained in the 2003 regulatory amendment to the CPS fisheries management plan (PFMC 2005b):

> Anchovy, sardine, hake, jack mackerel, and Pacific mackerel achieve the largest populations in the California Current region as well as in other major eastern boundary currents. These populations are key to the trophic dynamics of the entire California Current ecosystem. Anchovies and sardines are the only fish in the ecosystem that consume large quantities of primary production (phytoplankton), all five of the species are significant consumers of zooplankton. All five species of fish, particularly mackerels and hake, and also squid are important predators of the early life stages of fish. The juvenile stages of squid and all five species of finfish, and in many cases the adults, are important as forage for seabirds, pinnipeds, cetaceans, and other fish.

As coho salmon grow, fish make up a greater proportion of their diet (Shapovalov and Taft 1954). The diet of ocean-caught coho salmon is dominated by fishes such as herring, sand lance, sardines, and smelts (Sandercock 1991). Targeted CPS fisheries could reduce the amount of prey available to SONCC coho salmon. Such deficits could negatively impact salmon, marine mammals, and top predators. In addition, harvest of prey species could increase the predation pressure on juvenile salmon. Prey species provide alternate food sources for predators of juvenile salmonids such as hake, and the presence of prey species can reduce predation pressure on juvenile salmonids (Emmett and Sampson 2007). There is an ongoing debate over how to account for the needs of all predators in the ecosystem when developing models to determine acceptable harvest levels of prey species (e.g., Marine Fish Conservation Network 2007). The National Research Council concluded there was a need for an ecosystem-based assessment of fishery impacts, rather than management of a single fish species in isolation (NRC 2006). NMFS has recognized the need for ecosystem-based management on the west coast, most recently through formulation of the NOAA Ecosystem Approach to Management and establishment of the California Current Regional Ecosystem as a management area (NOAA 2004).

The PFMC has adopted a conservative, risk-averse approach to management of CPS, which reduces the likelihood of such negative effects on salmon and their ecosystem. The need to "provide adequate forage for dependent species" is recognized as a goal and objective of the CPS fisheries management plan (PFMC 2011b). A control rule is a simple formula used by the PFMC in evaluating allowable harvest levels for each of the CPS. The CPS control rules contain measures to prevent excessive harvest, including a continual reduction in the fishing rate as the biomass declines. In addition, the control rule adopted for species with significant catch levels explicitly leaves thousands of tons of CPS biomass unharvested and available to predators. No ecosystem model currently exists that could calculate the caloric needs of all predators in the ecosystem, so the amount of this set aside is necessarily an estimate that may be modified if new information becomes available. Ocean temperature is a factor in the control rule for Pacific sardine, in recognition of the effects of varying ocean conditions on fish production rates. Allowable harvest rates are automatically reduced in years of poor production. The PFMC developed the Fishery Ecosystem Plan (FEP) to enhance the PFMC's species-specific management programs with more ecosystem science, broader ecosystem considerations, and management policies that coordinate Council management across its Fishery Management Plans and the California Current Ecosystem (PFMC 2013b). The FEP includes an initiative to protect unfished lower trophic level (forage) fish species (PFMC 2013b). NMFS has determined CPS fisheries are not likely to adversely affect ESA-listed species, including the SONCC coho salmon ESU (PFMC 2014). Due to the conservative control rules used to manage CPS fisheries, and the preservation of a portion of CPS biomass for predator consumption, the CPS fishery poses a low threat to SONCC coho salmon recovery.

Pacific Halibut

Pacific halibut (*Hippoglossus stenolepis*) occur on the continental shelf from California to the Bering Sea. Harvest of this species (not to be confused with the California halibut, *Paralichthys californicus*) is managed by the International Pacific Halibut Commission (IPHC), which determines allowable catch. The Pacific Fishery Management Council then allocates portions of the catch to commercial, recreational, and tribal fisheries in California, Oregon, and Washington. Although fishing for this species is allowed in California, in the past ten years only one Pacific halibut was commercially landed in waters off California (Bruce Leaman, Executive Director, IPHC, personal communication 12/18/07). Even in areas where commercial fishing for this species is more prevalent, bycatch of salmonids is rare. Perhaps this is because the favored commercial halibut gear, demersal longlines, are set near the ocean floor at depths where salmonids rarely occur. The IPHC conducts an annual survey of the species caught on commercial Pacific halibut longlines. The survey includes 1,200 stations off of Washington and Oregon, with one station on the Oregon/California boarder. Less than one salmon is captured per year survey wide, on average (Claude Dykstra, Survey Manager, IPHC, personal communication 12/18/07).

The recreational fishery for Pacific halibut extends into California. A very small portion of the allowable catch (8,308 lbs. in 2007) was allocated to the U.S. recreational fisheries south of Humbug Mountain, Oregon. The number of salmon caught in the recreational halibut fishery off California appears to be very small. In 2007, there were only five reported cases when recreational fishermen caught salmon and Pacific halibut on the same trip (Melody Palmer-Zwahlen, CDFG, 12/19/07, personal communication).

Based on the low incidence of bycatch of Pacific salmon in commercial or recreational Pacific halibut fisheries, and the fact that relatively little Pacific halibut fishing occurs in California, effects from this fishery pose a low stress to SONCC coho salmon recovery.

State-Managed Fisheries

In Oregon, adipose-fin-clipped coho salmon (hatchery coho salmon) can be retained when caught recreationally in state-managed waters (streams, rivers, tidewaters and bays), subject to area-specific season and bag restrictions (ODFW 2011a). NMFS (2007a) estimated that 3.3 percent of Rogue/Klamath (R/K) hatchery coho salmon caught in this mark-selective fishery would die post-release. Retention of coho salmon caught in any California-managed fisheries in the range of the SONCC coho salmon ESU is prohibited (CDFG 2011). Some incidental coho salmon mortality likely occurs in association with the release of coho salmon in Chinook- and steelhead-directed freshwater fisheries, but is likely low (NMFS 1999a). The impact of California-managed inland fisheries on SONCC coho salmon has not been formally evaluated by NMFS. Formally evaluated means an ESA Section 7 consultation has been completed or a determination has been completed under any applicable limit in NMFS' protective regulations promulgated under ESA Section 4(d) (50 CFR 223.203).

Tribal-Managed Fisheries

The Yurok and Hoopa tribes have federally recognized fishing rights and pursue subsistence, ceremonial, and commercial fisheries for Chinook salmon and steelhead in the Klamath River basin (CDFG 2002a). The number of coho salmon harvested by these tribes is less than the number of Chinook salmon taken in subsistence fisheries in the Klamath River and the Trinity River. The Karuk tribe uses dip nets to catch salmonids at Ishi Pishi Falls on the Klamath River. The Round Valley tribe holds a federally recognized right to pursue fisheries for salmon in the Eel River (Langridge 2002). The impact of in-river tribal fishing on the SONCC coho salmon ESU has not been formally evaluated by NMFS. Formally evaluated means an ESA Section 7 consultation has been completed or a determination has been completed under any applicable limit in NMFS' protective regulations promulgated under ESA Section 4(d) (50 CFR 223.203 or 223.204).

Fishing for coho salmon within the Yurok tribe’s reservation on the lower Klamath River, which extends from about 2 miles upstream of Weitchpec, California, to the Pacific Ocean, has been monitored since 1992. During the period of monitoring, the Yurok Tribe has harvested approximately 70% of their catch below the Highway 101 bridge. The median Yurok harvest from the entire area from 1994 to 2012 was 345 coho salmon (YTFP 2014), which approximates an average annual maximum[6] harvest of 3.1 percent of the total run. The total run size for the Klamath basin was determined by combining wild and hatchery adult counts at the Trinity River, Iron Gate Hatchery, and Shasta and Scott river weirs (YTFP 2014). On average, about 42 percent of the coho salmon harvested by the Yurok Tribe were progeny of coho salmon that spawned in the wild (Williams 2010). The effect of the Yurok fishery on particular populations

[6]Denominator for calculation only includes coho salmon counts at Trinity River Weir, Scott and Shasta river, and Iron Gate Hatchery, and therefore does not include all Klamath and Trinity basin coho salmon escapement. Therefore, it is a maximum estimated harvest rate.

within the SONCC coho salmon ESU is unknown, because all nine of the Klamath River basin coho salmon populations migrate through the lower Klamath River.

Trinity River coho salmon are harvested by the Yurok and Hoopa tribes Table 3-7 describes the estimated percentage of the total Trinity coho salmon run harvested by each tribe.

Table 3-7. Estimated number of Trinity River coho salmon harvested by the Yurok and Hoopa tribes. Includes percentage of total adult run size harvested by Yurok and Hoopa tribes, from 1997 to 2008. M= Marked (hatchery), U = Unmarked (natural origin).

Year	Estimated Yurok harvest		Estimated Hoopa harvest[2]		Estimated total Trinity River adult escapement[3]		Percentage harvested by Yurok tribe		Percentage harvested by Hoopa tribe	
	M	U[1]	M	U	M	U	M	U	M	U
1997	22	2	39	3	1,885	271	1.2%	0.7%	2.1%	1.1%
1998	117	6	88	54	10,285	1,297	1.1%	0.5%	0.9%	4.2%
1999	120	9	65	36	4,785	630	2.5%	1.4%	1.4%	5.7%
2000	70	1	211	22	10,586	386	0.7%	0.3%	2.0%	5.7%

2004	553	302	312	80	27,167	10,092	2.0%	3.0%	1.1%	0.8%
2005	640	24	153	21	27,947	2,856	2.3%	0.8%	0.5%	0.7%
2006	241	24	442	38	18,774	1,734	1.3%	1.4%	2.4%	2.2%
2007	61	17	68	14	4,436	1,257	1.7%	1.4%	1.5%	1.1%
2008	147	13	262	53	6,864	1,302	2.1%	1.0%	3.8%	4.1%
Median 1997-2008	**134**	**15**	**182**	**29**	**13120**	**1300**	**1.9%**	**0.9%**	**1.7%**	**2.6%**

[1] Calculated as follows: (Estimated harvest of marked Trinity River Hatchery (TRH) fish, provided by Yurok Tribal Fisheries Program / estimated proportion of marked Trinity River Hatchery coho salmon that migrated upstream of the Willow Creek weir) - estimated harvest of marked Trinity River Hatchery fish. Jacks were excluded.
[2] Source: Hoopa Tribal Fisheries Program, unpublished data.
[3] Calculated as follows: Est. adult escapement above WC weir + Est. ocean incidental mortality[4] + Est. Yurok marked harvest + Est. Hoopa marked harvest + Est. recreational harvest upstream of WC weir (source: CDFG, unpublished data) + Est. recreational harvest downstream of WC weir (source: Hoopa Tribal Fisheries Program, unpublished data).
[4] Calculated as follows: (Est. Yurok marked harvest + Est. Hoopa marked harvest + Est. recreational harvest upstream of WC weir + Est. recreational harvest downstream of WC weir)* pre-season projected ocean incidental mortality rate (source: Pacific Fishery Management Council [PFMC] 2011).

Karuk fishermen are allowed by CDFW to catch salmon using dip nets at Ishi Pishi Falls on the Klamath River if they adhere to the same limits as Chinook salmon sport fishermen (CDFG 2002a). A Karuk tribe representative stated “its members rarely harvest more than 200 salmon and steelhead per year, that protected species such as coho salmon are never kept, and that these protected species are released alive" (Driscoll 2009).

Collection for Research Purposes

When NMFS re-affirmed the listing of SONCC coho salmon in 2005 (70 FR 37160, 37196; June 28, 2005), NMFS identified collection or handling of fish among activities that may harm certain listed salmon ESUs and thus result in violation of the ESA Section 9 take prohibition. Information on SONCC coho salmon populations is needed for the NMFS 5-year status reviews, as well as to determine the effectiveness of habitat restoration actions, and ultimately for de-listing. This information is derived from research studies of life-history strategies, abundance, distribution, and genetics, and involves take of individuals.

Within the ESA, there are two mechanisms to enable listed fish to be taken for research purposes, and exempt the permit holder from the prohibitions of the ESA. Under Section 10(a)(1)(A) and NMFS implementing regulations at 50 CFR § 222.308, NMFS may issue permits for scientific research purposes or to enhance the propagation or survival of species listed as threatened or endangered under the ESA. The permitted activities must not operate to the disadvantage of the listed species and must provide a bona fide and necessary or desirable scientific purpose or enhance the propagation or survival of the listed species. NMFS generally issues permits for up to five years, although permits for longer periods have been issued.

NMFS regulations under ESA Section 4(d) (50 CFR § 223.203(b)(7)), provide that take prohibitions for certain listed threatened species of anadromous salmonids, including SONCC coho salmon, do not apply to scientific research activities conducted by employees or contractors of certain tribes and state fish and wildlife agencies, including the California Department of Fish and Wildlife and the Oregon Department of Fish and Wildlife, or as a part of a monitoring and research program overseen by or coordinated with that agency, if the agency meets specific requirements listed in these regulations.

Specific activities authorized for research purposes by either a permit issued under ESA section 10(a)(1)(A) or the ESA section 4(d) regulations described above may include: direct observation, capture (electrofisher, nets, trawls, and traps), handling, anesthetizing, marking, tagging, tissue sampling, and other activities necessary to conduct various studies to promote the conservation of the species, enhance the species' survival, or add significantly to the body of knowledge of SONCC coho salmon. The primary effects of these activities are in the form of harassment associated with intentional take. Harassment generally leads to stress and other sub-lethal effects and is caused by observing, capturing, and handling fish. Unintentional mortality may occur during handling or after the fish has been released. Depending on the activities and life stage, NMFS anticipates from one to five percent of handled fish may die. Permits may include any conditions deemed necessary by NMFS, including reporting or inspection requirements for monitoring the impacts of permitted activities.

Prior to issuance of either a permit under ESA section 10(a)(1)(A) or approval of a research program under the ESA section 4(d) regulations described above, NMFS must determine whether the action is likely to jeopardize the continued existence of any listed species or result in the destruction or adverse modification of critical habitat.

3.2 Threats

Threats are the activities or processes that have caused, are causing, or may cause the stresses and thus the destruction, degradation and/or impairment of SONCC coho salmon and their habitat. The major factors listed in 1997 as responsible for the decline of SONCC coho salmon were timber harvest, road building, grazing and mining activities, urbanization, stream channelization, dams, wetland loss, beaver trapping, water withdrawals and unscreened diversions for irrigation (62 FR 24588, May 6, 1997). Many of these activities continue to threaten coho salmon populations in this ESU, while additional threats have emerged as significant factors that should be addressed in order for recovery to occur. NMFS' an analysis of current threats in this recovery plan has identified the following as currently contributing to the destruction, modification, or curtailment of habitat or range: dams and diversions, channelization and diking, agricultural operations, timber harvest, climate change, roads, urban/industrial/residential development, high severity fire, mining and gravel extraction, invasive species, hatcheries, and fishing and collecting (See Chapters 7 to 46).

These threats have led to significant stresses on coho salmon populations throughout the ESU (Chapters 7 to 46) and have contributed to the decline of the species. The following threats (Table 3-8) occur throughout the ESU and are believed to be the main causes of the previously described stresses (Table 3-4). Table 3-8 lists the ranking assigned to each threat in each population of the SONCC coho salmon ESU. Population-specific ratings are discussed in Chapters 7 to 46.

Table 3-8. Threat severity ranking by population.

	Threats

[1] Identified as a key limiting threat.

3.2.1 Climate Change

Climate change impacts salmonids throughout the Pacific Northwest and California (Battin et al. 2007, Moyle et al. 2013). The overwhelming majority of climate models predict a warming trend resulting from rising levels of greenhouse gases in the atmosphere, although the magnitude varies among models (Barnett et al. 2005, Daniels et al. 2012). Climate change is expected to detrimentally affect SONCC coho salmon in freshwater, estuarine, and ocean habitats. Climate change will likely alter runoff patterns by causing a precipitation shift from snow to rain (Kiparsky and Gleick 2003), earlier snowmelt (Knowles et al. 2006), lower summer flows (Barr et al. 2010), and more intense storms that will increase peak flows (Doppelt et al. 2008, Bates et al. 2008). In addition, ocean acidification is expected to reduce ocean productivity (Feely et al. 2008) and sea level rise will alter estuarine habitat (Galbraith et al. 2005).

Coho salmon are particularly vulnerable to climate change due to their need for year-round cool water temperatures (Welsh et al. 2001). SONCC coho salmon spend an extended period rearing in freshwater and, being near the southern end of their distribution, often reside in streams already near the upper limits of their thermal tolerance. Through effects on air temperatures and stream flows, climate change is expected to increase water temperatures to the detriment of coho salmon. Climate change effects on stream temperature within the SONCC coho salmon ESU are already apparent (Isaak et al. 2012). For example, in the Klamath River, Bartholow (2005) observed a 0.5 ºC per decade increase in water temperature since the early 1960s, and model simulations predict a further increase of 1-2 ºC over the next 50 years (Perry et al. 2011).

Models of future climate change project that the western United States will have reduced volumes and persistence of snowpacks across the region (Gleick 1987, Lettenmaier and Gan 1990), reduction in the fraction of precipitation that falls as snow rather than rain (Kiparsky and Gleick 2003), and hastening of the onset of snowmelt once snowpacks have been formed (Knowles et al. 2006), resulting in earlier runoff relative to current conditions (Kiparsky and Gleick 2003). Warmer winter air temperatures will decrease the snowpack in northern California and southern Oregon by up to 75% by 2040 and nearly 100% by 2080 (Doppelt et al. 2008). Snow acts as a natural reservoir by delaying runoff from winter months when precipitation is high, and climate change is projected to shift the timing and duration of releases from these natural reservoirs, altering instream conditions that salmon have evolved with (Kiparsky and Gleick 2003). Overall this would result in earlier and higher high flows, and earlier and lower low flows (Doppelt et al. 2008, NMFS and USFWS 2013). An analysis of the past 50 years in California has already revealed trends toward warmer winter and spring temperatures, a smaller fraction of precipitation falling as snow, a decrease in the amount of spring snow accumulation in lower and middle elevation mountain zones, and an advance in snowmelt of 5 to 30 days earlier in the spring (Knowles et al. 2006).

High flows and associated flooding are a natural process and can be beneficial to salmon and salmon habitat as a disturbance mechanism for scouring fine sediment from gravel, distributing large wood, recharging aquifers, allowing fish passage, transporting sediment and organic matter, and maintaining channel features (Lisle 1989). However, the potential increased rain and earlier snowmelt resulting from climate change could also detrimentally impact SONCC coho salmon populations by altering the timing of spring freshets, potentially increasing severity and quantity of flood events, increasing water temperatures, and altering the intensity of winter storms, thereby changing habitat accessibility, run timing, and egg development (Roos 2003). Eggs will likely develop faster in the higher winter and spring water temperatures, leading to earlier emergence. The early coho salmon fry could then be displaced downstream during high spring flows (Doppelt et al. 2008) thereby increasing exposure to predation. Even though higher spring temperatures would increase the growth rate of fry, the higher summer temperatures would decrease the amount of cold water refugia, which could lead to thermal stress and juvenile mortality (NMFS and USFWS 2013).

A potential shift to earlier and higher flows caused by climate change could have other effects on coho salmon and their habitat. Higher frequency and magnitude of winter flood events could affect coho salmon by increasing the risk of redd scouring, displacing eggs and alevins from the gravel before they emerge (Goode et al. 2013, NMFS and USFWS 2013). The timing of downstream migration by coho salmon smolts could be altered in relation to upwelling and ocean conditions and would likely influence smolt survival (NMFS and USFWS 2013). Increased erosion of hill slopes, roads, and streambanks could cause sedimentation of stream beds, which has been implicated as a principal cause of declining salmonid populations (Frissell 1992). Juveniles and smolts can be stranded by flood events, washed downstream out of rearing habitat, or washed out to sea prematurely.

Climate change may also decrease the frequency of fog on the California coast, which would increase air temperature and decrease humidity, leading to increased evapotranspiration by riparian vegetation, decreased stream flow, and increased water temperature. Data from 1901 to 2008 indicate that coastal temperatures have increased more than inland temperatures, accompanied by a reduced number of hours of coastal fog (Johnstone and Dawson 2010). If coastal fog continues to diminish, there will be increased drought stress and potentially a reduction in the range of coast redwoods and associated fish and wildlife communities.

Less snowpack, increased summer temperatures, and drought conditions lead to greater risk of wildfire. The summer of 2012 displayed the sorts of weather and climate extremes that climate change is bringing. Average temperatures for June through August were the third warmest on record, with July the hottest month ever recorded for the nation. Nearly two-thirds of the contiguous U.S. experienced drought conditions. Wildfires spanned more than 3.6 million acres across the western and central U.S. during August, a record for the month (NOAA 2012). An increased frequency of high severity wildfires not only can create lethal water temperatures for coho salmon, but also contributes to multiple stresses such as altered sediment supply and degraded riparian conditions, which are described below in Section 3.2.7 (High Severity Fire).

The impacts of climate change on coho salmon are not restricted to fresh water habitats. Survival of coho and other salmon species in the ocean is dependent on ocean food webs, which are strongly influenced by climate (Peterson et al. 2012, Rupp et al. 2012, Ruzicka et al. 2011, Sharma et al. 2013). Ocean acidification is increasing in surface waters off northern California more rapidly than previously estimated (Feely et al. 2008) and is likely to affect plankton and marine food webs, resulting in decreased coho salmon growth rates (Crozier et al. 2008). Global sea level has risen over the last several decades at a rate of about 20 cm per century and with climate change that rate is increasing (Cayan et al. 2009), causing a mean sea level rise expected to reach almost a meter by 2100 (Cayan et al. 2009, Laird et al. 2013). Sea level rise is projected to affect estuaries, coastal wetlands, and other low-lying lands, change the amount and location of critical estuarine and brackish habitats for salmon, and increase the salinity of rivers, bays, and groundwater tables (Intergovernmental Panel on Climate Change [IPCC] 2007). The IPCC (2007) suggests that by 2080, sea level rise could convert as much as 33 percent of the world's coastal wetlands to open water. Sea-level rise will also extend areas of salinization of groundwater and estuaries, resulting in a decrease in freshwater availability for fish and wildlife that inhabit these coastal areas (Kundzewicz et al. 2007). New brackish and freshwater wetland areas will be created as seawater inundates low-lying inland areas or as the freshwater table is pushed upward by the higher stand of seawater (Pfeffer et al. 2008).

The threat and stress assessment for this recovery plan included consideration of climate change and resultant environmental conditions. Climate change poses a serious threat to the viability of SONCC coho salmon populations (NRC 2004, Moyle et al. 2013, NMFS and USFWS 2013). Although SONCC coho salmon are diverse and resilient and have persisted through many climatic changes over the millennia, the modern climate change is happening at a rapid pace during an already warm period in which populations are already depressed and fragmented from intense human development (Battin et al. 2007, Isaak et al. 2012). The reduced genetic diversity resulting from depressed population size may limit the ability of individuals to adapt to changing climatic conditions. In addition, as climate change reduces the carrying capacity of the habitat within the range of SONCC coho salmon, species viability may be more difficult to achieve. Even if greenhouse gas emissions that cause climate change were stabilized, warming and sea level rise would continue for centuries because greenhouse gas emissions remain in the atmosphere for decades and there are time lags in climate system feedbacks (Solomon et al. 2009).

Beechie et al. (2012) recommended restoring stream flow, re-connecting floodplains, and re-aggrading incised channels as the best strategies to mitigate the anticipated effects of climate change on salmonids. Protecting beaver populations in watersheds vulnerable to climate change may help buffer some of the effects of climate change by reconnecting the floodplain, slowing and storing water in the basin, extending summer flows and restoring perennial flows to some streams. Beaver ponds help recharge groundwater tables and increase interaction between surface and groundwater flows, often cooling the water downstream of beaver dams. Beaver restoration can be an effective solution for many types of climate related issues in aquatic and riparian ecosystems, and it is generally far less expensive than alternatives (Scheffer 1938, Fouty 2003, Müller Schwarze and Sun 2003).

Furniss et al. (2010) describe the most effective response to a changing climate as a renewed commitment to the principles and practices of sound watershed management, with the objective of maintaining or improving watershed resilience. Watershed vulnerability assessments can evaluate relative resilience to changing climate and help set management priorities. Vital signs of a resilient watershed include capture and storage of rainfall, recharge of groundwater reservoirs, minimization of erosion, regulation of stream flows, storage and recycling of nutrients, and provision of habitat for native aquatic and riparian species.

3.2.2 Roads

Roads are a pervasive feature throughout the ESU and reflect a legacy of land use activities. Nearly all populations that comprise the SONCC coho salmon ESU are affected by high road density, with some populations having greater than 10 miles of road per square mile. Roads are ranked as a high or very high threat in 35 of 40 populations in the ESU (Table 3-8, Chapters 7 to 46). Roads can affect salmon populations by blocking migration, through interrupting and disrupting natural drainage patterns, increasing peak flow (Ziemer 1998), and increasing stream bed and bank instability (Chamberlin et al. 1991, McIntosh et al. 1994). Roads have been shown to impact spawning habitat, channel form, sediment inputs, and prey production. Additionally, roads placed immediately adjacent to watercourses can affect coho salmon through the removal of riparian vegetation, floodplain disconnection, and non-point source pollution inputs. Armentrout et al. (1998) used a reference of 2.5 mi/mi^2 of roads as a watershed management objective to maintain hydrologic integrity in Lassen National Forest watersheds harboring anadromous fish. Cederholm et al. (1981) found that fine sediment in salmon spawning gravels increased between 260 to 430 percent over background levels in watersheds with more than 4.1 mi/mi^2. Although some roads have been decommissioned, there are still many miles of existing roads and maintenance is often lacking, leading to chronic impacts on habitat. Road building for access to marijuana cultivation sites is common on many areas of the SONCC coho salmon recovery domain. Many of these roads are likely unpermitted and contribute excessive amounts of fine sediment to coho salmon streams. Across the ESU, sediment from roads has contributed to decreased emergence survival, and reduced carrying capacity for juvenile salmonids due to the filling of pools, channel simplification, and reduced feeding and growth due to high turbidity levels. Landslides triggered from road building-related activities are large sources of sediment (Spence et al. 1996) and may create large scale episodic mass wasting events that can severely impact a year class. Cederholm et al. (1981) reported that the percentage of fine sediments in spawning gravels increased above natural levels when more than two and a half percent of a basin area was covered by roads.

In addition to contributing fine sediment, roads can also affect water quality through the addition of heavy metal, gas, oil and other pollutants deposited on roads and subsequently washed into streams (Sandahl et al. 2007). These pollution inputs are difficult to remedy since they come from a variety of sources and can be spread out along the entire road length. Many pollution inputs occur during the winter months, which may have an effect on embryo and alevin salmon life stages, further decreasing survival and altering reproductive success.

Despite recent efforts to address impacts associated with roads, there still remains inadequate funding for road maintenance and rehabilitation projects, inadequate regulations for maintenance and building on private roads, and a large number of existing problems associated with private and public roads throughout the ESU.

Plans Addressing Road Sediment

While management programs and plans that help alleviate effects from road development are lacking in many areas of the ESU, several counties within northern California have worked collaboratively to develop a comprehensive manual to guide road installation, maintenance, and remediation. To qualify their road programs under the applicable limit in NMFS' protective regulations promulgated under ESA Section 4(d) [4(d) rule; 50 CFR 223.203(b)(10)], Humboldt, Del Norte, Trinity, Siskiyou and Mendocino counties (Five Counties) collaboratively developed the "Water Quality and Stream Habitat Protection Manual for County Road Maintenance in Northwestern California Watersheds" (Five Counties Salmon Conservation Program 2002; hereafter referred to as "Manual"), which is based largely on the Oregon Department of Transportation (ODOT) Road Maintenance Handbook (ODOT 1999). The Manual includes design and construction guidelines and best management practices that minimize erosion and maintain or improve fish passage. This manual is the first to be developed in California and represents a collaborative effort in addressing road maintenance impacts on coho salmon. Since 1998, the Five Counties effort has assessed and prioritized 245 road crossings for repair or replacement, using the biological needs of salmonids as their main driving factor. This program has repaired or replaced 56 road culverts, improved or enabled access to 137 miles of fish habitat, and completed Road Erosion Inventories on over 2,000 miles of road (Five Counties Salmonid Conservation Program 2010). In 2007, NMFS approved the Five Counties' Manual under the 4(d) rule.

Similarly, ODOT's "Routine Road Maintenance Water Quality and Habitat Guide Best Management Practices" (ODOT 1999) is utilized across the state of Oregon to identify and implement measures, or best management practices, that minimize potential environmental impacts associated with ODOT activities. In California, the state transportation agency (Caltrans) utilizes the "Caltrans Storm Water Quality Handbook, and Construction Site Best Management Practices Manual" to provide contractors and Caltrans staff with detailed information of construction site best management practices (BMPs) to be used on state-managed roads.

Other important programs to address road-related sediment issues include the Northwest Forest Plan for land administered by U.S. Forest Service and Bureau of Land Management, the North Coast Regional Water Quality Control Board's regulation of private and state timber lands, and the Habitat Conservation Plans (HCPs) for lands managed by Humboldt Redwood Company, Green Diamond Resource Company, and Fruit Growers Supply Company. Information about these programs is included in Section 3.2.5 (Timber Harvest).

3.2.3 Channelization and Diking

NMFS identified stream channelization and diking as a threat to SONCC coho salmon at the time of listing and it remains a threat today in 26 of 40 populations in the ESU (Table 3-8, Chapters 7 to 46). Diking and channelization are especially prominent in the low-lying areas of most watersheds (Ricks 1995). Stream reaches have been channelized and diked to aid in the conversion of land from forest and riparian to agricultural, industrial, and urban land use. In nearly all the lowlands and estuaries within the ESU, the majority of historical floodplain and off-channel habitat have been diked for agriculture purposes and flood protection (Chapman and Knudsen 1980).

Diking leads to the direct loss of habitat through disconnection of channel, floodplain, and wetland habitat. The simplified channel disrupts normal hydrologic function, often increasing the velocity of the water and in turn displacing complex woody structures that provide important rearing habitat for juvenile coho salmon. Channelization and diking will often transition a complex channel containing pools, riffles, and side channels, into a single thread channel primarily dominated by riffle habitat. In the fall, juvenile coho salmon typically move from summer nursery areas to off-channel habitat such as side channels, ponds, and sloughs to rear in the winter (Brown and Hartman 1988; Nickelson et al. 1992). During the winter coho salmon also selectively inhabit deep pools with substantial accumulations of LWD (Bustard and Narver 1975; Murphy et al. 1984). Juvenile coho salmon seek these slow water habitats associated with complex channels to avoid being displaced by the high velocity flows in the mainstem channel during the winter. Quinn and Peterson (1996) found a positive correlation between reach scale complexity and the overall survival and body size of juvenile coho salmon. More recently, Sommer et al. (2005) found that salmonids that were able to access floodplain habitat in the winter increased in size substantially faster due to higher prey consumption, and that survival of fish released into floodplain habitat was higher than of those released into the main channel.

Channelization and diking disrupts natural hydrologic processes, leading to long term geomorphic changes to the stream channel. Levees and dikes reduce bank overflow and access to the floodplain. Because levees are designed to decrease the width of the flow, rivers respond by cutting deeper channels and reaching higher velocities (Poff et al. 1997). Natural erosion and floodplain deposition processes are prevented when the channel banks are hardened and restricted from overflow. Additionally, channel migration and formation of secondary channels is prevented in the channelized stream setting (Shankman and Drake 1990). Because channelization disconnects the channel from sloughs, wetlands, and the floodplain which could hold water that breaches the banks, the magnitude of floods can often be increased. The reduction in upstream water storage will result in accelerated water delivery downstream. Much of damage caused by flooding is a result of levee failures as rivers try to reestablish historical connections to the floodplain (Poff et al. 1997).

Water quality is often degraded due to the disconnection of stream channels from floodplain and wetland features. Channelized coastal plain streams were found to have higher nutrient concentrations than unchannelized streams due at least in part to loss of contact between flowing water and the riparian forests (Kuenzler et al. 1977). Wetlands can be characterized as nutrient sinks and, because most are hydrologically connected to other waters and wetlands, the loss of those wetlands has potentially negative impacts on the water quality of downstream systems. Richardson et al. (2007) found that a multi-phased restoration of a stream and its adjacent wetlands resulted in a significant reduction of downstream nutrients, coliform bacteria, and sediment. In addition, storm water nutrient budgets indicated a substantial attenuation of nitrogen and phosphorus after passing through the wetlands.

Many California and Oregon estuaries have been significantly reduced in size due to the construction of levees and irrigation canals. Estuaries constitute important rearing habitats and migration corridors for juvenile coho salmon, as described in Section 3.1.9 (Impaired Estuarine Function).

3.2.4 Agricultural Practices

Conversion of many lowland areas to agricultural use has greatly altered the form and function of streams and their riparian corridors. Irrigated agriculture and livestock grazing can negatively impact coho salmon habitat (Nehlsen et al. 1991) and can directly impact juvenile coho survival and fitness. Agricultural operations located immediately adjacent to watercourses and stream channels have degraded habitat and limited both water quality and quantity through the filling and diking of wetlands, installation of irrigation diversions, channelization, grazing in riparian areas, compaction of soils in upland areas, and indirectly through the use of pesticides and fertilizers (Botkin et al. 1995, Spence et al. 1996). A large proportion of estuaries and floodplains have been converted to agricultural land through the diking and filling of floodplain habitat (see section 3.2.3). The loss of these areas has had major impacts on the form and function of watersheds and their ability to support salmon, especially juvenile coho salmon, which require diverse, complex rearing habitats and floodplain connectivity. In the SONCC coho salmon ESU, Agricultural Practices ranks as a high or very high threat in 18 of 40 populations (Table 3-8, Chapters 7 to 46).

One of the major stresses associated with agricultural practices has been the removal of water from many streams for irrigation or stock watering, which has led to reduced stream flows in the summer and fall, including seasonal loss of surface flow in some streams. Water is the most essential component of fish habitat; without adequate water, coho salmon cannot survive. Water diversions can cause fragmented habitats and increase stream temperatures while impeding the geomorphological processes that maintain stream health (Cone and Ridlington 1996). Decreased water availability can create stressful situations for salmonids, and can decrease fitness and survival of juveniles rearing in areas with degraded water quality (Bjornn and Reiser 1991). For instance, water use in the Scott River Valley, California, has been associated with reductions in summer and fall base flows (Van Kirk and Naman 2008), which has been cited as a limiting factor in coho salmon production in this system (NRC 2004). Consumptive water use has also lowered the water table near affected streams, which has limited the ability of riparian plant species to proliferate and contributes to low flow barriers. In some areas, seasonal and permanent dams are constructed to provide water for agricultural operations and have resulted in altered stream function, migration barriers, changes in stream temperature, and temporary increases in sedimentation.

Agricultural practices can result in the degradation or elimination of riparian areas. Within many riparian areas, the vigor, composition, and diversity of natural vegetation are altered by livestock grazing and agriculture. This alteration has affected the ability of riparian areas to control erosion, provide stability to stream banks, and provide shade, cover, and nutrients to the stream (Mundy 1997). Soil compaction in riparian and upland areas has appreciably reduced soil productivity and caused bank and slough erosion (Bellows 2003). Bank damage can lead to channel widening, lateral stream migration, increased water temperature, and sedimentation (Scholz et al. 2000).

Agriculture is a key producer of non-point-source pollution in the form of nutrients and sediments, which can enter streams with runoff from livestock areas or cultivated fields, and agricultural chemicals. Marijuana cultivation has become abundant in many areas of the SONCC coho salmon recovery domain. Although the number of plants grown each year is unknown, the herbicides, pesticides, and fertilizers used to support these plants are likely impairing water quality in coho salmon streams.

Impacts of agricultural chemical use on coho salmon has been identified as a concern throughout the Pacific Northwest (Laetz et al. 2009); pesticides known to harm salmonids (NMFS 2008) are used within the SONCC coho ESU. For example, herbicide use has resulted in fish kills in the Rogue River basin, including juvenile coho salmon in Bear Creek in 1996 (Ewing 1999). The USEPA is currently consulting with NMFS Office of Protected Resources for the re-registration of 37 pesticide active ingredients that are commonly used in agricultural practices, urban landscaping, and forestry practices. To date, NMFS has completed six opinions addressing 27 active ingredient including organophosphate and carbamate insecticides, thiobencarb, and various herbicides and fungicides. Of these 27 pesticide ingredients with completed consultations, NMFS determined that the continued use of a third of those would jeopardize the continued existence of SONCC coho salmon. Reasonable and Prudent Alternatives (RPAs) were developed for the registration of the following chemicals: Naled, Phosmet, 2, 4-D, Carbaryl, Carbofuran, Methomyl, Chloropyrifos, Diazinon, and Malathion. RPAs include elements such as relabeling, application restrictions in windy conditions or prior to a precipitation event, necessary buffer zones around water bodies, reduced concentrations, reporting requirements for fish mortality, and the implementation of a monitoring program. In April 2013, the National Academy of Sciences' National Research Council released their recommendations for assessing risks from pesticides to listed species under the ESA and the Federal Insecticide, Fungicide, and Rodenticide Act. The USEPA, U.S. Department of Agriculture (USDA), USFWS, and NMFS are working collaboratively to review the report and identify improvements in the current scientific procedures used in evaluating the potential impacts of pesticides to endangered and threatened species. The Federal agencies will develop an implementation plan to provide a timeline and approach for responding to the panel's recommendations and implementing the appropriate revisions to these procedures and approaches. The plan is expected to be available to the public soon.

Agricultural Regulations

Historically, the impacts to fish habitat from agricultural practices have not been closely regulated. Oregon's Agricultural Water Quality Management Act, also known as Senate Bill 1010, was enacted in 1993 (requirements are currently codified at Oregon Revised Statutes 568.900 to 568.933), and is the basis for the Oregon Department of Agriculture's Agricultural Water Quality Program, which includes Agricultural Water Quality Management Area Plans (see Oregon Administrative Rules Chapter 603, Divisions 90 and 95). Although these plans are intended to reduce the impacts of agricultural practices on water quality, state water quality standards are still not met. The state of California does not have regulations that directly manage agricultural practices, but relies on the TMDL process to improve water quality from all applicable parties. See Section 3.1.2 for more information on the TMDL process. The TMDL process is one way that the federal government, through state agencies, is able to regulate the amount of pollutants and other contaminants that enter a watercourse.

Another more direct federal regulation is the registration of fertilizers and pesticides by the Environmental Protection Agency (USEPA). USEPA has established a program to monitor and regulate pesticides and other chemicals that may harm listed species (Washington State Department of Agriculture (WSDA) 2010). USEPA has accomplished this through the implementation of a pesticide registration and registration review program for a suite of chemical fertilizers used across the United States. USEPA's strategy is to address listed species concerns within the context of the pesticide Registration and Registration Review process. The intent of this program is to provide appropriate protection to listed species and their critical habitat from pesticides while avoiding unnecessary burden on pesticide users and agriculture (WSDA 2010). In order to address the ESA during the pesticide Registration and Registration Review process, USEPA developed the Endangered Species Protection Program (ESPP). The ESPP requires refinements to geographic and biological components of the ecological risk assessment as they apply to listed species. The USEPA may use Bulletins (described below) to mitigate risk to listed species either prior to initiation of consultation or as a mechanism to implement Reasonable and Prudent Alternatives (RPAs) and Reasonable and Prudent Measures (RPMs) identified through consultation with the National Marine Fisheries Service and the U.S. Fish and Wildlife Service (WSDA 2010).

Once risks to listed species are identified through either the USEPA registration process or consultation with the NMFS and U.S. Fish and Wildlife Service, USEPA issues Endangered Species Protection Bulletins (Bulletins) that specify mitigation or protective measures. Bulletins describe specific geographic areas within individual U.S. counties where use limitations exist. When needed, Bulletins are referenced in pesticide label statements that inform users the product may harm a threatened or endangered species or their critical habitat (WSDA 2010). The use limitations specified in Bulletins are supplemental label language enforceable for the county specified.

3.2.5 Timber Harvest

Substantial timber harvest has occurred throughout the SONCC coho salmon ESU. Timber harvest is ranked as a high or very high threat in 20 of 39 populations in the ESU (Table 3-8, Chapters 7 to 46). In many of these populations, while timber harvest activity has decreased since the peak over 50 years ago, and practices and management have improved, the effects of future timber harvest continues to be a potential threat to coho salmon. In many streams, timber harvest in the riparian areas has resulted in reduced inputs of leaf litter, terrestrial insects, and large wood (Reeves et al. 1993, Nakamoto 1998). Reduction of large wood from the harvest of streamside timber has resulted in the reduction of cover and shelter from turbulent high flows (Cederholm et al. 1997). Numerous studies have identified impacts including reduced large woody debris, increased water temperature, and increased erosion and sedimentation. These impacts have been shown to impair the reproductive success of salmon due to increased turbidity, loss of interstitial spaces for use by juveniles, the smothering of eggs by fine sediments, loss of deep pools, and blockage of spawning habitat by landslides (Beschta and Taylor 1988, Beschta 1978, Brown and Krygier 1971).

The threat from future timber harvest lies in the inability of already degraded landscapes to rebound from continued impacts. If detrimental timber harvest (i.e., clear cutting, decreased age of trees removed) continues, cumulative effects and large scale, landscape-size issues may be perpetuated. In many populations of the SONCC coho salmon recovery domain, forest lands are likely being cleared and graded to create new marijuana cultivation sites. In most cases the land disturbance is not regulated, and likely contributes to excessive amounts of fine sediment in coho salmon streams. The continuation of these harmful timber harvest practices will result in decreased cover and reduced storage of gravel and organic debris, and will likely result in continued loss of pool habitat and a reduction in overall hydraulic complexity (CDFG 2002a).

By altering hydrology and slope stability, timber harvest can increase the amount of fine sediment delivered to streams and impair water quality. There is a strong relationship between the percent of a watershed harvested in the past 15 years and the duration of stream turbidity that exceeds thresholds of salmonid feeding impairment (Klein 2012). Timber harvest reduces the amount of precipitation intercepted by vegetation, resulting in increased peak flows during storm events (Grant 2008). Increased peak flows have only been detected during storms with a return period of 6 years or less (Grant 2008), and the effect diminishes over time as vegetation recovers (Keppeler et al. 2003). Long-term paired watershed studies in Caspar Creek on the Mendocino Coast, where road-related erosion is only a minor contributor to sediment, found that despite robust riparian buffer strips, increased peak flows induced by timber harvest increased gully erosion in small stream channels, expanding drainage networks and contributing significantly to suspended sediment yields (Reid et al. 2010). Timber harvest can also affect slope stability and increase the frequency of shallow landslides. Studies on the Oregon Coast found reduced root strength in clear cuts and industrial forests relative to old-growth conifer forests (Schmidt et al. 2001), and that shallow landslides tended to occur in localized areas with reduced root strength such as gaps in the root network between large trees or in areas lacking large trees (Roering et al. 2003).

One of the greatest continuing stresses from timber harvest is the residual effects of increased input of fine sediment into streams. This impact does not cease when timber harvest activities are complete, but instead continues a legacy of negative effects that begin anew during each winter storm event or high flow. Road building and other timber harvest activities have resulted in mass wasting and surface erosion that will continue to elevate the level of fine sediments in spawning gravels and fill the substrate interstices inhabited by invertebrates (Platts et al. 1989, Suttle et al. 2004). Changes in channel morphology will continue to alter the hydrology and timing of flows in areas affected by these chronic events. Bisson et al. (1997) estimated that, due to anthropogenic activities such as timber harvest, the frequency of major floods was 2 to10 times greater, debris flows and dam-break floods were 5 to 10 times more frequent, and slumps and earth flows were 2 to 10 times more frequent, compared to natural, background conditions. This increase in catastrophic events will likely continue to dramatically alter the conditions in which coho salmon spawn and rear and cause a reduction in food supply, reduced quality of spawning gravels, and an increased severity of peak flows during heavy precipitation. Additionally, the continued removal of riparian canopy cover from these events will result in increased solar radiation, which will create further increase in water temperature (Spence et al. 1996).

While harmful timber harvest practices have been shown to be detrimental to salmon populations, new timber harvest methods that promote stand diversity, thin overcrowded plantations, and help restore fire-damaged lands should be implemented to provide an active recovery for degraded systems throughout the ESU. Appropriate timber harvest will aid in the re-establishment of riparian vegetation, sediment storage, and stand diversity, all ecosystem characteristics that are beneficial to salmonid populations. When thinning, stands should be thinned from below (i.e., the largest trees should be left standing), and post-thinning densities of canopy conifers should generally not be less than 200 trees per acre, unless it can be demonstrated, using properly calibrated forest growth models (e.g., Forest Vegetation Simulator) that more intensive thinning is likely to increase long-term production rates of large dead wood. Trees > 50 cm diameter should not be cut for thinning purposes. Thinned trees should be felledon site and placed in streams and other water bodies, if possible, unless they would greatly increase fire hazard (dry forests only),

USFS Land Resource Management Plans and BLM Resource Management Plans

The Northwest Forest Plan (NWFP) is a comprehensive ecosystem management strategy for federally managed lands administered by the U. S. Forest Service (USFS) and Bureau of Land Management (BLM) within the range of the northern spotted owl (USFS and BLM 1994). Approximately 53 percent of the land area within the SONCC coho salmon ESU is managed under the NWFP. Over 70 percent of the land in the Trinity River basin is managed by the USFS, and within that area, about 85 percent is designated as critical habitat for SONCC coho salmon. Additionally, within the Six Rivers National Forest which is within the NWFP jurisdiction, there are four independent SONCC coho salmon populations, and public lands account for 75 percent of the population areas.

The Aquatic Conservation Strategy (ACS), a primary component of the NWFP, was designed to protect salmon and steelhead habitat on federal lands managed by the USFS and BLM by maintaining and restoring ecosystem health at watershed and landscape scales (NMFS 1997). Aquatic ecosystem elements embedded in the ACS include: maintenance of hydrologic function, high water quality, adequate amounts of coarse woody debris, complex stream channels that provide a diversity of aquatic habitat types, and riparian areas with suitable microclimate and vegetation. There are four primary components of the ACS: 1) Riparian Reserves, 2) Key Watersheds, 3) Watershed Analysis, and 4) Watershed Restoration. The ACS contains nine objectives that describe general characteristics of functional aquatic and riparian ecosystems, and these objectives are intended to maintain and restore good habitat in the context of ecological disturbance.

Some types of USFS and BLM Land Management Plans contain protective management direction, in some cases more protective than the ACS. With the intention of maintaining connected late-successional and old-growth ecosystems, a system of late-successional reserves and riparian reserves was delineated across federal lands and represents one of these more protective types of Land Management Plans. Late-successional reserves are large blocks of lands designed to maintain well-distributed habitat for the late-successional-dependent species. The riparian reserve network was intended to reverse habitat degradation for at-risk fish species or stocks, including coho salmon, and to serve a terrestrial function by providing a system of old forest structural elements to connect the late-successional reserves. Late-successional reserves provide increased protection for all stream types. Late-successional reserves and riparian reserves serve as core areas of high quality stream habitat, fish refugia, and centers from which degraded aquatic systems can be recolonized once they are restored.

The ACS, late-successional reserves, and riparian reserves are intended to prevent further degradation of aquatic ecosystems and restore habitat over broad landscapes (Lanigan et al. 2012). While the NWFP covers a very large area, the overall effectiveness of the NWFP in conserving Oregon and California coho salmon is limited by the extent of USFS and BLM federal land ownership, which is not uniformly distributed in watersheds within the ESU. However, where administered, the NWFP has made improvements on the landscape through better management of both timber harvesting and road maintenance and construction. A report by Lanigan et al. (2012) documented trends in watershed, riparian and upslope condition throughout the area of the NWFP. Ten percent of watersheds displayed a positive change in indicator categories, with these changes attributed to the combined effects of natural vegetation growth and road decommissioning. A greater proportion of positive changes in watershed condition occurred on late-successional reserve and matrix lands than on congressionally reserved lands (e.g., wilderness areas and national parks), which were already in good condition (Lanigan et al. 2012). Declines in watershed condition were seen in some areas, with declines attributed to the Biscuit Fire of 2002, and other fire complexes that occurred during the 15 years of the study. Overall road density changed only slightly across the area of the NWFP; however, dramatic changes were accomplished in targeted watersheds. For example, road density in Lower Fish Creek in the western cascades declined from 3.3 mi/mi^2 in 1994 to 0.8 mi/mi2 in 2008 through the decommissioning of 118 miles of roads (Lanigan et al. 2012). Overall, Lanigan et al. (2012) stated that road decommissioning in landslide prone areas provided the most benefits.

Although public lands tend to be located in the upper reaches of watersheds or river basins, upstream of the highest quality coho salmon habitat, Lanigan et al. (2012) documents that efforts made by both the USFS and BLM through the NWFP have begun to improve coho salmon habitat, and provided improved water quality conditions starting in headwater areas. In other areas, public lands are distributed in a checkerboard fashion, resulting in fragmented landscapes that are more difficult to improve.

State Forest Practices Acts

State forest practices acts in both Oregon (1971) and California (1973), along with their associated forest practice rules, were designed to promote the continuous economic activity of growing and harvesting forest trees while meeting federal and state environmental standards, rules, and regulations (e.g., CWA, ESA). The state forest practices acts and forest practice rules apply to all non-federal forestland, including private, state-owned and local government-owned forestlands. Because of the preponderance of private timberland and timber harvest activity in the range of this ESU, and potential adverse effects, careful consideration of state forest practices rules and regulations is prudent. At the time of listing, most reviews of the forest practice rules indicated that implementation and enforcement of these rules did not adequately protect coho salmon or their habitats (CDFG 1994, Murphy 1995, Ligon et al. 1999, IMST 1999). The state forest practices acts and forest practice rules in both Oregon and California are continually reviewed, and state regulatory agencies in Oregon and California receive recommendations for improved aquatic habitat protection. Neither has fully adopted recent recommendations, and both Oregon and California Forest Practices Acts are inadequate for the complete protection of salmon in the SONCC coho salmon ESU (NMFS 2009, Ligon et al. 1999). Although the California forest practice rules have a requirement for disapproval of timber harvest plans that would result in a ‘taking’ or finding of jeopardy for listed species (14 CCR § 898.2(d)), the rules do not explicitly describe the method for effectively implementing this requirement.

California Forest Practices

In 1997, at the time of the original listing of the SONCC coho salmon ESU (62 FR 24588, May 6, 1997), timber harvest was identified as a significant threat to the species and their habitat.

Specifically, NMFS identified inadequacies of the forest practice rules to address large wood recruitment, streamside tree retention, canopy retention standards, monitoring of timber harvest operations, and salvage harvesting. A scientific review panel was formed in November 1998 to evaluate the effectiveness of the California forest practice rules in protecting salmonid species and their habitat. The scientific review panel concluded that the forest practice rules, including their implementation process, do not ensure protection of anadromous salmonid populations (Ligon et al. 1999). One of the primary finding was that cumulative effects were not properly accounted for, suggesting the need for a watershed analysis approach.

In July 2000, The California State Board of Forestry and Fire Protection (BOF) adopted interim Threatened or Impaired Watershed Rules (T&I rules) to protect and restore watersheds with threatened or impaired values. The T&I rules were intended to minimize impacts to salmonid habitat resulting from timber harvest by requiring special management actions in watersheds where either state or federally listed threatened, endangered or candidate populations of anadromous salmonids are present or where they can be restored. Examples of special management actions required by the T&I rules include constructing watercourse crossings that allow for unrestricted fish passage, increasing large wood recruitment, and increasing soil stabilization measures. The T&I rules also require coordination between the California Department of Forestry and Fire Protection (CalFire) and the State and Regional Water Quality Control boards to minimize sediment discharge. The BOF never permanently adopted the T&I rules. Rather, the BOF readopted the T&I rules six times subsequent to 2000.

The T&I rules expired in December 2009, and the Anadromous Salmonid Protection (ASP) rules replaced them in 2010. The BOF's primary objectives in adopting the ASP rules were to: (1) ensure rule adequacy in protecting listed anadromous salmonid species and their habitat, (2) further opportunities for restoring the species' habitat, (3) ensure the rules are based on credible science, and (4) meet Public Resources Code (PRC) § 4553 for review and periodic revisions to the forest practice rules. NMFS staff have actively engaged and participated in BOF meetings and expressed concern to the BOF that the ASP rules, while resulting in some improvements to riparian protections, would not adequately protect anadromous salmonids until several inadequacies in the forest practice rules are addressed (NMFS 2009). Specifically, take of listed salmonids resulting from timber harvest operations in California could be minimized (but not entirely avoided) if the following protections were added to the existing ASP rules: (1) provide Class II-S (standard) streams with the same protections afforded Class II-L (large) streams, (2) include provisions to ensure hydrologic disconnection between timber management roads and streams, and (3) include provisions to avoid hauling logs on hydrologically connected roads during winter periods (NMFS 2009). In addition, NMFS believes the use of scientific guidance will provide additional limitations on the rate of timber harvest in watersheds to avoid cumulative impacts of multiple harvests, and provide greater protections to ensure the integrity of high gradient slopes and unstable areas. This may include limiting the areal extent of harvest in such areas.

ASP rules do not apply where the following plans, permits, or measures apply: an approved Habitat Conservation Plan (HCP) that addresses anadromous salmonid protection; a valid Incidental Take Permit (ITP) issued by CDFG; a valid Natural Community Conservation Planning (NCCP) permit approved by CDFG; or project revisions, guidelines, or take avoidance measures pursuant to a Memorandum of Understanding (MOU) or a planning agreement between the plan submitter and CDFG in preparation of obtaining a NCCP that addresses anadromous salmonid protection. ASP rules also do not apply to upstream watersheds where permanent dams block anadromy and reduce the transport of fine sediment downstream, or watersheds that do not support anadromy and feed directly into the ocean.

The California Forest Practice Rules (CalFire 2013) include an Article 6 on Watercourse and Lake Protection under the Coast, Northern, and Southern Forest District Rules subchapters. The section on Intent of Watercourse and Lake Protection (14 CCR §§ 916, 936, and 956) under this Article and each of these subchapters provides, in relevant part:

> The purpose of this article [6] is to ensure that timber operations do not potentially cause significant adverse site-specific and cumulative impacts to beneficial uses of water, native aquatic and riparian-associated species, and the beneficial functions of riparian zones; or result in an unauthorized take of listed aquatic species; or threaten to cause violation of any applicable legal requirements. This article also provides protective measures for application in watersheds with listed anadromous salmonids and watersheds listed as water quality limited under Section 303(d) of the Federal Clean Water Act.
>
> It is the intent of the BOF to restore, enhance and maintain the productivity of timberlands while providing appropriate levels of consideration for the quality and beneficial uses of water relative to that productivity. Protections include: guidelines for the removal of debris and soil, prohibition of road construction, prohibition of use of tractor roads, requirements to comply with TMDLs, objectives for streamside bank protection, riparian buffers, and providing appropriate shading.

NMFS is working collaboratively with the BOF to limit the effects of forestry operations on threatened and endangered salmonid populations in California, including the SONCC coho salmon ESU. At this time, however, the effects of present timber harvest activities in California continue to pose an ongoing threat to the ESU.

Oregon Forest Practices

At the time of listing, the Oregon Forest Practices Act (OFPA), modified in 1995 and improved over the previous OFPA, did not have implementing rules that adequately protected coho salmon habitat. In particular, the OFPA did not provide adequate protection for the production and introduction of large wood to medium, small and non-fish-bearing streams. Since the listing of SONCC coho, the Oregon Plan for Salmon and Watersheds (Oregon Executive Order 99-01; 1999) directed the creation of the Forest Practices Advisory Committee to help the Oregon Board of Forestry assess forest practices changes that may be needed to meet state water quality standards and protect and restore salmonids. As of 2003, draft water protection rules and non-regulatory recommendations based on the recommendations of Forest Practices Advisory Committee had been developed, but had not been adopted by the Board of Forestry. A review of OFPA and forest practice rules (IMST 1999) showed the regulations in place may be ineffective at protecting water quality and promoting riparian function and structure, especially in small- and medium-sized streams. In their review of the forest practice rules, the Oregon IMST found that one of the greatest shortcomings of the current rules is that they are dominated by site- and action-specific strategies which, taken together are insufficient for recovering habitat of listed stocks of salmonids (Everest and Reeves 2007). Everest and Reeves (2007) report that current forest practice rules in the Pacific Northwest represent improvements over their preceding rules, but continued change and evolution of the forest practices rules is of vital interest.

Though significant improvements have been made to the current rule package, the Oregon Forest Practice Rules represent the least conservative forest practice regulations administered by the state governments within the SONCC coho salmon ESU. Some riparian areas may be protected by narrow, no-harvest zones; however, the stands located upslope of the no-harvest zones could be subject to intense harvest, leading to diminished riparian function and cumulative effects to anadromous salmonid habitat. In a 2010 status review of Oregon Coast (OC) coho salmon, NMFS concluded that the Oregon Forest Practices Act does not adequately protect OC coho habitat in all circumstances. In particular, disagreements persist regarding: (1) whether the widths of riparian management areas (RMAs) are sufficient to fully protect riparian functions and stream habitats; (2) whether operations allowed within RMAs will degrade stream habitats; (3) operations on high-risk landslide sites; and (4) watershed-scale effects. On some streams, forestry operations conducted in compliance with this act are likely to reduce stream shade, slow the recruitment of large woody debris, and add fine sediments. Since there are no limitations on cumulative watershed effects, road density on private forest lands, which is high throughout the range of this ESU, is unlikely to decrease under the Oregon Forest Practices Act (NMFS 2009).

Other State Regulatory Mechanisms

Additional mechanisms designed to protect aquatic habitat and species have been put in place to provide further review prior to timber harvest. For example, all Timber Harvest Plans (THPs) on private land must be submitted to CalFire. CalFire distributes the THPs to state and federal reviewing agencies including CalFire, CDFW, the California Regional Water Quality Control Board, NMFS, and the California Geological Survey. Filed THPs are open to public comment. Pre-harvest inspections occur at the proposed harvest site, and recommendations and changes are made to the THP prior to approval by the CalFire director, who takes into account BOF rules, the review teams recommendation, and public comment. Finally, CalFire Unit Forest Practice Inspectors periodically inspect the timber harvest operation to ensure compliance with the approved THP and all laws and regulations.

In addition to their role as a reviewer of THPs, CDFW permits certain activities associated with timber harvest such as road building, which may require Lake and Stream Bed Alteration Agreements when stream crossings are present. CDFW ensures that all activities comply with the California Endangered Species Act and California Environmental Quality Act. The Regional Water Quality Control Boards (Regional Water Boards) are active in regulating discharges from timber harvest and associated activities. The Regional Water Boards are responsible for enforcing the Porter-Cologne Water Quality Act that restricts the discharge of materials that adversely affect the beneficial uses of the waters of the State. The Regional Water Board issues permits, referred to as Waste Discharge Requirements (WDRs) and Waivers of WDRs, which establish conditions or requirements to control discharges of waste to waters of the State. Discharges associated with timber harvesting activities typically include sediment from erosion and/or increased water temperature from loss of riparian canopy.

Habitat Conservation Plans

Habitat conservation plans (HCPs), Natural Community Conservation Plans (NCCP), and other landscape scale plans, which contain robust monitoring programs and adaptive management elements, have enhanced management of private timberlands in northern California. The monitoring conducted by those engaged in such landscape plans is essential to evaluate whether populations of SONCC coho salmon and their habitat remain viable as management occurs over time. These plans allow for meaningful adjustments in the event that the goals or objectives of the plans are not being achieved. NMFS has approved three private timberlands HCPs within the range of SONCC coho salmon.

The Humboldt Redwood Company (HRC) HCP (formerly Pacific Lumber Company [PALCO] HCP) covers approximately 210,000 acres of industrial timberlands in northern California and includes activities related to timber management, forest road construction and maintenance, and rock quarrying (PALCO 1999). The HCP was finalized in 1999 and is valid through 2049. The major watersheds covered by the HRC HCP include portions of Freshwater Creek, Elk River (in Humboldt Bay Tributaries population), Eel River, Van Duzen River, and the Mattole River. The HRC HCP is habitat-based, having a defined goal of achieving or trending towards properly functioning aquatic conditions. An Aquatics Conservation Plan (ACP) was developed within the HCP with a defined goal to maintain or achieve, over time, properly functioning aquatic habitat conditions. The key variables in the ACP are water temperature, canopy cover, sediment, instream large wood, large wood recruitment, pool frequency, and pool quality. The HRC HCP relies heavily on watershed analysis, monitoring, and adaptive management tools to ensure achievement of habitat goals. HRC has agreed to assess all roads and associated sediment sources on its lands and stormproof all high- and medium-priority sites at a rate of 75 miles per year. As part of the HCP, HRC conducts monitoring for the Best Management Practices Evaluation Program, compliance monitoring, and effectiveness monitoring. Specifically, parameters such as large wood debris levels, water temperature, and in-stream sediment levels are monitored. This type of monitoring is the basis for evaluating the results of carrying out prescriptions on the features or processes that occur on the hill slope and the in-stream environment. The monitoring and effectiveness studies provide for the adaptive management component of the HCP.

Finalized in 2006 and valid through 2056, the Green Diamond Resource Company Aquatic Habitat Conservation Plan (AHCP) applies to approximately 410,000 acres in coastal northern California. This AHCP includes portions of all coastal coho salmon population areas from the Oregon border south to, and including, the Eel and Van Duzen rivers (GDRC 2006). The Yurok Tribe assumed responsibility for and holds an AHCP and ITP for 22,000 acres of the original 410,000 AHCP (Yurok Tribe and GDRC 2011).

The biological goals and objectives of the GDRC AHCP reflect in biological terms the intended result of the operating conservation program (GDRC 2006). The five goals of the AHCP are to: 1) maintain cool water temperature temperatures for aquatic species covered by the AHCP, 2) minimize and mitigate human-caused sediment inputs, 3) provide for the recruitment of large woody debris for instream habitat, 4) maintain or increase amphibian species across the landscape, and 5) monitor and adapt the plan as new information becomes available to provide those habitat conditions as needed to optimize conservation measures that benefit the covered species. Objectives that identify measurable parameters for each goal have also been set and are described in the plan.

Green Diamond describes the conservation benefits of the AHCP as follows (GDRC 2006):

> In addition to the measures to avoid or address specific impacts, the plan includes measures to improve conditions for the covered species and/or their habitats. These additional measures provide a level of mitigation that exceeds the anticipated impacts of taking. Examples include the road decommissioning and upgrading measures (and the accelerated implementation of the measures) and the LWD recruitment measures. Green Diamond also believes that the plan as designed provides for a significant improvement in the habitat conditions for all covered species within the plan area in all HPAs [Hydrographic Planning Areas]. In particular, the Road Management Measures will significantly accelerate the recovery of stream conditions negatively impacted by sediment, and other measures will provide similar improvements of habitat conditions.
>
> The extra measures supply added assurance that a sufficient level of conservation is being provided to address any concern about the sufficiency of any particular measure to address the extent of a particular type of impact. Furthermore, the improvement in conditions that will result from these measures exceeds that needed to meet the ITP [Incidental Take Permit] "minimize and mitigate" standard and will contribute both to the recovery of the ITP species and to efforts to preclude the need to list the ESP [Enhancement of Survival Permit] species.

As part of a conservation program within the AHCP, Green Diamond will remove 50 percent of the high and moderate priority road sites within the first 15 years of plan implementation. These measures, coupled with provisions for riparian protection, mass wasting avoidance, and adaptive management, ensure that adverse impacts to coho salmon rearing, migration, and spawning habitats are minimized, avoided or mitigated. Effectiveness monitoring will track the success of the Conservation Program in relation to the AHCP's biological goals and objectives and provide the basis for the AHCP's Adaptive Management Measures. Four categories of monitoring will be implemented: 1) rapid response monitoring, 2) response monitoring, 3) long-term trend monitoring/research, and 4) experimental watersheds program. Monitoring thresholds will trigger management responses when exceeded.

The Fruit Growers Supply Company (FGSC) HCP covers over 150,000 acres of industrial timberlands in Siskiyou County and includes activities related to timber management and forest road construction and maintenance (FGSC 2012). The plan was finalized in 2012 and is valid through 2062. The timberland covered under the HCP exists primarily in the Upper Klamath watershed, including Scott Valley and portions of Cottonwood Creek. It is the intent of the FGSC HCP to promote hydrologic and forest conditions that contribute to a larger regional recovery strategy for covered species. The four biological objectives of the Aquatic Species Conservation Program included in the HCP are: (1) Protect hydrologic and riparian processes that influence water quality, aquatic habitat, and riparian functions; (2) Maintain a high level of stream shading that contributes to cool water temperature regimes that are consistent with the requirements of the individual Covered Species; (3) Provide for the recruitment of LWD into streams so as to maintain and allow the development of functional stream habitat conditions; (4) Minimize and mitigate human-caused sediment inputs; and (5) Monitor to ensure compliance and effectiveness of the aquatic protection measures for providing those habitat conditions needed to meet the general goals that benefit the Covered Species (FGSC 2012). Specific targets for sediment control include a 50 percent reduction of road-related erosion delivery potential within the first 10 years of the Permits (FGSC 2012)

3.2.6 Urban/Residential/Industrial Development

Substantial development and urbanization has contributed to habitat impairment throughout the ESU. Development ranks as a high or very high threat in 13 of the 40 populations of the SONCC coho salmon ESU (Table 3-8, Chapters 7 to 46). Although most of the range of the SONCC coho salmon ESU is considered to be rural, there are three highly urbanized population centers. The Humboldt Bay and Yreka areas in California and the Medford/Grants Pass area in Oregon all have urban centers with high percentages of impervious surfaces that contribute to the degradation of habitat and coho salmon viability. Development and urbanization often leads to degraded habitat through stream channelization, floodplain disconnection, damage or loss of riparian and wetland areas, point and non-point source pollution, bank hardening, and consumptive water use (Botkin et al. 1995). When watersheds are developed, natural vegetative ground cover is removed and/or replaced by impervious surfaces or structures, water infiltration is reduced, and runoff from the watershed is flashier, with increased flood hazard (Leopold 1968). Flood control and unnatural drainage patterns may concentrate runoff, resulting in increased bank erosion, which causes an additional loss of riparian vegetation and undercut banks, and eventually causes widening and down cutting of the stream channel. Streams that are channelized and/or diked frequently lack native riparian vegetation and provide little coho salmon habitat value.

In developed areas, point-source and nonpoint-source pollution are common. Sediments washed from urban and industrial areas often contain trace metals such as copper, cadmium, zinc, and lead (California State Lands Commission 1993, Sandahl et al. 2007). An acute example of this phenomenon is when toxic storm water runoff from urban and industrial sources led to high pre-spawn mortality of adult coho salmon in tributaries to Washington's Puget Sound (Booth et al. 2006). Improperly maintained underground septic systems in residential areas can leach bacteria and nutrients into the water table. One significant emerging issue is the input of pharmaceuticals, endocrine disruptors, and personal care products to the watershed, products that are not effectively removed in standard treatment processes (Sumpter and Johnson 2005). These products, together with pesticides, herbicides, fertilizers, gasoline, and other petroleum products, contaminate drainage waters and harm juvenile coho salmon and their aquatic invertebrate prey (Crisp et al. 1998, Flaherty and Dodson 2005). The North Coast Regional Water Quality Control Board (NCRWQCB 2001) reported that non-point-source pollution is the cause of 50 to 80 percent of impairment to water bodies in California.

Additionally, the magnitude of peak flow and pollution increases with increased total impervious area (TIA; e.g., rooftops, streets, parking lots, sidewalks). Spence et al. (1996) recognized that channel damage from urbanization is clearly recognizable when TIA exceeds 10 percent, and that reduced fish abundance, fish habitat quality and macroinvertebrate diversity are seen with total impervious area levels from 7 to 12 percent (Klein 1979, Shaver et al. 1995). May et al.

(1997) showed almost a complete simplification of stream channels as total impervious area approached 30 percent and measured substantially increased levels of toxic storm water runoff in watersheds with greater than 40 percent total impervious area. Booth and Jackson (1997) found that total impervious area greater than 10 percent caused increased peak flows, decreased base flows, simplified channel conditions, increased non-point-source storm water pollution, and resulted in a loss of aquatic system function.

Urban Growth Management

Urban growth management in both Oregon and California has some significant shortcomings that prevent the full protection of coho salmon habitat. Inside Oregon's urban growth boundaries, some upgraded riparian area protection was afforded under the Oregon Coastal Salmon Restoration Initiative (The Oregon Plan; State of Oregon 1997) and local governments amended their local comprehensive county general plans to implement these new requirements. Unfortunately, this goal only provides general guidance and does not require establishment and protection of riparian vegetation and wetlands. Buffer widths or types for riparian and wetlands are not included in these guidelines, resulting in insufficient stream bank and riparian vegetation protection, and continuing to allow for the degradation of coho salmon habitat. Rapid population growth in California has caused harm to coho salmon and their habitat and may constitute a reason to evaluate urban growth management practices and their effectiveness at protecting SONCC coho salmon.

County and city planning in both Oregon and California (Mendocino, Humboldt, Siskiyou, Trinity, Del Norte, Lake, Curry, Josephine, Jackson, and Klamath counties) benefit from the development and implementation of comprehensive general plans that include some protective measures for fish and wildlife species and habitat. The Humboldt County General Plan helps to sustain and enhance water resources throughout Humboldt County. Through its policies and standards, the General Plan is an effective tool to ensure that any new development occurs without damaging water resources on an individual and cumulative basis. The Plan also serves to guide the County in its interaction with neighboring counties, state, and federal agencies and lawmakers and guides the County's activities and commitment of resources. The plan includes a water resources element, which addresses water planning issues including river and stream water quality, stormwater runoff, groundwater management, water needs of fish and wildlife, water consumption, conservation and re-use methods, and state and federal regulations. The goals of the water resources element include: high quality and abundant surface and groundwater water resources that satisfy the water quality objectives and beneficial uses; river and stream habitat capable of supporting abundant salmon and steelhead populations and sufficient water flows; support of salmon and steelhead recovery plans, recreation activities, and the economic needs of river dependent communities; and no additional upper or mid-level watershed exports from rivers flowing through the county. Siskiyou County also has a comprehensive General Plan that works towards protection of water quality, ecosystem processes and the natural environment.

3.2.7 High Severity Fire

Fires provide for many ecological functions including recycling woody and detritus fuels, preparing mineral seed beds, facilitating vegetative reproduction, and reducing understory vegetation (Stephens and Fry 2005). Fire has always been an important part of the disturbance process in the western United States (Bisson et al. 2003). Recent findings support the notion that fire can also be a valuable restorative tool because it has the capacity to increase physical and biological diversity and can support the maintenance of complex and productive aquatic habitats (Reeves et al. 1995; Benda et al. 2003; Bisson et al. 2003). Frequent yet dispersed surface fires were once a dominant fire regime in many forests. That regime has been altered throughout the ESU range due to the loss of Native American ignition sources, implementation of fire suppression policies starting in the 1930s, and other changes brought about by Euro-American settlement and land-use (Brown 2007; Scanlon 2007;). High severity fire is ranked as a high or very high threat in 9 of the 40 populations in the ESU (Table 3-8, Chapters 7 to 46).

Low severity fires are beneficial to coho salmon habitat because they burn on the ground and remove many of the smaller trees and shrubs, while leaving the larger, more fire resistant trees (Minshall 2003). This type of fire dampens fuel loading and forest vegetation crowding, while potentially boosting invertebrate production (Minshall 2003). High severity fires, on the other hand, refer to severe surface burns or crown fires that result in the creation of an entirely new stand (stand replacing fire; Agee 1998). High severity fires threaten aquatic organisms via direct physical effects, such as mortality from rapid increases in temperature and accumulation of toxic chemicals, and indirect effects, such as habitat destruction, reduced extent and connectivity of habitat, and the temporary reduction or elimination of food resources (Rieman et al. 2012, Reeves et al. 1995). Fires pose the greatest threat to coho salmon in terrestrially dry, inland areas where high severity fire naturally occurs. Many watersheds have experienced a change in their fire regime due to past land use, drought and climate change (Fried et al. 2004).

High severity fire may cause significant changes to the ecosystem, including: alteration of soil structure, such as increased hydrophobicity (water repellency) and iron oxidation; increased air and water temperatures as a result of tree canopy mortality; white ash deposition and charred organic matter; and the consumption of the soil organic layer and surface litter of all sizes (Turner et al. 1994; Ryan 2002). Fire severity is an important indicator of the potential for water runoff and erosion (Robichaud et al. 2000; Keeley 2009) and hydrophobic soils have been linked to floods and increased erosion (Rieman et al. 2012). Snow pack and water retention are also reduced in denuded areas, which affects the hydrology of the basin (Minshall 2003). Instream wood typically declines immediately after fires due to fire consumption, and declines may be significant if a large portion of the riparian vegetation (including debris jams) is burned completely, or if remaining wood is transported out of the stream system during periods of elevated flows (Rieman et al. 2012). Fire in upslope areas can lead to increased soil erosion and sediment delivery, which may result in stream aggradation, pool filling, and in extreme cases landsliding, debris torrents, or other forms of mass wasting (Elder et al. 2002). Population level implications of wildfire appear to depend on longer-term processes, and there are no known examples of population extirpation associated with the immediate effects of wildfires (Rieman et al. 2012).

Catastrophic fires are known to fully expose riparian areas, which may temporarily increase water temperatures through the loss of riparian shading (Dwire and Kauffman 2003, Minshall 2003, Spencer et al. 2003). Riparian plants have evolved a tolerance to disturbance and ability to rapidly recover following fires, as evidenced by epicormic and basal sprouting as well as strategic seed dispersal adaptations (Reeves et al. 2006). In some cases, water temperature changes can become permanent if a fire initiates a transition to vegetation types that are better suited to a warming climate (Isaak et al. 2010, Rieman et al. 2012). For example, if riparian vegetation transitions from mature native trees to herbaceous non-native species as a result of fire, and the conversion is amplified by climate change, then the pre-fire mesic (cool, wet) conditions may never be restored due to intense competition and eventual displacement.

According to a report completed by the Intergovernmental Panel on Climate Change, climate in the western United States is projected to warm substantially before the end of this century (Young 2012). Climate variability affects fire occurrence, with more frequent and larger fires associated with warmer, drier regimes (Bisson et al. 2003). Higher temperatures, reduced snowpack, and earlier spring snowmelt all contribute to the frequency, intensity, and extent of fires. Combined effects of climate change and fire places populations at even greater risk of extirpation during or shortly after a severe fire. The reduction in habitat connectivity, reduction of refugia, and lack of shading from stand-replacing fires in the riparian zone may threaten already reduced numbers of coho salmon. Subsequent increases in water temperature may result in areas becoming uninhabitable for cold water species (Young 2012). Many watersheds have experienced a change in their fire regime due to past land use, drought and climate change (Fried et al. 2004). The probability of large fires (more than 500 acres) might increase by more than 75 percent in areas within the Klamath and Smith River basins, with increases of 50 percent predicted throughout the inland areas of Northern California and Southern Oregon (Luers et al. 2007). However, active forest management through thinning second growth stands, creating fuel breaks, and completing controlled understory burns has reduced the potential threat of catastrophic fire in some areas by increasing the number of fire resistant stands (Pollet and Omi 2002).

3.2.8 Mining and Gravel Extraction

Currently, mining within the SONCC coho salmon ESU is primarily in the form of instream gravel mining, placer mining, suction dredging and upslope hardrock mining. The greatest threat from instream gravel mining is the alteration of channel morphology and hydraulic processes that alter the quantity and quality of instream habitat (e.g., pools and riffles) (Kondolf 1997). The greatest threat from upslope mining is the increased potential for chemicals, sediment or other types of contaminants to enter watercourses. Threats from placer mining and suction dredging include the rearrangement or destabilization of substrate and subsequent changes to macroinvertebrate assemblages (Kondolf and Wolman 1993). Mining and gravel extraction are listed as a high or very high threat in five populations of 40 SONCC coho salmon populations (Table 3-8).

Gravel extraction has the potential to impact channel form, sediment delivery, and hydrologic functions in a river or stream (Brown et al. 1998). The severity of this threat is primarily dependent on the location of activity, the intensity, and the types of methods used. Instream gravel mining affects habitat primarily through the removal of gravel from the top of gravel bars by skimming. Lowered bars result in unstable riffles that scour redds, wider and shallower channels that present migration barriers, and simplified habitat with fewer pools for juvenile rearing and adult holding (Kondolf and Swanson 1993). Extensive mining for sand, gravel, construction aggregate and gold in a stream’s floodplain and channel can create major habitat impacts already exacerbated by flow regulation in systems such as the Trinity River, Mad River, and Eel River. Flow reductions and the associated reduction in sediment transport into a regulated, mined system can modify a stream's geomorphological and hydrological processes. These modifications can result in very limited gravel recruitment and sediment transport (Kondolf 1997). With altered hydrologic and geomorphological processes, remaining salmonid spawning gravel is immobile and susceptible to compaction and/or armoring. When armoring occurs, the potential salmonid habitat becomes unavailable for salmonid production. Furthermore, mining tailings often leave much of the floodplain perched. These impacts, coupled with channel incision due to the sediment and hydrograph budget modification, can further reduce the availability of needed rearing habitat. Armored banks from remaining dredge tailings do not allow lateral channel migration, accelerating channel scour further decoupling the river from its floodplain and potentially eroding remaining spawning gravel (Brown et al 1998, Kanehl and Lyons 1992, Kondolf 1997). Instream gravel mining is regulated at the federal, state, and county levels in California and Oregon. Federal laws and regulations that apply in both states include permitting under Section 404 of the Clean Water Act (administered by the Army Corps of Engineers), the General Mining Law of 1872, the Federal Land Policy and Management Act (FLPMA), and ESA section 7 and implementing regulations requiring consultation on issuance of federal permits or other federal agency actions that may affect listed species or critical habitat.

Hydraulic mining (placer and suction dredging) can have a negative effect on habitat quality and lead to direct mortality through entrainment of eggs and offspring and the disturbance and alteration of streambed substrate (Griffith and Andrews 1981). Seasonal protections to minimize these effects have been effective by limiting the timing of permitted suction dredging to when eggs and larvae will not be entrained. Material is often deposited into tailing piles, creating unnatural channel formations and flows. The persistence of such features is variable and the impacts can be seasonal and site-specific or long-term and widespread. Tailings piles are unstable and egg-to-fry survival was found to be reduced for Chinook salmon that spawn in tailings (Harvey and Lisle 1999), a finding that likely also applies to coho salmon. Lode or hard-rock mining in upland areas has the potential to unearth contaminants, which can eventually make their way into tributary and river systems.

Placer mining has the potential to alter riparian areas, damage instream habitat, and input fine sediment and pollutants. Past placer mining has damaged some riparian areas to the point where future recruitment of vegetation is impossible. Additional threats from placer mining include removal of riparian vegetation leading to long-term increases in water temperature and lack of wood recruitment, potential water diversions, potential streambank failures and increased sediment. When stream channels are changed or sediment concentrations are increased through placer mining, it can affect benthic invertebrates in the stream. Their populations can decline, or the species types may change and these changes can place stress on fish populations (Wagener and LaPerriere 1985). Results showed that placer mining caused increased turbidity and increased amounts of settleable solids and suspended sediments. These effects were correlated with decreased density and biomass of invertebrates (Wagener and LaPerriere 1985).

Federal Regulations

The Bureau of Land Management (BLM) has primary responsibility for administering the laws and regulations regarding the removal of all minerals from all federally owned lands. The BLM's statutory authority here is derived from the General Mining Law of 1872, as amended (30 U.S.C.

§ 21 et seq.), the original public land authority in 43 U.S.C. §§ 2, 15, 1201 and 1457, and FLPMA (43 U.S.C. 1701 et seq.). These statutes, together with the implementing regulations (43 CFR Parts 3710-3870) generally make up the body of the mining law system. Most Federal agencies have regulations to protect the surface resources of Federal lands during exploration and mining activities. In addition, CWA section 404 and Army Corps of Engineers (Corps) implementing regulations require a permit from the Corps for placement of material, impoundments, or other control of water in waters of the United States.

California Regulations

In California, state requirements include the need to obtain a Streambed Alteration Agreement from CDFW, and compliance with the Surface Mining and Reclamation Act (SMARA). SMARA is implemented by each individual county through the issuance of Conditional Use Permits. For suction dredging, new regulations in California including special closed areas, closed seasons, and restrictions on methods and operations have been developed to minimize and prevent negative impacts from mining operations. These new regulations are in place to help protect habitat, but careful monitoring of mining activity must occur to ensure that there is compliance.

In August 2009, all California instream suction dredge mining was suspended following enactment of state law SB 670 (Wiggins),which prohibits the use of vacuum or suction dredge equipment in any California river, stream or lake regardless of whether the operator has an existing permit issued by CDFW. The moratorium does not apply to suction dredging operations performed for the regular maintenance of energy or water supply management infrastructure, flood control, or navigational purposes. While CDFW was in the process of completing a court-ordered environmental review of its permitting program, a new state law, AB 120, was enacted to extend the moratorium until June 30, 2016. Two other specifications of AB 120 are that any "new regulations fully mitigate all identified significant environmental impacts." and that the suction dredge permit fees be increased to fully fund all of CDFW's costs for administrating the suction dredge program.

Oregon Regulations

The State of Oregon has a number of mining regulations. Many state prohibitions exist, and most public lands are off-limits to exploration or development of mining claims. The Oregon Department of Environmental Quality requires issuance a permit before mining can begin. Operating an in-stream suction dredge and discharging the resultant wastewater requires a national pollutant discharge elimination system (NPDES) General Permit 700-PM. Persons assigned to the NPDES 700-PM permit must not operate a suction dredge more than 16 horsepower or with an inside diameter intake nozzle greater than four inches in essential salmon habitat. Suction dredging is allowed only during the in-water work schedule to protect fish and wildlife resources (ODFW 2008c), and measures must be taken to prevent the spread of invasive species. Suction dredging is prohibited on any stream segment that is listed as water quality limited for sediment, turbidity, or toxics on the list published by ODEQ. Mining must not cause any measureable increase in turbidity in selected wilderness and reserve areas. A measureable increase in turbidity is measured as visible turbidity. Performing small-scale, non-chemical off-stream placer mining adjacent to a waterway requires a Water Pollution Control Facility (WPCF)

General Permit 600, which prohibits discharge of wastewater generated by the operation to the waters of the state. These permit requirements were set in place to protect and preserve fish and wildlife species inhabiting the waterways of the state of Oregon (Oregon Division of State Lands 1999). In July 2013, Senate bill 838 passed the Oregon legislature and included several measures to better protect Oregon streams from suction dredging, including an increase in permit fees to cover the cost of a more rigorous permitting and enforcement program and a limit of 850 permits. Under the Senate bill, the state is required to draft new protective measures by the end of 2014 with an implementation date of 2015. If new measures are not implemented, a five year moratorium will go into effect in January of 2016.

Oregon state law currently restricts equipment size, nozzle diameter, and suction speed and efficiency. In the SONCC coho salmon ESU, as of June 1998, portions of the Rogue, Illinois, and Elk rivers, as well as areas of the North Fork of the Smith River are closed to mineral entry except for federal mining claim holders working within valid claims under approved Plans of Operations. While these prohibitions and requirements help curtail mining activities, illegal mining has been recently documented in the SONCC coho salmon ESU (e.g., Preusch 2009, Learn 2011).

National Marine Fisheries Service Gravel Extraction Guidance

In 2005, the 1996 NMFS National Gravel Extraction Policy was revised and reissued as the NMFS National Gravel Extraction Guidance (Hogarth 2005). The revised Gravel Guidance includes updated information, recommendations and references that can provide meaningful assistance to NMFS staff and other managers involved in regulatory activities were gravel mining in or near streams may affect anadromous fishes and their habitat. The guidance document is meant to be adaptable and address regional needs and local physical and biological settings.

Recommendations in the guidance are as follows: 1) upland aggregate sources, terraces and inactive floodplains be used preferentially to active channels, their deltas and floodplains. 2) pit excavations located on the adjacent floodplain or terraces should be preferentially sited outside the channel migration zone, and as far from the stream as possible. NMFS recommends pits be separated from the active channel by a bugger designed to maintain this separation for several decades, 3) larger rivers and streams by used preferentially to small rivers and streams, 4) braided river systems be used preferentially to other river systems, 5) instream gravel removal quantities be strictly limited so that gravel recruitment and accumulation rates are sufficient to avoid prolonged impacts on channel morphology and anadromous fish habitat, 6) gravel bar skimming be allowed only under restricted conditions, 7) prior to gravel removal, a thorough review of sediments and point and non-point sources of contaminants be conducted, 8) removal or disturbance of instream roughness elements during gravel extraction activities be avoided, and that those that are disturbed be replace or restored, 9) gravel extraction operations be managed to avoid or minimize damage to stream/river banks and riparian habitats, 10) cumulative impacts of gravel extraction operations to anadromous fishes and their habitats be addressed by the Federal, state, and local resource management and permitting agencies and be considered in the permitting process, 11) an integrated environmental assessment, management, and monitoring program be a part of any gravel extraction operation, and encouraged at Federal, state, and local levels, 12) mitigation be an integral part of the management of gravel extraction projects, and 13) gravel extraction projects proposed as stream restoration activities be regarded with caution.

3.2.9 Dams and Diversions

Dams and diversions are among the most significant threats to SONCC coho salmon populations. Permanent dams are almost always associated with water control features for flood control, municipal or agricultural water uses, and/or hydropower operations. Temporary dams are usually built for recreational or agricultural purposes on private land. Many dams are associated with water diversions. Dams and diversions can be potential barriers to fish passage, and if diversions are not screened, fish can be entrained and die. In addition, dams and diversions can alter stream flows (Magilligan and Nislow 2005), sediment transport (Graf 2006), channel morphology (Ligon et al. 1995), water quality (USDOI and CDFG 2012), and food webs (Power et al. 1996). These changes can lead to reduced survival and production of coho salmon. NMFS analyzed stream flow, precipitation, water use, reservoir storage, and Geographic Information Systems (GIS) data to calculate a series of quantitative indicators, which were then used in conjunction with other information to inform professional judgments of the magnitude of the threat of dams and diversions for each coho salmon population and life stage (Asarian 2014). NMFS ranked dams and diversions as a high or very high threat in 18 of 40 populations (Table 3-8, Chapters 7 to 46).

Dams and diversions alter the hydrologic regime by shifting the timing and magnitude of flow. The hydrologic effects of dams vary according to factors such as management objectives (e.g., flood control, hydropower, summer water supply, and/or conservation of aquatic resources), the volume of the reservoirs relative to stream flow, and the location of dams within the hydrologic network. Large dams often reduce the magnitude and frequency of high flow events, and reduce differences between annual minimum and annual maximum flows (Graf 2006). The primary purpose of most large dams within the SONCC coho salmon ESU is to store water from high flows in the fall, winter, and spring so that it can be used for irrigation and municipal supply during the low-flow summer months. This can affect coho salmon by reducing flows when juveniles and smolts are migrating downstream in spring and adults are returning in the fall to spawn. While large reservoirs generally have greater hydrologic impacts, if a large number of small reservoirs are present they can act cumulatively to substantially alter the hydrology, particularly at the start of the rainy season (Deitch et al. 2013); however this phenomenon likely affects only a very small portion of the SONCC coho salmon ESU. Both juveniles and adults use flow events as migratory cues and depend on natural flow regimes for migration and access to habitat. Additional information on the hydrologic effects of dams and diversions is provided in Section 3.1.7 (altered hydrologic function).

Dams also impede the geomorphological processes that maintain stream health (Ligon et al. 1995). By halting recruitment of coarse sediment from upstream (Kondolf 1997) and decreasing the frequency and magnitude of bed-mobilizing flows, dams simplify channels and degrade salmonid habitat (Ock and Kondolf 2012, Ligon et al. 1995). Re-establishing flow regimes that mimic the natural hydrograph has the potential to reduce the detrimental effects of dams on geomorphology, fish habitat, and riparian vegetation (USFWS and HVT 1999, Burke et al. 2009).

Dams and diversions can also degrade water quality. As discussed in section 3.1.7 , water diversions can deplete stream flows and increase summer water temperatures. By stagnating water and exposing it to solar radiation, shallow reservoirs can increase summer water temperatures (Spence et al. 2006). In contrast, deeper reservoirs that stratify and release water from their depths can provide an important source of cold water during the summer, such as occurs at dams on the Trinity and Rogue rivers. When nutrient-rich water is impounded, reservoirs can host prolific summer blooms of blue-green algae that degrade downstream water quality, such as occurs on the mainstem Klamath River (USDOI and CDFG 2012). As human population growth continues, the number of water diversions increase and threaten SONCC coho salmon populations. For example, recent investments in residential water storage have significantly reduced summer water withdrawals in areas such as the headwaters of the Mattole River (Klein 2012).

An emerging threat to SONCC coho salmon is water diversion related to marijuana cultivation. Although the number of plants grown each year is unknown, the water diversion required to support these plants is placing a high demand on a limited supply of water (Bauer, S., pers. comm. 2013a). Most diversions for marijuana cultivation occur at headwater springs and streams, thereby removing the coldest, cleanest water at the most stressful time of the year for coho salmon (Bauer, S., pers. comm. 2013b). Based on an estimate from the medical marijuana industry, each marijuana plant may consume 900 gallons of water per growing season (Humboldt Growers Association 2010).

Permanent and seasonal dams can be partial or complete barriers to coho salmon migration. For example, dams completely block access to more than 15 percent of potential coho salmon habitat in the following populations: Upper Rogue River (16%), Shasta River (18%), Upper Klamath River (43%), Upper Trinity (47%), and Upper Mainstem Eel River (80%) (Asarian 2014). Recent dam removal projects throughout the ESU have allowed for improved passage in the Rogue River, and efforts towards installing fish screens have significantly decreased impacts to salmonids. For example, many diversions in the Shasta basin now have CDFG- and NMFS-approved fish screens, and Scott Valley has 100 percent of the diversions located in coho habitat screened to reduce impacts to SONCC coho salmon.

Recent efforts in the Klamath Basin have brought about the creation of the Klamath Basin Hydroelectric Settlement Agreement (KHSA) and the Klamath Basin Restoration Agreement (KBRA). The KHSA describes the process for conducting necessary additional studies, environmental reviews, and a decision by the Secretary of Interior (Secretarial Determination) as to whether removal of the lower four dams on the Klamath River owned by PacifiCorp 1) will advance restoration of the salmonid fisheries of the Klamath Basin, and 2) is in the public interest, which includes but is not limited to consideration of potential impacts on affected local communities and Tribes. The KHSA includes provisions for the interim operation of the dams prior to dam removal as well as the process to transfer, decommission, and remove the dams if the Secretarial Determination is affirmative. The KHSA establishes 2020 as the target date for dam removal. This timeline allows for completion of necessary environmental and regulatory reviews and the collection of $200 million for dam removal from PacifiCorp customers if the Secretarial Determination is affirmative.

The KBRA is a settlement agreement among many diverse parties that creates a solid path forward on long-standing, resource disputes in the Klamath Basin. The KBRA takes a multi-dimensional approach that resolves complex problems by focusing on species recovery while recognizing the interdependence of environmental and economic problems in the Basin's rural communities. The goals of the KBRA are to 1) restore and sustain natural production and provide for full participation in harvest opportunities of fish species throughout the Klamath Basin; 2) establish reliable water and power supplies that sustain agricultural uses and communities and National Wildlife Refuges; and 3) contribute to the public welfare and the sustainability of all Klamath Basin communities. The key negotiated outcomes of the KBRA include mutually-beneficial agreements for the Klamath, Karuk, and Yurok Tribes not to exercise water right claims that would conflict with water deliveries to the Bureau of Reclamation's Klamath Project water users and for project water users to accept reduced water deliveries. As a result, there would be more support for fisheries restoration programs, greater certainty about water deliveries at the beginning of each growing season, and agreement and assurances that certain of the parties will work collaboratively to resolve outstanding water-right contests pending in the Oregon Klamath Basin Adjudication process. In addition, the KBRA includes an Off-Project voluntary Water Use Retirement Program in the Upper Basin, three restoration projects intended to increase the amount of water storage in the Upper Klamath Basin, regulatory assurances, county and tribal economic development programs, and tribal resource management programs. Copies of the KHSA and KBRA in their entirety are available electronically at: http://klamathrestoration.gov/. The implementation of these two agreements will be a significant step forward in restoring fish populations in the Klamath River Basin, once a stronghold for SONCC coho salmon.

Several timber companies have developed HCPs that include improved water diversion practices. These activities will help to reduce the impact of these diversions on the SONCC coho salmon landscape. The HCPs are described in Section 3.2.5.

Federal and State Acts and Water Allocation

Federal statutes that include provisions relevant to instream flow protection include the ESA, CWA, National Environmental Policy Act (NEPA), and the Federal Power Act.

Given the lack of federal regulatory authority over instream flow in many areas and waterbodies, state water laws are the primary mechanism for protecting instream flow in many areas. In the SONCC coho salmon ESU, the states of Oregon and California are charged with allocating and adjudicating water quantities to qualified users, as well as enforcing water rights.

Oregon's water rights system is based primarily on the doctrine of prior appropriation, although some form of riparian water rights still exist (Oregon Water Resources Department [OWRD] 2009) and instream flow rights can be established through water right purchase or lease. Surface and groundwater use in Oregon is administered by the OWRD, which is responsible for implementing Oregon's water policy.

Oregon was one of the first western states to recognize instream flow as a beneficial use. In 1955, the state adopted minimum stream flows to support aquatic life through administrative rules, and in 1983 amendments were adopted that authorized ODFW, ODEQ, and the Oregon

Department of Parks and Recreation to apply for minimum instream flow rights. In 1987 and 1993, further amendments strengthened instream flow rights, allowing for transfers and for the use of water markets to acquire instream flow rights (OWRD 2009). Instream flows for particular watersheds can be found under the relevant "basin program" (e.g., Rogue Basin Program contains Rogue tributaries) here: http://www.oregon.gov/owrd/pages/law/oar.aspx.

State resource managers in Oregon have also attempted to protect and conserve instream flows, and promote water conservation, through the implementation of voluntary programs for private water users. The allocation of conserved water program, administered by OWRD, allows a water user who conserves water to use a portion of the conserved water on additional lands, lease or sell the water, or dedicate the water to instream use. The program is intended to promote the efficient use of water to satisfy current and future needs, both out of stream and instream. Oregon's instream leasing program is also designed to provide a voluntary means to aid the restoration and protection of stream flow. This arrangement provides water users with options that protect their water rights while leasing water for instream benefits. The success of this program is largely dependent on the participation of landowners and therefore the program may be unable to meet the instream flow needs of coho salmon populations in some areas.

In Oregon, a permit is generally necessary to use water from any source, including underground. Certain activities are exempt from this requirement (e.g., stock watering, watering lawns or noncommercial gardens, domestic, industrial, or commercial purposes) (OWRD 2009). Groundwater withdrawal has a cumulatively substantial effect on the amount of water available in streams (Barlow and Leake 2012). Groundwater withdrawal works together with the removal of water through surface water rights to alter availability of water at low flows. The analysis of altered hydrologic function in this document, which describes the amount and timing of water availability, finds it ranks a high or very high stress for many Oregon populations (see Chapters 7-9, 12-14, and 30-32).

Responsibility for water allocation and use enforcement in California is shared among several agencies. California courts have jurisdiction over the use of percolating ground water, riparian use of surface waters, and the appropriate use of surface waters initiated prior to 1914 (California Department of Water Resources [CDWR] 2001). The State Water Resources Control Board (SWRCB) is responsible for the water rights and water quality functions of the state (CDWR 2001). The SWRCB has the jurisdiction to issue permits and licenses for appropriation of water from surface and underground streams. This board also has the authority to declare watercourses fully appropriated. Many of the streams and rivers in the California portion of the ESU have been deemed to be fully appropriated by the SWRCB (SWRCB 1998). A declaration that a stream system is fully appropriated means that the supply of water in the stream system is being fully applied to beneficial uses, and the SWRCB has determined that no water remains available for appropriation. From and after the date of adoption of a declaration that a stream system is fully appropriated, and subject to subdivision b of California Water Code section 1206, the SWRCB shall not accept any application for a permit to appropriate water from the stream system and the board may cancel any application pending on that date.

Table 3-9. Stream systems declared fully appropriated by the SWRCB.

County	Stream	Tributary to	Critical Reach
Del Norte County	Smith River	Pacific Ocean	refer to Section 5093.54 of California Wild and Scenic Rivers Act for specific critical reaches
	Jordan Creek	Lake Earl	from the confluence with Lack Earl upstream
Humboldt County	Eel River	Pacific Ocean	the main stem from 100 yards below Van Arsdale Dam to the Pacific Ocean

The CDWR is responsible for planning the use of state water supplies and consults with the California Water Commission to develop rules and regulations for this purpose (CDWR 2001). The vast majority of California's groundwater is unregulated and the state does not have a comprehensive groundwater permit process to regulate ground water withdrawal. The lack of groundwater regulation has led to overutilization of this resource, which has had major impacts on surface flow and constitutes a major shortcoming of California water law.

In 1991, California adopted changes to its water laws that permitted the transfer of existing consumptive water rights to the purpose of instream flow through either purchase or lease. When a new water use permit application is submitted, the State Water Board (Board) must notify CDFW, which has the authority to recommend amounts of water necessary to preserve fish, wildlife, and recreation in the affected stream. The Board then considers these recommendations and may set instream flow requirements as conditions for the new permit. In this way, current flows can be protected even though new appropriations for instream flow rights are prohibited (California Environmental Protection Agency 2011).

Other efforts to protect instream flows include the adoption of California Water Code section 1259.4, and the adoption and use of Section 1707. California Water Code section 1259.4

addresses the draft guidelines that CDFG and NMFS (2002) presented to the SWRCB for maintaining instream flows downstream of water diversions in mid-California coastal streams. The draft joint guidelines call for limiting new water diversions to only the winter period from December 15 to March 31, establishing bypass flows for new dams, establishing a cumulative maximum rate of withdrawal, and restricting construction of new on-stream dams. Water transfers for dedicated instream uses are accomplished through Section 1707. An instream flow dedication under Section 1707 allows a water user to transfer all or a portion of any water right to instream uses – for example, designating that such conserved water must remain in the watercourse for the benefit of aquatic habitat. It is available to owners of either riparian or appropriative water rights, and can be crafted for either short-term (less than a year) or long-term duration. These transfers may be used to ensure that water flows downstream to satisfy any applicable federal, state, or local regulatory requirements governing water quantity, water quality, instream flows, fish and wildlife, wetlands, recreation, and other instream beneficial uses.

In November 2009, the California State Legislature passed a series of bills that encourage stricter groundwater monitoring and enforcement of illegal diversions, more ambitious water conservation policy, and water recycling and conservation programs. If effectively implemented, these California water bills should contribute to improved instream habitat in the future.

Instream Flow Requirements

Many rivers within the SONCC coho salmon ESU contain large dams. Dam operators at most of these dams have regulatory mandates to maintain adequate instream flows for the protection of fish and wildlife species. Examples of dams with flow requirements include J.C. Boyle, Copco 1, Copco 2, and Iron Gate dams on the Klamath River; Trinity and Lewiston dams on the Trinity River; R.W. Matthews Dam (Ruth Lake) on the Mad River, and Scott Dam (Lake Pillsbury) in the Eel River. Large dams lacking instream flow requirements include William L. Jess Dam (Lost Creek Reservoir) on the Rogue River, Applegate Dam on the Applegate River, and Dwinnell Dam on the Shasta River.

On the Trinity River, the Bureau of Reclamation is required to release between 369,000 and 815,000 acre feet to the Trinity River annually depending on the water year type. Discharge from Lewiston Dam remains at 450 cubic feet per second (cfs) during the summer months, 300 cfs during the winter months, and has a variable flow regime in the spring depending on the water year type.

The total volume of water impounded and diverted by the Humboldt Bay Municipal Water District (HBMWD) represents a small percentage of the natural yield of the Mad River watershed. The Mad River's average annual discharge into the Pacific Ocean is just over 1,000,000 acre-feet (available at http://www.hbmwd.com/water_supply). Ruth Lake, in its entirety, represents less than 5 percent of the total average annual runoff from the Mad River basin. The entire 48,030 acre-feet capacity of Ruth Lake is not drawn down each year, so the amount of winter-season runoff captured in the reservoir is yet a smaller percentage of the total runoff. With respect to diversions, the current withdrawal rate at Essex is approximately 25 to 30 MGD (28,000 to 34,000 acre-feet per year), which is only 3 percent of the total annual average runoff of the Mad River watershed (available at http://www.hbmwd.com/water_supply). The full diversion capacity of 75 MGD (84,000 acre-feet per year) is just 8 percent of the total annual average runoff of the watershed.

From 1992 to 2004, up to approximately 160,000 acre-feet of Eel River water was annually diverted into the East Fork of the Russian River for hydropower production and agricultural uses. From 2007-2012 the Potter Valley Project annually diverted approximately 22% of the estimated unimpaired flow at the point of diversion (i.e., Cape Horn Dam), with an average diversion of 77,000 acre-feet (Kubicek, P., pers. comm. 2013). Until 2004, flows released downstream of Cape Horn Dam were approximately 3 cfs during most of the summer. In 2004, the Federal Energy Regulatory Commission issued an order requiring Pacific Gas and Electric (PG&E) to implement an instream flow regime consistent with the Reasonable and Prudent Alternative in the NMFS (2002b) Biological Opinion. The new flow requirement increased the minimum Cape Horn Dam release flows and incorporated within-year and between-year variability. Minimum flows are dependent on a number of factors and formulas, including cumulative inflow into Lake Pillsbury, current and previous water year, and time periods.

Habitat Conservation Plans

Finalized in 2012 and valid through 2022 except under certain circumstances, the PacifiCorp's Klamath Hydroelectric Project Interim Operations Habitat Conservation Plan for Coho Salmon (dated February 16, 2012) (PacifiCorp 2012) addresses the impacts of PacifiCorp's Klamath Project on coho salmon. The goals of PacifiCorp's HCP are to:

- Offset biological effects of blocked habitat upstream of Iron Gate dam by enhancing the viability of the Upper Klamath coho salmon population;
- Enhance coho salmon spawning habitat downstream of Iron Gate dam;
- Improve instream flow conditions for coho salmon downstream of Iron Gate dam;
- Improve water quality for coho salmon downstream of Iron Gate dam;
- Reduce disease incidence and mortality in juvenile coho salmon downstream of Iron Gate Dam;
- Enhance migratory and rearing habitat for coho salmon in the Klamath River mainstem corridor; and
- Enhance and expand rearing habitat for coho salmon in key tributaries.

These goals are accompanied by specific biological objectives and measures, which are detailed in the HCP.

Finalized in 2004 and valid through 2054, the Humboldt Bay Municipal Water District's Habitat Conservation Plan (HBMWD 204) addresses the impacts of HBMWD's Mad River operations on coho salmon, Chinook salmon, and steelhead. Activities covered under the HCP include:

- Flow release and management activities;
- Diversion activities in the Essex Reach of the Mad River;
- Maintenance activities, including repair of existing structures if damaged; and
- Periodic excavation and fill activities.

The primary benefit to coho salmon described in the HCP is augmented baseflow in the Mad River during the dry season.

3.2.10 Invasive/Non Native/Alien Species

Invasive or non-native alien species pose a high or very high threat to seven of 40 populations in the SONCC coho salmon ESU (Table 3-8, Chapters 7 to 46). Sacramento pikeminnow are prevalent throughout much of the Eel River basin and have recently been discovered in Martin Slough, a tributary to Elk River in Humboldt Bay; and brown trout have been observed in the Upper and Lower Trinity River (CDFG 1997, Waters 1983, Dewald and Wilzbach 1992, Wang and White 1994, McHugh and Budy 2006). Both species reduce native coho salmon populations by increasing competition for food resources, increasing predation on juveniles, and utilizing less than desirable water quality conditions to flourish and become more abundant, out-competing native salmonids. The effects of these species are explained under Section 3.1.4 (increased disease, predation, and competition). Additionally, recent reports have shown that the New Zealand mud snail has been observed in Redwood Creek (Benson, K., pers. comm. 2010), although little if any information exists on the effects that these animals have on local salmonids.

Reed canary grass is an invasive non-native perennial grass that was not identified as a threat at the time of SONCC coho salmon federal listing. The grass prohibits native riparian growth, chokes stream channels, provides poor to non-existent habitat for fish and other native aquatic wildlife, inhibits the mobility of fish at lower flows, increases sedimentation, contributes to low levels of dissolved oxygen, and causes overbank flooding during winter and spring base flow conditions (Miller et al. 2008). Over 150 adult unspawned coho salmon were found dead in a field dominated by reed canary grass, likely stranded by the dense reed canary grass when high flows receded quickly in an ill-defined channel (Carrasco 2000). The invasive grass is found throughout southern Oregon and northern California and is a threat to SONCC coho salmon and their habitat. Overall, the threat of reed canary grass has increased since the last status review.

Some basins in the SONCC coho salmon ESU, including Hunter, Strawberry, and Norton/Widow White creeks, have extensive residential development in their lower floodplains and riparian areas. In these areas, it is likely that invasive plant species will spread from residential landscaping into riparian areas, particularly if there are pre-existing gaps in the riparian vegetation. Some of these species could impede restoration of riparian forests and wetlands. The extent to which this has already occurred is unknown.

3.2.11 Hatcheries

Hatcheries can pose a significant threat to populations where they occur in the SONCC coho salmon ESU. As discussed in Section 3.1.1, hatcheries and the introduction of hatchery fish into wild populations can have direct and indirect effects on wild, native fish populations. More information regarding hatcheries can be found under adverse hatchery related effects in the above-mentioned stress section.

3.2.12 Fishing and Collecting

Fisheries Harvest Management

Significant changes in fisheries harvest management have occurred in recent decades, resulting in substantial reductions in harvest of SONCC coho salmon. Currently, fishing-related incidental mortality of SONCC coho salmon occurs primarily from hooking and handling in Chinook-directed commercial and recreational fisheries off the coasts of California and Oregon. Incidental hooking and handling mortality occurs in the mark-selective hatchery coho salmon fishery in the Rogue River, and also in Chinook and steelhead-directed fresh water fisheries in both Oregon and California

In establishing fishing seasons and regulations each year, the Pacific Fishery Management Council (PFMC) considers the potential impacts on various ESA-listed stocks within the region. Because there are no data on exploitation rates on wild SONCC coho salmon, Rogue and Klamath (R/K) hatchery stocks have traditionally been used as a fishery surrogate stock for estimating exploitation rates on SONCC coho. The annual coho salmon exploitation rate averaged approximately 5% from 2000 to 2013, with a maximum exploitation rate of approximately 10% in 2003 to a low of 1.6% in 2008. California's statewide prohibition of coho salmon retention maintains consistently low impacts from freshwater recreational fisheries on SONCC coho salmon.

Collection for Research Purposes

NMFS authorizes scientific collection activities through ESA section 10(a)(1)(A) research permits and ESA section 4(d) programs. The authorized activities must not operate to the disadvantage of the listed species and must provide a bona fide and necessary or desirable scientific purpose or enhance the propagation or survival of the listed species. In addition, NMFS must determine whether the scientific collection is likely to jeopardize the continued existence of any listed species or result in the destruction or adverse modification of critical habitat. These provisions ensure the threat from collection activities is low for all populations.

More information about the effects of fishing and collecting can be found in Section 3.1.10.

3.2.13 Inadequate Regulatory Mechanisms

Inadequate regulatory mechanisms were identified as a factor when SONCC coho salmon were listed in 1997, and the problems associated with these regulations continues to hinder salmon recovery. The set of regulatory mechanisms that will govern recovery of this species span a full range of protective strengths and weaknesses and provide a varying degree of protection for populations in the SONCC coho salmon ESU. Since 1997, many regulatory mechanisms that were originally cited as being inadequate have been strengthened in their ability to protect coho salmon and their habitat. In addition, many new management plans and programs have been implemented that either directly or indirectly benefit coho salmon. However, because of the lack of coordination in implementation and management, some regulations are not fully implemented or monitored for compliance and therefore do not provide adequate, or even minimal protection. In addition, there is an overall lack of regulations to fully address the range and magnitude of current and future threats to recovery. As discussed below, the regulatory landscape in which recovery will take place has both strengths and weaknesses in terms of its ability to protect and restore SONCC coho salmon and habitat.

Although some of the current land and resource management policies in place are specifically designed to protect SONCC coho salmon and their habitat (e.g., Federal and State Endangered Species Acts), many are designed for other purposes and only indirectly protect the species (e.g., state forest practice rules). Several federal and state land management regulations and acts have been enacted to protect and preserve public lands for current and future public use, and to ensure that these lands are held in good condition, and species utilizing these lands are protected to ensure continued survival. Additionally, many federal and state regulations and acts aid in the protection of private lands and also work towards the protection of salmonids and other species not protected under state and federal laws for public lands. These regulatory mechanisms are in place to control and regulate mining activities, timber harvesting, instream dredging and construction, and urban growth. Many aspects of these regulations are regulated and monitored by both Federal and State agencies, and may apply to both public and private lands in both Oregon and California. Several inadequate regulatory mechanisms identified in the final rule listing the SONCC Coho Salmon ESU (62 FR 24588, 24596-24598; May 6, 1997) are discussed elsewhere in this chapter: Northwest Forest Plan (Section 3.2.5), State Forest Practices (Section 3.2.5), Water Quality Programs (Section 3.1.2), State Agricultural Practices (Section 3.2.4), Harvest Management (Section 3.2.12), and Hatchery Management (Section 3.2.11).

Dredge, Fill, and In-water Construction Programs

The Army Corps of Engineers (ACOE) regulates removal/fill activities under section 404 of the Clean Water Act (CWA) (see http://www.epa.gov/OWOW/wetlands/laws/). When listing the SONCC coho salmon ESU under the ESA, NMFS noted that ACOE did not have a method to adequately assess the cumulative effects in issuing permits for removal/fill activities under CWA section 404 (62 FR 24588, 24596; May 6, 1997). Although currently the ACOE requires an evaluation of cumulative impacts from these permits, the effectiveness of such evaluations at preventing cumulative impacts is unknown. Similarly, the section 401 water quality certification program, which is regulated by the states of California and Oregon, applies only to activities that require a federal permit or license (i.e., 404 permit or FERC license, respectively). Because the 401 certification requirements depend on the initiation of the 404 permitting or FERC licensing process, the 401 program also does not address exclusively upland activities. Therefore, the lack of review and jurisdiction for upland activities limits the ability of the 404 and 401 regulatory programs to provide adequate protection for coho salmon and its habitat.

California Endangered Species Act

In 2005, the state of California listed coho salmon between Punta Gorda and the Oregon border as threatened. The California listing protects coho salmon from direct take, and helps to ensure that projects or activities that have incidental adverse effects to coho salmon are reviewed and take is mitigated. In connection with the California state listing, a coho salmon recovery strategy was formally approved and adopted by the California Fish and Game Commission on February 4, 2004 (CDFG 2004a). The recovery strategy includes over 700 conservation recommendations covering a wide variety of land use activities, and over 200 more related to agricultural practices within the Scott and Shasta rivers, tributaries to Klamath River. To facilitate implementation, the CDFG has integrated the recovery strategy with the Fisheries Restoration Grant Program (FRGP). Currently the recovery plan is being implemented throughout the California portion of the ESU and a 5-year progress report is under development. Limited funding and staff have impacted the state's ability to fully implement the plan in recent years.

Federal Endangered Species Act Protections

The major provisions of the Endangered Species Act of 1973, as amended,16 U.S.C. § 1531 et seq., set forth eligibility and procedural requirements for listing species as endangered or threatened, provide protections for those listed species, require Federal agencies to ensure that their actions are not likely to jeopardize listed species or result in the destruction or adverse modification of their designated critical habitat without special exemption, and create a framework for cooperation with states to conserve listed species and their habitat. The most direct mechanism for protection under the ESA is the section 9 take prohibition. Section 7(a)(1) makes it clear that Federal agencies must utilize their authorities in furtherance of the purposes of the ESA by carrying out programs for the conservation of endangered species and threatened species. Although Federal agencies have an affirmative obligation to conserve, an agency's 7(a)(1) actions are discretionary and priorities are often obligated to other management objectives.

Section 7(a)(2) states, in part, "[e]ach Federal agency shall, in consultation with and with the assistance of the Secretary [of Interior or Commerce, as appropriate], insure that any action authorized, funded, or carried out by such agency…is not likely to jeopardize the continued existence of any endangered species or threatened species or result in the destruction or adverse modification of [critical] habitat of such species...unless such agency has been granted an exemption for such action by the Committee pursuant to subsection (h) of this section." Since the time of listing, NMFS has conducted over 1,000 consultations on the effects of Federal actions on SONCC coho salmon and their critical habitat, including major projects on the Rogue, Trinity, Klamath, and Eel rivers. Interagency consultation, including technical assistance and section 7 consultations (both informal and formal) have often reduced or eliminated adverse effects to SONCC coho salmon, their designated critical habitat, or both.

Section 10(a)(1)(B) of the ESA allows NMFS to issue permits to non-Federal parties for incidental take of listed species, as long as, among other requirements, the impacts of the taking are minimized and mitigated to the maximum extent practicable and the taking will not appreciably reduce the likelihood of the survival and recovery of the species in the wild. Neither section 7(a)(2) consultations nor section 10 permits are intended to require Federal agencies or permit holders to contribute to the recovery of listed species. However, in section 7(a)(2) consultations and in issuance of section 10(a)(1)(B) permits, the action or taking must not appreciably reduce the likelihood of survival and recovery of the listed species in the wild. Further, in biological opinions, NMFS frequently provides discretionary conservation recommendations, which, if implemented, would assist the action agency in meeting its section 7(a)(1) responsibilities.

Whenever a species is listed as threatened under the federal ESA, section 4(d) authorizes the Secretary to issue regulations as he deems necessary and advisable to provide for the conservation of such species, including taking prohibition or limitation of the taking prohibition for certain identified activities.

3.2.14 Ocean Conditions

Poor ocean conditions have played a prominent role in the decline of coho salmon in California and Oregon and will greatly influence the ability to recover SONCC coho salmon. In general, coho salmon marine survival is about 10 percent (Bradford 1995), although there is a wide range in survival rates (from less than one percent to about 21 percent) depending upon population location and ocean conditions (Beamish et al. 2000, Quinn 2005). Marine survival and successful return as adults to spawn in natal streams is critically dependent on an individual's first few months at sea (Peterman 1982, Unwin 1997, Ryding and Skalski 1999, Koslow et al. 2002). In addition, large smolts have higher ocean survival than small smolts (Bilton et al. 1982, Henderson and Cass 1991, Lum 2003, Quinn 2005, Jokikokko et al. 2006, Muir et al. 2006). In addition, larger smolts produce larger adults (Lum 2003, Henderson and Cass 1991), which have higher fecundity than smaller adults (Weitkamp et al. 1995, Fleming 1996, Heinimaa and Heinimaa 2004).

The ocean upwelling process (and resulting productivity) is important to the growth and survival of juvenile salmonids in the upwelling zone off the west coast (Nickelson 1986; Fisher and Pearcy 1990; Pearcy 1992; Logerwell et al. 2003). Two aspects of upwelling are of greatest importance to juvenile salmonids during their first summer at sea: the strength of upwelling (Nickelson 1986) and the starting date of the upwelling season, also called the date of spring transition (Logerwell et al. 2003). Upwelling-supported zooplankton production correlates well with juvenile salmon survival (Ruzicka et al. 2011).

For Pacific salmon, the conditions of the waters in the California Current are a key to understanding ocean survival. Differences from year to year in both the source of waters that feed the California Current and the volume of water transported each year seem to be controlled by the phase of the Pacific Decadal Oscillation (PDO) (Jacobson et al 2012). The PDO is a spatial pattern in sea surface temperature seen across the entire Northern Pacific Ocean. When the PDO was first described by Mantua el al. (1997) it was noted that the phase of the PDO shifted on a decadal time scale. Since 1998, the phase of the PDO has oscillated with a much higher frequency of about five years. Recently the frequency of the oscillation appears to have increased again, with a two-year cool phase from 2008 to 2009 followed by one warm phase year (mid-2009 – mid 2010) and one cool year (mid-2010 -2011). Jacobson et al. (2012) has used this extreme variability to compare the response of juvenile salmon to a large variety of ocean conditions. New research suggests that the mechanistic link between PDO and salmon growth and survival is due to shifts at the base of the food chain between lipid-poor and lipid-rich plankton communities. These changes in the food chain lead to changes in feeding conditions for salmon and forage fishes (Peterson and Keister 2003; Peterson and Schwing 2003; Peterson and Hooff 2005; Hoof and Peterson 2006; Daly et al. 2010; Litz et al. 2010; Keister et al. 2011; Bi et al. 2011)

When PDO is in a negative (cold) phase, boreal, lipid-rich cold-water copepod species dominate the lower trophic levels in the California Current. When the PDO is in positive (warm) phase, warm water and lipid-poor copepod species become important in the Northern California Current and in some years dominate. Shifts in the PDO also result in other changes in the coastal food web (Jacobson et al 2012). Warm ocean conditions associated with the positive-phase PDO result in changes in the abundance of fish predators and fish prey in coastal waters of the Northern California Current. Adult and juvenile hake move up the shelf waters during warm ocean periods, resulting in increased predation on juvenile salmon (Emmett and Krutzikowsky 2008). Forage fishes (anchovy and smelts), which as juveniles are prey of juvenile salmonids, tend to be less abundant during warm ocean conditions (Emmett et al. 2006; Emmett and Sampson 2007). Thus, the PDO may affect the survival of salmon through both its effects at the base of the food web as well as on salmon predators at higher trophic levels.

Pacific salmon sustain heavy and highly variable losses in the ocean, with natural mortality rates often exceeding 90-95% (Bradford 1995). Most of this mortality is thought to occur in coastal marine ecosystems during two critical periods: an early period of predation-based mortality that occurs within the first few weeks or months of ocean entry, and a later period of starvation-based mortality that occurs following the first winter at sea (Beamish and Mahnken 2001).

Both predation- and starvation-based mortality are size-dependent (Willette et al. 2001; Hurst 2007). Therefore, ocean conditions that lead to slower growth likely increase mortality during these critical periods of marine life, thereby reducing adult returns (Pearcy 1992; Beamish et al. 2004). Slower marine growth may also reduce the ability of adult salmon to complete their spawning migration (Crossin et al. 2004). Production in freshwater and riparian ecosystems may consequently be reduced through a reduction in marine-derived nutrients (Cederholm et al. 1999, Kiffney et al. 2014). Moreover, smaller adult fish tend to produce smaller eggs and fry, which are more vulnerable to predation than larger cohorts (Ruggerone and Rogers 1993; Quinn et al. 2004). In multiple populations of coho salmon Jacobson et al (2012) found a positive and significant relationship between marine growth and adult abundance, providing strong evidence that variation in marine productivity directly controls marine abundance of salmon. Furthermore, the data suggest that estimates of juvenile salmon growth soon after ocean entry may be used to estimate adult salmon returns.

Changes in the marine environment over the past decade demonstrate the impacts that changing ocean conditions can have on coho salmon populations (Beamish et al. 2000, Logerwell et al. 2003). For at least two decades, beginning about 1977, marine productivity conditions were unfavorable for the majority of salmon populations in the Pacific Northwest. Recent data from across the range of coho salmon on the coast of California and Oregon reveal there was a 72 percent decline in returning adults in 2007/08 compared to the same cohort in 2004/05 (MacFarlane et al. 2008). The Wells Ocean Productivity Index, a measure of Central California ocean productivity, revealed poor conditions during the spring and summer of 2006, when juvenile coho salmon from the 2004/05 cohort entered the ocean (MacFarlane et al. 2008). Poor ocean productivity can be especially detrimental to coho salmon along the Oregon and California coast, because these regions lack extensive bays, straits, and estuaries which could buffer adverse oceanographic effects (Bottom et al. 1986).

3.2.15 Stochastic Pressure from Small Population Size

A recent development in the field of conservation biology is the hypothesis that random events in small populations may have a large impact on population dynamics and population persistence.

The peril that small populations face may be either deterministic (the result of systematic forces that cause population decline such as overexploitation, development, deforestation, loss of pollinators, inability to find mates, or inability to defend against predators) or stochastic (the result of random fluctuations that have no systematic direction). These forces have been shown to reduce population size, and when populations are reduced to very low densities, they can experience reduced rates of survival and reproduction (Allee 1938, Wood 1987). Over the long term, a series of unlucky generations in which there are successive declines in population size can lead to extinction even if the population is growing, on average.

Most independent populations in the SONCC coho salmon ESU have declined in numbers to below the depensation threshold and are therefore being influenced by stochastic (random natural) processes that may make recovery of the ESU more difficult than currently thought (CDFG 2004a). As natural populations get smaller, the number of interacting stochastic processes that influence the population increases. These stochastic processes can create alterations in genetics, breeding structure, and population dynamics that may interfere with recovery efforts and need to be considered when evaluating how populations within the ESU are going to respond to recovery actions. This stochastic pressure can express itself in three ways: genetic, demographic and environmental.

Genetic stochasticity refers to changes in the genetic composition of a population that are unrelated to systematic forces (selection, inbreeding, or migration, i.e., genetic drift). Genetic stochasticity can have a large impact on the genetic structure of populations, both by reducing diversity within populations and by increasing the chance that deleterious recessive alleles are expressed. When populations are at levels below depensation, stochasticity can make both population viability and survival difficult to predict, due to the random variables that are now acting on the population. These processes, when working together, can cause reduced genetic diversity in a population (or populations), further decreases in population size, or shifts in life-history traits. Reduced diversity could limit a population's ability to respond adaptively to future environmental changes. In addition, the increased frequency with which deleterious recessive alleles are expressed (because of increased homozygosity) could reduce the viability and reproductive capacity of individuals.

Demographic stochasticity refers to the variability in population growth rates arising from random differences among individuals in survival and reproduction within a season. This variability will occur even if all individuals have the same expected ability to survive and reproduce and if the expected rates of survival and reproduction don't change from one generation to the next. Even though it will occur in all populations, it is generally important only in populations that are already fairly small. Environmental stochasticity is the type of variability in population growth rates that refers to variation in birth and death rates from one season to the next in response to weather, disease, competition, predation, ocean conditions, or other factors external to the population.

In these small populations, recovery from low densities may be significantly delayed or not occur at all and the populations may suffer a decrease in population growth rate. This reduced population growth rate at low densities is also known as depensation (Liermann and Hilborn 2001). Many mechanisms can lead to depensation, and depensatory effects are usually displayed through changes in the following mechanisms: reduced probability of fertilization, impaired group dynamics, conditioning of the environment, and predator saturation (Liermann and Hilborn 2001). A population's dynamics are depensatory if the growth rate decreases along with density or abundance decreasing to low levels. Components of the life-history, such as fecundity or survival, or the mechanisms that affect these components, are called depensatory if they decrease the growth rate along with density or abundance. At extremes, these depensatory dynamics have negative population growth rates at low densities and are called critical depensation (Clark 1985). The critical density at which the per-individual growth rate becomes negative is of particular interest, since populations reduced below this density face further decline and possibly extinction (Liermann and Hilborn 2001). The ability to recognize when populations are entering or are in a depensatory state is therefore vitally important in the efforts leading to recovering a species. Recognizing when depensation is occurring has proven to be difficult; current research utilizing parametric statistical analyses is now used to help better understand the population dynamics occurring in these small populations.

Stochastic processes are likely influencing populations throughout the SONCC ESU. These processes and pressures should be taken into account when prioritizing watersheds and associated recovery actions to ensure that efforts made to recover extremely small populations are successful, and that other processes are not hindering or defeating recovery efforts. These processes, while not serious when acting alone, can become significant contributors to population instability and decline when acting synergistically with other threatening processes. It may be difficult to know when additional stochastic factors are playing a role in a population's recovery and viability, and so including, where possible, statistical population models to determine current pressures and threats is needed. Models like the Population Viability Analysis (PVA) have been shown to be extremely useful in obtaining a better understanding of the processes and pressures that are affecting small populations like those seen in the SONCC coho salmon ESU.

4. Recovery Goals, Objectives, and Criteria

The following goals guide recovery of SONCC coho salmon as described in recovery documents from the State of Oregon, the State of California, and NMFS.

First, the populations must reach desired levels of biological viability and the recovery effort must sufficiently reduce the impact of the stresses and threats in order to warrant removal of the SONCC coho salmon ESU from the threatened and endangered species list (referred to in this plan as either delisting or ESA recovery). Section 4.1 describes the recovery goals and criteria.

Second, the States of California and Oregon seek to rebuild wild populations to reach 'broad sense recovery' to provide for sustainable fisheries and other ecological, cultural, and social benefits. Section 4.2 describes broad sense recovery goals.

4.1 ESA Recovery Goals

The goal of this recovery plan is to recover the Southern Oregon/Northern California Coast Coho Salmon (*Oncorhynchus kisutch*) ESU to the point where the species is viable and so no longer needs the protections afforded by the federal ESA and can be removed from the ESA threatened and endangered species list. A viable SONCC coho salmon ESU is naturally self-sustaining, with a low risk of extinction. Recovery of SONCC coho salmon requires a viable ESU and a sufficient reduction in the factors that contributed to the need for the protections of the ESA, which are reflected in the stresses and threats; both elements are assessed against recovery criteria. The specific recovery objectives and criteria are provided below.

Delisting criteria are objective, measurable criteria that, when met, would result in a determination by NMFS that the ESU is not endangered and is not likely to become endangered within the foreseeable future throughout all or a significant portion of its range. The delisting criteria for biological parameters are the biological recovery criteria, and the delisting criteria that address listing factors are the stress and threat criteria. As new information emerges, NMFS may revisit the delisting criteria through the status review process, described in Chapter 6.

4.1.1 Recovery Objectives

Chapter 2 describes the biological characteristics of an ESU that is at low risk of extinction (viable). Chapter 4 describes the criteria to be met by each population to reach lower risks of extinction, and to achieve a viable ESU. Section 4.1.2 lists the biological recovery objectives and criteria that describe the desired characteristics of the populations that make up the ESU. The stress and threat criteria that describe when these factors will be sufficiently addressed are described in Section 4.1.3.

Recovery criteria can be viewed as the targets, or values, by which progress toward recovery objectives can be measured. We identify what a species' populations, habitat, stresses, and threats are expected to look like when the species is recovered so that we will be better able to determine how far the species needs to move to reach those objectives, and the actions needed to achieve each objective.

4.1.2 Biological Recovery Objectives and Criteria

Biological Recovery Objectives

NMFS developed biological objectives based on ESU and population viability metrics established by Williams et al. (2008). At the ESU level, SONCC coho salmon must demonstrate representation, redundancy, and connectivity (Williams et al. 2008). Representation relates to the genetic and life-history diversity of the ESU, which is needed to conserve its adaptive capacity. Redundancy addresses the need to have a sufficient number of populations so the ESU can withstand catastrophic events. Connectivity refers to the dispersal capacity of populations to maintain long-term demographic and genetic processes.

At the population level, biological recovery objectives are based on the viable salmonid population (VSP) parameters (McElhany et al. 2000). Each SONCC coho salmon population must achieve sufficient abundance, growth rates, spatial structure, and diversity. However, the minimum needed conditions for each population vary depending on each population’s role in recovery as described in this recovery plan (Figure 4-1). Spawner abundance is an important parameter because, all else being equal, small populations are at greater risk of extinction than larger populations. Large populations are generally better able to withstand the detrimental effects of environmental variation, genetic processes, demographic stochasticity, ecological feedback, and catastrophes than small populations (Shaffer 1981). Productivity describes the growth rate of a population. Spatial distribution is important to reduce extinction risks from genetic risks and demographic stochasticity. A population’s spatial distribution depends on habitat quality (including accessibility), population dynamics, and dispersal characteristics of individuals in the population. Genetic and life-history diversity allows species to adapt to a variety of environments that provide for the needs of the species and protect against short-term environmental change while also providing the genetic material necessary to survive environmental change.

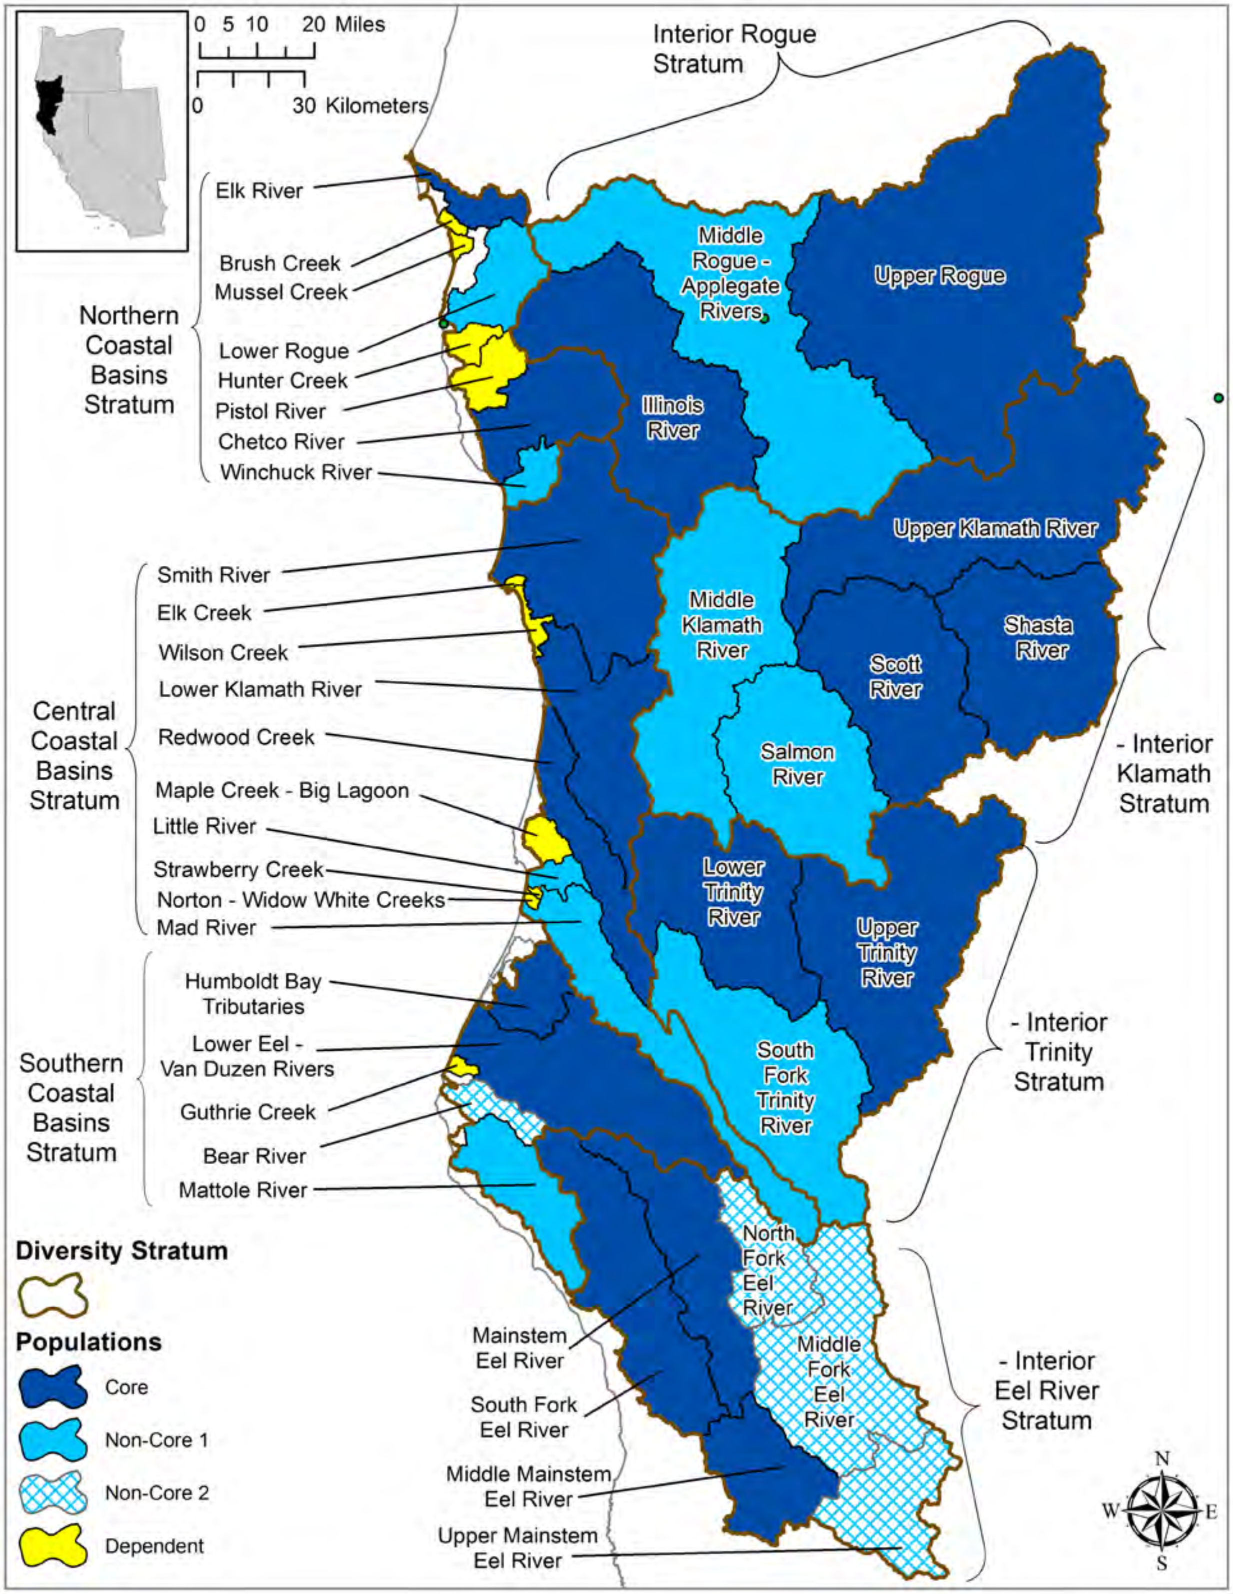

Figure 4-1. Core, non-core, and dependent populations within diversity strata of the SONCC coho salmon ESU.

Biological Recovery Criteria

The biological recovery criteria for each population type are described in Table 4-1 and the specific abundance criterion to be met by each population is shown in Table 4-2. The biological recovery criteria described in this section reflect NMFS' opinion of how to best achieve a viable ESU most quickly. **In a recovered ESU, biological recovery criteria for all four parameters (abundance, productivity, spatial structure, and diversity) must be met** [Emphasis added].

Each population plays a role in recovery, and NMFS identifies four categories of populations as described in Chapter 2: Core, Non-Core 1, Non-Core 2, and Dependent. Core populations are independent populations that are likely to respond to recovery actions and achieve a low risk of extinction[7] most quickly[8]. All but four of the remaining independent populations are categorized as "Non-Core 1". In a recovered ESU, these Non-Core 1 populations will be at least at a moderate risk of extinction. The remaining four Independent populations are categorized as "Non-Core 2", as their populations are thought to be extirpated. In a recovered ESU, Non-Core 2 and Dependent populations will support emigrants from other populations. Figure 4-1 shows the category assigned to each population. Table 4-1 and Table 4-2 describe the recovery objectives and criteria for each population category.

[7] Excluding the areas above some dams; see footnote 3 in Table 4-1.

[8] The rationale for choice of core populations is described in Appendix C.

Table 4-1. Biological recovery objectives and criteria for SONCC coho salmon. All biological recovery criteria must be met in a recovered ESU.

VSP Parameter	Population Role	Biological Recovery Objective	Biological Recovery Criteria[1]
Abundance	Core	Achieve a low risk of extinction[2]	The geometric mean of wild adults over 12 years meets or exceeds the "low risk threshold" of spawners for each core population[2,3,4]
	Non-Core 1	Achieve a moderate or low risk of extinction[2]	The annual number of wild adults is greater than or equal to four spawners per IP-km for each non-core population[2]
Productivity	Core and Non-Core 1	Population growth rate is not negative	Slope of regression of the geometric mean of wild adults over the time series ≥ zero[4]
Spatial Structure	Core and Non-Core 1	Ensure populations are widely distributed	Annual within-population juvenile distribution ≥ 80%[4] of habitat[5,6] (outside of a temperature mask[7])
	Non-Core 2 and Dependent	Achieve inter- and intra-stratum connectivity	≥ 80% of accessible habitat[4] is occupied in years[8] following spawning of cohorts that experienced high marine survival[9]
Diversity	Core and Non-Core 1	Achieve low or moderate hatchery impacts on wild fish	Proportion of hatchery-origin adults (pHOS) < 0.05
	Core and Non-Core 1	Achieve life-history diversity	Variation is present in migration timing, age structure, size and behavior. The variation in these parameters[10] is retained.

[1] All applicable criteria must be met for each population in order for the ESU to be viable.
[2] See Table 4-2 for specific spawner abundance requirements needed to meet this objective.
[3] In the Shasta River, Upper Trinity River, and Upper Rogue River populations, IP above some anthropogenic dams was excluded from the spawner target, so the low-risk threshold for these populations is based on the IP downstream of those dams.
[4] Assess for at least 12 years, striving for a coefficient of variation (CV) of 15% or less at the population level (Crawford and Rumsey 2011).
[5] Based on available rearing habitat within the watershed (Wainwright et al. 2008). For purposes of these biological recovery criteria, "available" means accessible. 80% of habitat occupied relates to a truth value of +1.0,(true: juveniles occupy a high proportion of the available rearing habitat within the watershed (p. 56, Wainwright et al. 2008).
[6] The average for each of the three year classes over the 12 year period used for delisting evaluation must each meet this criterion. Strive to detect a 15% change in distribution with 80% certainty (Crawford and Rumsey 2011).
[7] Williams et al. (2008) identified a threshold air temperature, above which juvenile coho salmon generally do not occur, and identified areas with air temperatures over this threshold. These areas are considered to be within the temperature mask.
[8] If young-of-year are sampled, sampling would occur the spring following spawning of the cohorts experiencing high marine survival. If 1+ juveniles are sampled, sampling would occur approximately 1.5 years after spawning of the cohorts experiencing high marine survival, but before outmigration to the estuary and ocean.
[9] High marine survival is defined as 10.2% for wild fish and 8% for hatchery fish; Sharr et al. 2000. If marine survival is not high, then this criterion does not apply.
[10] This variation is documented in the population profiles in Chapters 7 to 46 of this plan.

Table 4-2. The minimum number of spawners (male and female) needed in each population to meet the biological recovery criteria.

Diversity Stratum	Independent Population	Population Role	Minimum Number of Spawners[1]
Northern Coastal Basins	Elk River	Core	2,400
	Brush Creek	Dependent	None- Juv. Occupancy
	Mussel Creek	Dependent	None- Juv. Occupancy
	Lower Rogue River	Non-Core 1	320
	Hunter Creek	Dependent	None- Juv. Occupancy
	Pistol River	Dependent	None- Juv. Occupancy
	Chetco River	Core	4,500
	Winchuck River	Non-Core 1	230
Interior Rogue River	Illinois River	Core	11,800
	Middle Rogue and Applegate rivers	Non-Core 1	2,400
	Upper Rogue River	Core	13,800
Central Coastal Basins	Smith River	Core	6,800
	Elk Creek	Dependent	None- Juv. Occupancy
	Wilson Creek	Dependent	None- Juv. Occupancy
	Lower Klamath River	Core	5,900
	Redwood Creek	Core	4,900
	Maple Creek/Big Lagoon	Dependent	None- Juv. Occupancy
	Little River	Non-Core1	140
	Strawberry Creek	Dependent	None- Juv. Occupancy
	Norton/Widow White Creek	Dependent	None- Juv. Occupancy
	Mad River	Non-Core 1	550
Interior Klamath River	Middle Klamath River	Non-Core 1	450
	Upper Klamath River	Core	8,500
	Salmon River	Non-Core 1	450
	Scott River	Core	6,500
	Shasta River	Core	4,700
Interior Trinity River	Lower Trinity River	Core	3,600
	Upper Trinity River	Core	5,800
	South Fork Trinity River	Non-Core 1	970
Southern Coastal Basins	Humboldt Bay tributaries	Core	5,700
	Lower Eel and Van Duzen rivers	Core	7,900
	Guthrie Creek	Dependent	None- Juv. Occupancy
	Bear River	Non-Core 2	None- Juv. Occupancy
	Mattole River	Non-Core 1	1,000
Interior Eel River	South Fork Eel River	Core	9,300
	Mainstem Eel River	Core	2,600
	Middle Fork Eel River	Non-Core 2	None- Juv. Occupancy
	North Fork Eel River	Non-Core 2	None – Juv. Occupancy
	Middle Mainstem Eel River	Core	6,300
	Upper Mainstem Eel River	Non-Core 2	None- Juv. Occupancy

[1]See Table 4-1 for biological recovery criteria. Abundance estimates should strive for a CV of 15 percent or less at the population level (Crawford and Rumsey 2011).

High Risk Spawner Threshold

If only a single spawner were present in a 1-mile reach within a population, the salmon population as a whole would likely to face significant demographic risks such as difficulties in finding mates (Wainwright et al. 2008). Therefore, Williams et al. (2008) chose 1 spawner per mile density as the high risk (depensation) threshold and converted the density into IP-km for the SONCC coho salmon ESU, which is approximately 1 spawner per IP-km.

Moderate Risk Spawner Threshold

Because one spawner per IP-km is the depensation threshold, Williams et al. (2008) identified the minimum spawner density needed to achieve a moderate risk of extinction as any number greater than 1 adult per IP-km (Table 4-3). To provide a reasonable buffer against falling below the threshold, the abundance criterion for Non-Core 1 populations is set at four spawners per IP-km (Table 4-1). Four spawners per IP-km was chosen based on the following rationale.

Other authors have identified a number of spawners per IP-km below which depensation occurs, and these numbers of spawners are typically much higher than that chosen by Williams et al. (2008; Table 4-3). Wainwright et al. (2008) considered a population with value of 4.2 spawners/IP-km to have an uncertain probability of incurring depensation, a value similar to that of Sharr et al. (2000) and Chilcote (1999). Barrowman et al. (2003) note that there is little evidence for depensation in coho salmon, unless less than one female per kilometer of river returned to spawn. Parameter estimates for the upper 95% confidence interval presented in Barrowman et al. (2003) are given in Table 4-3. NMFS chose 4 spawners per IP-km as the moderate risk target, because according to Sharr et al. (2000), four spawners per IP-km would translate into an extinction risk of approximately 10% over four generations (Table 4-3 and Figure 4-2).

Table 4-3. Depensation levels identified by various authors. Results are standardized to IP-km.

Reference	Value below which depensation occurs
Barrowman et al. (2003) 95% Upper CI Type 2 Beverton-Holt Model	2.26 spawners/IP-km
Barrowman et al. (2003) 95% Upper CI Type 2 Logistical Hockey Stick Model	1.6 spawners/IP-km
Sharr et al. (2000)	4.2 spawners/IP-km
Chilcote (1999)	4.1 spawners/IP-km

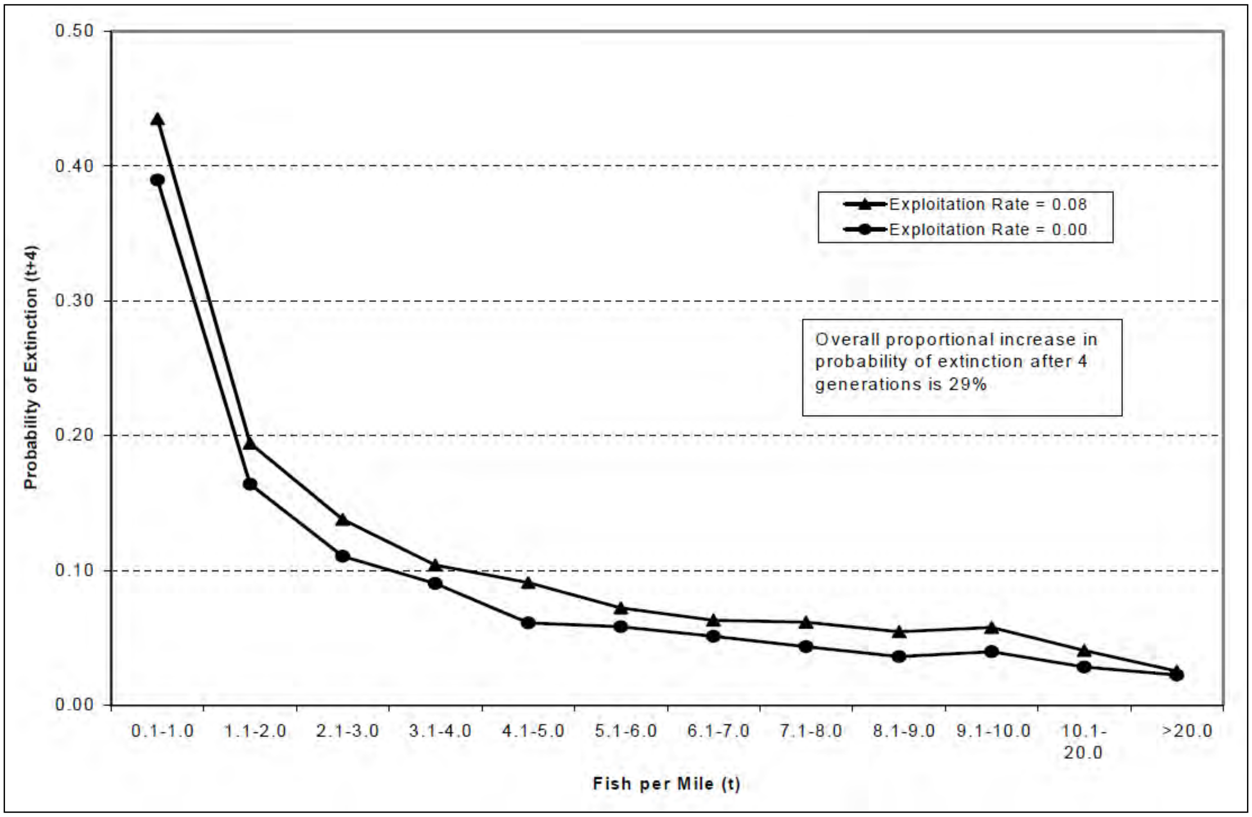

Figure 4-2. Probability of basin level extinction in four generations as a function of spawner density. For fishery exploitation rates of 0.0 and 0.8 in all Oregon coastal basins combined. Source: Sharr et al. (2000).

Low-Risk Spawner Threshold

As shown in Table 4-1, the biological recovery criterion for Core population abundance is the low-risk threshold, which is the number of IP-km multiplied by the applicable spawner density used by Williams et al. (2008; Figure 4-3). Spawner density is based primarily on Bradford et al.'s (2000) finding that an average density of 19 females/km is required to fully seed freshwater habitats with juveniles. Assuming males generally outnumber females (Jensen and Hyde 1971, Spindle et al. 1998, Holtby and Healey 1990, Nickelson 2001), Williams et al. (2008) approximated 19 females/km to be equivalent to 40 spawners/km. Because IP-km is weighted, one km of habitat averages to about 0.6 IP-km. Therefore 40 spawners/km is approximately equal to an average of 66 spawners/IP-km.

Williams et al. (2008) may have used 40 spawners/IP-km as the density to fully seed juveniles in freshwater habitat and to establish the low-risk threshold for populations, as opposed to 66 spawners/IP-km, in order to avoid overestimating the historical spawner abundance. Williams et al. (2008) decreased the spawner density requirement to a minimum of 20 spawners/IP-km for larger watersheds based on their assumption that larger populations can diverge farther from historical conditions before extinction risk is substantially increased. A population with ten times more habitat potential (i.e., IP-km >340) than the smallest population will likely require an average spawner density of half that of the smallest population (Williams et al. 2008), and populations between these two sizes required spawner densities linearly between the two reference points (Williams et al. 2008). This approach establishes a population-specific abundance that is scaled to the amount of potential habitat and avoids the use of fixed abundance criteria.

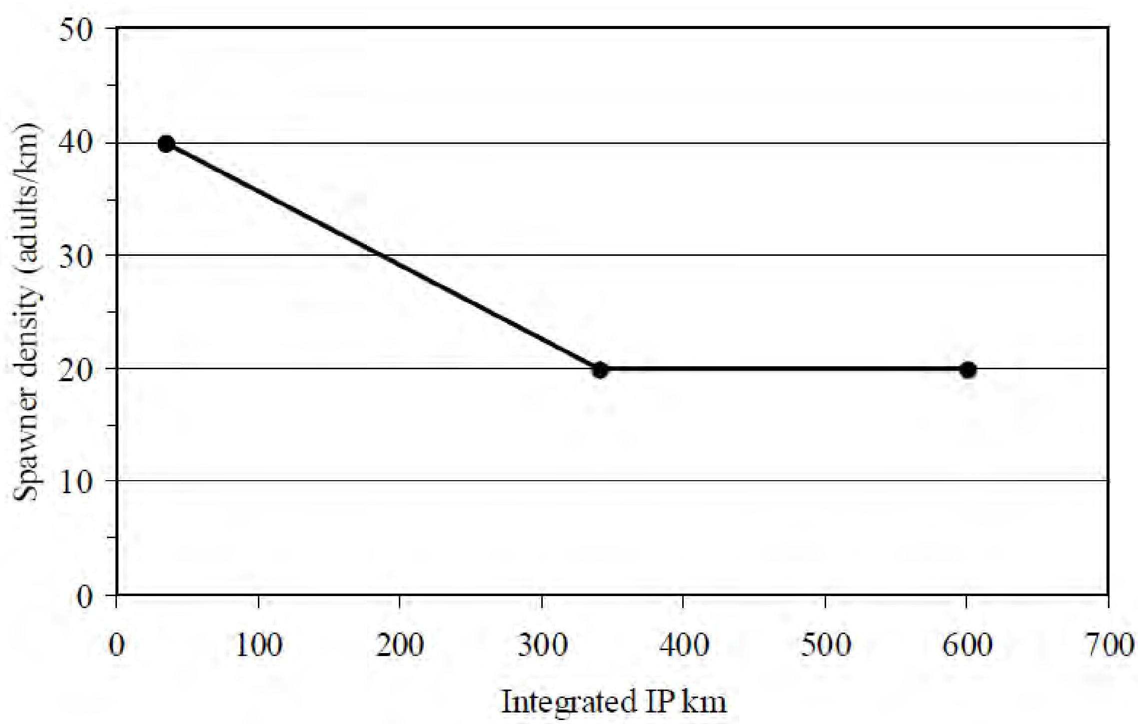

Figure 4-3. Minimum required spawning density based on amount of coho salmon IP-km (Williams et al. 2008).

Comparison of targets to historical abundance estimates

Despite efforts to not overestimate, the low risk spawner targets may appear overly ambitious when compared to current conditions. However, these targets should be viewed in the context of historical conditions. Williams et al. (2008) compared these spawner targets to historical estimates along the Oregon Coast, the Rogue River, and in the Eel River. Comparisons with these datasets suggest that the spawner targets do not overestimate the historical carrying capacities of coho salmon populations.

Using cannery records from 1892 to 1915, Meengs and Lackey (2005) estimated historical run sizes of Oregon coho salmon populations by 1) converting salmon pack data (in cases) into pounds of salmon caught (by assuming a certain constant "waste" in processing); 2) converting pounds of salmon captured into numbers of adult fish (by assuming an average weight for adult fish of 4.46 kg); 3) converting numbers of harvested salmon into an estimate of total population sizes (assuming a specific catch efficiency rate); and 4) using the five years of highest abundance in each watershed as indicative of run size. The historical abundance estimates for these Oregon coho salmon populations (Table 4-4) are well over the spawner targets derived from Williams et al.'s (2008) method. All the spawner targets were between 3% and 12% of historical estimates of abundance (Table 4-4).

Table 4-4. Comparison of abundance estimates and IP model-driven density-based abundance targets for coastal watersheds in Oregon (Williams et al. 2008). IP-km are integrated IP-km values.

Population	Historical estimates of abundance derived from cannery records (Meengs and Lackey 2005)	IP km	Estimated historical spawner density (spawners/IP km)	Projected abundance target based on MRSD (20 spawners/IP km)[a]	Projected abundance target as percent of historical estimate
Nehalam	236,000	1,116	211	22,300	9.3%
Tillamook	234,000	537	436	10,700	4.7%
Nestucca	107,000	299	358	6,800	6.4%
Siletz	122,000	310	394	6,800	5.6%
Siuslaw	547,000	902	607	18,000	3.3%
Yaquina	65,000	385	169	7,700	12.3%
Alsea	153,000	466	328	9,300	5.9%
Coquille	342,000	883	387	17,700	5.3%
Coos	161,000	552	292	11,000	6.8%

[a] – The Nestucca and Siletz populations have less than 340 IP km, therefore the MRSD values used for these calculations were 23 spawners/IP km for the Nestucca population and 22 spawners/IP km for the Siletz population.

In the Rogue River, Meengs and Lackey (2005) estimated the Rogue River had about 114,000 coho salmon during the late 1800s when land use in this watershed already included mining, water diversions, and timber harvesting (Atwood and Gray 2002 *in* Spence et al. 2008). In addition, Mullen (1981) estimated 58,000 coho salmon were harvested in the Rogue River in 1892. In order for the ESU to be recovered, the four populations in the Rogue River needs to contribute at least 28,320 spawners (Table 4-2) which is about 25 percent of Meengs and Lackey's (2005) historic estimate.

Relatively recent spawner estimates are available for the Upper Rogue River population to compare with the spawner target of 13,800 for this population (Table 4-2). As recently as 2000, the wild coho salmon spawner count at the Gold Ray Dam in the Upper Rogue River population was approximately 15,500 (ODFW 2010). Because the dam is not at the downstream-most location of the population unit, coho salmon spawners counted at the Gold Ray Dam represent only a portion of the Upper Rogue River population and the total number of coho salmon spawners in the Rogue River population is likely to be higher than the count at Gold Ray Dam for that year.

In the South Fork Eel River, the average number of coho salmon spawners counted at Benbow Dam from 1941[9] to 1950 was 14,900. Benbow Dam is located about 67 km upstream of where the South Fork Eel River enters the mainstem Eel River. Counts at this dam, consequently, represent only a portion of the South Fork Eel River population. To compare with this historic average, Williams et al. (2008) estimated the fraction of total IP-km upstream of Benbow Dam and multiplied this fraction by the overall abundance target to obtain estimates of the coho salmon spawner target upstream of Benbow Dam. The resulting coho salmon spawner target upstream of Benbow Dam is 6,836, which is about 46 percent of the average returns from 1941 to 1950.

In summary, where there are estimates of abundance of coho salmon to compare with spawner targets, the methods described in Williams et al. (2008) and any of NMFS' adjustments to Williams et al. (2008) targets do not appear to overestimate the historical carrying capacities of coho salmon populations.

Possible change to low-risk threshold

NMFS developed biological recovery criteria based on the productivity, spatial structure, and diversity components of the viability salmonid population (VSP) framework described by McElhany et al. (2000). Chapter 4 describes the biological recovery criteria for all four VSP parameters, including the low-risk threshold abundance targets identified by Williams et al. (2008). Future research is needed to determine whether the low-risk threshold abundance target could be increased or decreased if the other VSP parameters are well-estimated. Recovery actions for this research are identified in Chapter 5.

4.1.3 Stress and Threat Reduction Objectives and Criteria

Chapter 1 describes the listing factors identified when SONCC coho salmon were listed as a threatened species under the Endangered Species Act (ESA). Listing factors are those factors

[9] While records of fish counts at Benbow Dam began in 1938, 1941 is used as the starting period here to exclude hatchery influences on the spawner counts. Hatchery releases in the Eel River basin occurred from 1935 to 1938 (Williams et al. 2008).

that contributed to the decline of the species to the point where ESA protection was warranted. The possible delisting of coho salmon in the future would require that the biological recovery criteria in 4.1.2 are met. In addition, delisting would require that NMFS determine that the factors that led to the listing of SONCC coho salmon are sufficiently addressed. By establishing criteria for each of the five listing factors, the recovery plan will ensure that the underlying causes of decline have been addressed and mitigated prior to considering a species for delisting.

In order to develop criteria responsive to the listing factors, NMFS identified those stresses and threats associated with each listing factor (Table 4-5). Stresses are attributes of the ecology of a particular life stage of coho salmon that are impaired, directly or indirectly, by human activities. For example, impaired water quality, specifically high water temperature, can impair growth or kill coho salmon. Threats are activities or processes that have caused, are causing, or may cause a stress. For example, land management activities may require withdrawal of water from a river. This reduced flow can result in higher water temperature, impairing water quality and harming or killing coho salmon. The stresses and threats are described in Chapter 3, the methods used to assess them are described in Appendix B, and the results of the assessment for each population are summarized in Chapters 7 to 46.

The stress and threat reduction objectives and criteria are presented in Table 4-5, organized according to the five listing factors introduced in Chapter 3. The ratings of some stresses are informed by comparison of site-specific data to reference data values, which reflect the needed habitat conditions (Table 4-6). Appendix B describes how these indicators are used to inform the stress ranks. The indicators used in the assessment of stresses in this plan are shown in Table 4-6. Other indicators may be used instead of, or in addition to, these indicators in future assessments of stresses.

Table 4-5. Recovery objectives and criteria for stresses and threats.

Listing Factor	Stress/Threat	Recovery Objective	Recovery Criteria
A. Habitat Destruction, Modification or Curtailment	Lack of floodplain and channel structure	Habitat destruction, modification or curtailment does not limit attainment of population-specific recovery criteria	Lack of floodplain and channel structure is rated a medium or low stress[1] for all life stages of coho salmon in Core and Non-Core 1 populations based on GRTS[2] sampling of each population area.
	Altered sediment supply		Altered sediment supply is rated a medium or low stress[1] for all life stages of coho salmon in Core and Non-Core 1 populations based on GRTS[2] sampling of each population area.
	Altered hydrologic function		Altered hydrologic function is rated a medium or low stress[1] for all life stages of coho salmon in Core and Non-Core 1 populations based on GRTS[2] sampling of each population area.
	Impaired water quality		Impaired water quality is rated a medium or low stress[1] for all life stages of coho salmon in Core and Non-Core 1 populations based on GRTS[2] sampling of each population area.
	Degraded riparian forest conditions		Degraded riparian forest conditions is rated a medium or low stress[1] for all life stages of coho salmon in Core and Non-Core 1 populations based on GRTS[2] sampling of each population area.
	Barriers		Barriers do not limit access to areas determined to be necessary to attain coho salmon recovery[3].
	Impaired Estuary Function		Impaired estuarine function is rated a medium or low stress[1] for all life stages of coho salmon in Core and Non-Core 1 populations based on GRTS[2] sampling of each population area.
A. Habitat Destruction, Modification or Curtailment	Roads, Timber Harvest, Channelization, Diking, Agricultural Practices, Dams, Diversions, Mining, Gravel Extraction, and Urbanization	Threats to habitat do not limit attainment of population-specific recovery criteria	The recovery criteria listed above for all the stresses associated with Listing Factor A are met.
B. Over-utilization for commercial, recreational, scientific or educational purposes	Fisheries	Commercial, recreational and tribal fisheries impacts do not limit attainment of population-specific recovery criteria.	Commercial, recreational and tribal fisheries impacts do not, and likely will not, limit attainment of the desired status of populations relative to population-specific viability criteria. The desired status is identified in plans to manage these fisheries, and the plans are approved by NMFS.
	Collection	Collection impacts do not limit attainment of population-specific recovery criteria.	All scientific collection is authorized under Sections 10(a)(1)(a) or 4(d) of the Endangered Species Act.

Listing Factor	Stress/Threat	Recovery Objective	Recovery Criteria
C: Disease and predation	Disease	Disease does not limit attainment of population-specific recovery criteria.	Mean mortality and infection from diseases is not higher than natural background levels[4] for coho salmon juveniles in populations where disease is identified as a high or very high stress.
C: Disease and predation	Predation	Predation does not limit attainment of population-specific recovery criteria.	Predation does not, and likely will not, limit attainment of population-specific recovery criteria[5].
D: The inadequacy of existing regulatory mechanisms	Land and resource management	Regulatory mechanisms have been maintained and/or established and are being implemented in a way that allows the desired status of the ESU and its constituent populations, as defined by the biological criteria in this recovery plan, to be attained and maintained.	Regulatory programs that govern land use and resource extraction are in place, enforced, monitored, and adaptively managed adequately to ensure effective protection of coho salmon habitat, including water quality, water quantity, and stream structure and function, and do not limit the continued attainment of the biological recovery criteria in this recovery plan. Regulatory programs are in place and are being implemented, monitored, evaluated and adaptively managed adequately to manage fisheries at levels consistent with the biological recovery criteria of this recovery plan. Regulatory programs have adequate funding, prioritization, enforcement, and coordination mechanisms to ensure habitat protection and effective management of fisheries. Regulatory programs are in place and are being implemented, monitored, evaluated and adaptively managed adequately to manage the effects of climate change (e.g., management for droughts, floods, and sea level rise).
E: Other natural or man-made factors affecting continued existence	Climate change	Other natural or man-made factors must not limit attainment of population-specific recovery criteria.	Recovery criteria are met for stresses in Listing Factor A affected by climate change (altered hydrologic function, impaired water quality, degraded riparian forest conditions, impaired estuary/mainstem function, disease/predation/competition) and recovery criteria in Listing Factor D are met relating to land and resource management of climate change effects.
	Invasive species		Regulatory measures to minimize the risk of introduction of additional or spread of existing exotic species in the range of the ESU have been developed and implemented.
	Hatchery management		All hatcheries affecting SONCC coho salmon have NMFS-approved HGMPs, and the effects[6] of these hatcheries are within the levels described in the respective HGMPs.

[1] NMFS will consider the ratings of applicable indicators (Poor, Fair, Good, or Very Good) shown in Appendix B, Table B.3 in order to determine the current level of stress or threat (Very High, High, Medium, or Low). This consideration process is described in Appendix B, Section B.3.
[2] Generalized Random Tessellation Stratified technique (Stevens and Olsen 2004)
[3] Recovery action will determine which areas blocked by barriers are necessary to attain coho salmon recovery.
[4] NMFS assumes natural background levels of *C. shasta* equates to the lowest recorded mortality in coho salmon sentinel juveniles at the Beaver Creek site in the Klamath River in May and June (i.e., 10% mortality; Bartholomew 2012). These background levels will be used as the NMFS recovery criterion for this threat.
[5] Recovery actions will determine what levels of predation do not limit attainment of population-specific recovery criteria.
[6] The concept of the proportion of natural influence (PNI), developed by the Hatchery Science Review Group (HSRG 2004), may be a useful tool for limiting the risks of fitness loss in natural populations due to straying of hatchery fish.

Table 4-6. Indicators of aquatic habitat suitability for coho salmon habitat, to used to rate applicable stresses and determine if stresses are rated "medium" or "low". Adapted from Kier Associates and NMFS (2008).

Stress	Indicators	Good	Very Good
Lack of Floodplain and Channel Structure	Pool Depths	3-3.3 ft	>3.3 ft.
	Pool Frequency (length)	41-50%	>50
	Pool Frequency (area)	21-35%	>35%
	D50 (median particle size)	51-60 & 95-110 mm	60-95 mm
	LWD (key pieces[1]/100 m)	2-3	>3
	LWD <20 ft. wide[2]	54-84 pieces[3]/mi	>85 pieces[3]/mi
	LWD 20-30 ft. wide[2]	37-64 pieces[3]/mi	>65 pieces[3]/mi
	LWD >30 ft. wide[2]	34-60 pieces[3]/mi	>60 pieces[3]/mi
Altered Sediment Supply	% Sand <6.4mm (wet)	15-25%	<15%
	% Sand <6.4mm (dry)	12.9-21.5%	<12.9%
	% Fines <1mm (wet)	12-15%	<12%
	% Fines <1mm (dry)	8.9-11.1%	<8.9%
	V Star (V*)	0.15 - 0.21	<0.15
	Silt/Sand Surface (% riffle area)	12-15%	<12%
	Turbidity (FNU)[4]	120-360 hrs > 25 FNU	<120 hrs >25 FNU
	Embeddedness (%)	25-30	<25
Impaired Water Quality	pH (annual maximum)	8.25-8.5	<8.25
	D.O. (COLD) (mg/l 7-DAMin)	6.6-7.0 mg/l	>7.0 mg/L
	D.O. (SPAWN) (mg/l 7-DAMin)	10.1-11 mg/l	>11.0 mg/l
	Temperature (MWMT[5])	16-17 °C	<16 °C
	Aq Macroinverts (EPT)	19-25	>25
	Aq Macroinverts (Richness)	31-40	>40
	Aq Macroinverts (B-IBI)	60.1-80	>80
Degraded Riparian Forest Conditions	Canopy Cover (% shade)	71-80%	>80%
	Canopy Type (% Open + Hardwood)	20-30%	<20%
	Riparian Condition (conifers >36" dbh / 1000ft for 100 ft wide buffer)	125.1-200	>200
Disease	*Ceratonova shasta*	No greater than 10% mortality of sentinel coho salmon juveniles at Beaver Creek confluence in the Klamath River during May and June	

[1] Key pieces of large woody debris are pieces with a minimum diameter of 60 cm (2 feet) and a minimum length of 100 m (33 feet) (Foster et al. 2001).
[2] The number of pieces of wood in streams with a wetted width of less than 20 feet, between 20 and 30 feet, or greater than 30 feet (The Nature Conservancy 2006).
[3] Pieces of wood are defined as all wood pieces that are greater than 12 inches in diameter at 25 feet from the large end (The Nature Conservancy 2006).
[4] Formazin Nephelometric Units.
[5] Maximum weekly maximum temperature: Average of the daily maximum temperatures during the warmest 7-day period of the year.

4.2 Broad-Sense Recovery Goals

When the SONCC coho salmon ESU is recovered under the ESA and delisted, returning wild coho salmon spawners may number in the tens of thousands but may not be numerous enough to use all available spawning habitat throughout the ESU. Many streams may remain unoccupied or under-occupied by coho salmon. Tens of thousands of coho salmon may not be enough to maintain a fishery. The cultural, economic, and ecological benefits of having numerous coho salmon spawning throughout the ESU are not maximized under a scenario where only ESA recovery is achieved. While the delisting criteria need to be objective and measurable, broad-sense recovery is more open-ended.

The recovery objectives and criteria in this plan define which populations must be at low risk of extinction to delist, but other populations have the potential to achieve a low risk of extinction as well. Broad-sense recovery means maximizing the viability of all populations. The goal of broad-sense recovery is to achieve a low risk of extinction for all independent populations in the SONCC, both Core and Non-Core populations. Broad sense recovery is a long-term goal. Enhancing the abundance, spatial structure, diversity and productivity of the Non-Core and dependent populations beyond the ESA delisting criteria is not required to delist SONCC coho salmon. However, doing so will increase resiliency of SONCC coho salmon, with associated opportunities for cultural, economic, and ecological benefits.

4.2.1 Recovery Action Implementation

All 40 populations of SONCC coho salmon have a profile that summarizes available scientific data and other pertinent information, including the stresses and threats affecting that population (Chapters 7 to 46). These population profiles help guide restoration and recovery efforts for coho salmon and their habitats. Population profiles are available for stakeholders to work toward broad-sense recovery. The recovery action table in each profile includes actions needed for each population to contribute to ESU viability. ESA delisting is expected to require implementation of those recovery actions with all priorities except Broad-Sense Recovery actions (those coded BR). Implementation of BR actions, in addition to implementation of those actions necessary to provide for ESA recovery of the species/ESU, would facilitate broad-sense recovery.

4.2.2 Oregon's Broad-Sense Recovery Goals and Criteria

Oregon's broad sense recovery goal is to achieve populations of naturally produced salmon and steelhead that are sufficiently abundant, productive, and diverse (in terms of life histories and geographic distribution) that the ESU as a whole (a) will be self-sustaining, and (b) will provide significant ecological, cultural, and economic benefits. This recovery goal was developed under Oregon's native fish conservation policy (ODFW 2003) to fulfill the mission of the Oregon Plan for Salmon and Watersheds (State of Oregon 1997). The Oregon Plan for Salmon and Watersheds is founded on the principle that citizens throughout the region value and enjoy the substantial ecological, cultural and economic benefits that derive from having healthy, diverse populations of salmon and steelhead. The goal is consistent with ESA delisting, and is designed to achieve a level of performance for the ESU and its constituent populations that is more robust than needed to remove the ESU from ESA protection. Broad-sense recovery incorporates ESA delisting goals in the sense that ESA delisting goals would be achieved first during an extended and stepwise process of achieving broad sense recovery goals.

Oregon's broad-sense recovery goal for the SONCC coho salmon ESU has not yet been agreed upon by a public advisory committee. The goal described above was developed for other recovery plans in Oregon and will be used as a placeholder until a public advisory committee has been formed and provided guidance on the broad-sense goal for SONCC coho salmon populations in Oregon.

The State of Oregon developed broad-sense criteria that go beyond the criteria for ESU delisting. These broad-sense criteria are designed to attain population goals that will provide significant ecological, cultural, and economic benefits consistent with the Oregon Plan (State of Oregon 1997).

Oregon's broad-sense recovery criteria for salmonids are:

• All SONCC coho salmon populations have a "very low" extinction risk and are "highly viable"[10] over 100 years throughout their historical range; and

• The majority of SONCC coho salmon populations are capable of contributing social, cultural, economic and aesthetic benefits on a regular and sustainable basis.

4.2.3 California's Broad-Sense Recovery Goal

The primary purpose of the *Recovery Strategy for California Coho Salmon* (CDFG 2004a), which the California Department of Fish and Wildlife submitted to the California Fish and Game Commission in February 2004, is to recover coho salmon to the point where the regulations or other protections for coho salmon listed under the California Endangered Species Act are not necessary.

To achieve recovery of coho salmon in California, the *Recovery Strategy* lists five delisting goals and associated criteria, concerned with increasing populations and restoring suitable habitats. In addition, Goal VI of the *Recovery Strategy* seeks to reach and maintain adequate coho salmon population levels to allow for the resumption of Tribal, recreational, and commercial fisheries for coho salmon in California.

---

[10] Having a "very low" extinction risk is equivalent to being "highly viable" in the parlance of population status assessment for recovery plans. A "highly viable" naturally-producing salmonid population with a "very low" extinction risk has less than a 1% probability of extinction over a 100-year period, corresponding to at least a 99% persistence probability. Probabilities result from an integrated assessment of the population's abundance, productivity, spatial structure, and diversity status.

5. Monitoring and Adaptive Management

5.1 Information needed to delist a species

Chapter 4 describes the objective, measurable criteria by which NMFS will determine whether the SONCC coho salmon ESU should be removed from the list of threatened and endangered species. Monitoring provides information to track progress toward recovery by evaluating the species' status relative to these criteria, and to identify if the species can be delisted using the listing status decision framework (Figure 5-1). NMFS recommends the monitoring described in this chapter be carried out, and may determine that other monitoring is also appropriate and necessary.

5.1.1 Adaptive management

In addition to its role in assessing the status of coho salmon relative to recovery targets, monitoring data is essential for adaptive management. Adaptive management is the process of improving management policies and practices as conditions change. Adaptive management is an approach to natural resources policy that embodies the idea that policies are experiments; monitoring data are collected and examined so that expectations can be compared to what was observed – adaptive management is not trial and error (Lee 1993). Information is rarely complete and there is often uncertainty. What is known is researched, examined, and tested, knowledge is extended, and management is adjusted. Adaptive management requires care and consideration both before monitoring (by employing sampling designs that adequately inform decision making) and after monitoring (by using results to improve future conservation efforts).

New scientific research may provide information that may warrant adjustments to the recovery plan, implementation, or both. In addition, adaptive management for this recovery plan relies on tracking of stresses and threats and assessment of the effectiveness of restoration actions. Adaptive management guides the implementation of salmon recovery activities through repeated adjustments in strategies and actions, as information from monitoring and evaluation become available (Figure 5-2). Strategies and actions needed for recovery can evolve as effectiveness of actions increases through monitoring and evaluation. Figure 5-2 shows the steps on the road to recovery, including adaptive management.

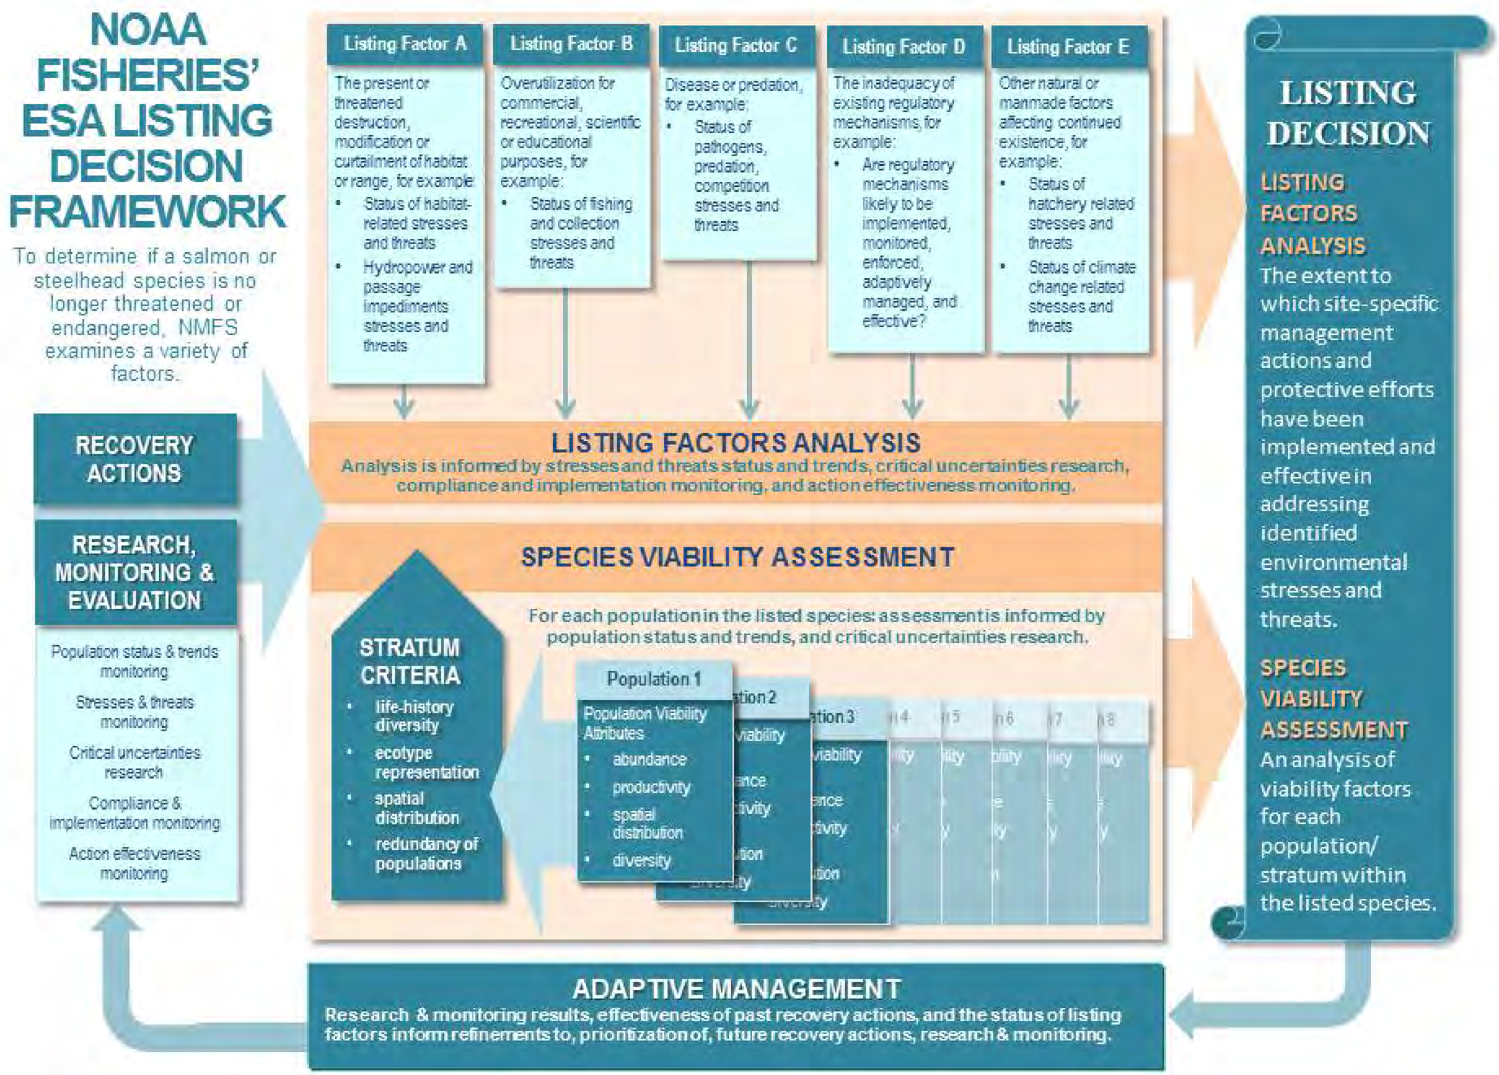

Figure 5-1. NMFS listing status decision framework.

Figure 5-2. The steps on the road to recovery.

5.2 Methods for monitoring coho salmon populations

For the purposes of describing SONCC coho salmon and its habitat, the spatial scale to be characterized is the population. Sampling at a coarser spatial scale (e.g., diversity stratum) would not provide the information needed to assess the status and trends of SONCC coho salmon populations. In addition, it is necessary to detect population changes with an appropriate level of certainty (Chapter 4); for example, spawner abundance estimates should strive to achieve a coefficient of variation (CV) of 15% or less at the population level (Crawford and Rumsey 2011).

The States of California and Oregon have established programs and methods for monitoring salmonids. Data designed to measure progress toward meeting SONCC coho salmon recovery criteria should be collected using the methods described below.

5.2.1 California's Coastal Monitoring Program

The California Department of Fish and Wildlife and the National Marine Fisheries Service designed California's Coastal Salmonid Monitoring Program (CMP) (Adams et al. 2011) to guide biological monitoring of salmonid populations in the state. The following excerpt from Adams et al. (2011) describes the overall strategy, design and methods of the monitoring plan.

The goals and objectives of the CMP are to develop broad and intensive monitoring strategies and techniques that:

1) Create a monitoring framework that includes all coho salmon, Chinook salmon and steelhead in coastal California;
2) Provide regional (ESU-level) and population abundance estimates for both status and trend of salmonid populations;
3) Estimate pro4ductivity trends from status abundance data;
4) Provide estimates of regional and population level spatial structure of coastal salmonids;
5) Consider the diversity of life-history and ecological differences in the three species of interest; and
6) Create permanent LCM [Life Cycle Monitoring] stations that will allow deeper evaluation of both freshwater and marine fish-habitat relationships and provide long-term index monitoring.

Methods for collection of adult and juvenile coho salmon data in California are described in Adams et al. (2011). California plan implementers should use these methods to collect data to be used to measure progress toward recovery.

5.2.2 Oregon Plan for Salmon and Watersheds

The Oregon Plan is a comprehensive plan to restore salmonids and the systems they rely on by combining scientifically sound actions with local watershed-based public support (State of Oregon 1997). This plan has four key elements:

1) Voluntary restoration actions by landowners, with support from local government;
2) Coordinated state and federal agency and tribal actions to support restoration efforts, implement regulatory programs, manage public lands, and promote public education and awareness;
3) Monitor watershed health, water quality, and salmon recovery to document existing conditions, track changes, and determine the impact of programs and actions.
4) Strong scientific oversight by the Independent Multidisciplinary Science Team to evaluate the plan's effectiveness, identify needed changes, and guide research investments (State of Oregon 2013).

Methods for collection of adult and juvenile coho salmon data in Oregon are described in Stevens (2002). Methods for assessment of coho salmon habitat in Oregon are described in Moore et al. (1997) and Rodgers et al. (2005). Plan implementers should use these methods to collect data to be used to measure progress toward recovery.

5.3 Population Viability

Monitoring spawner abundance and distribution, juvenile distribution, diversity, and productivity is necessary to assess progress toward recovery. The monitoring goals, purpose, and potential methods are described in Table 5-1 by population role. At a minimum, adults and juveniles should be monitored in all Core and Non-Core 1 populations, while juveniles should be monitored in all Dependent and Non-Core 2 populations. Table 5-2 shows the monitoring needed for each population. Monitoring entities should strive for spawner and juvenile data with an average coefficient of variation of 15 percent or less per population (Crawford and Rumsey 2011).

In addition to the adult and juvenile monitoring described above, life cycle monitoring (LCM) stations should be established. Adams et al. (2011) describes the utility and needed components of LCM stations. LCM stations are places where smolt and adult abundance are monitored. LCM stations are an integral component of monitoring for SONCC coho salmon. LCM stations can be used to: (1) estimate abundance of adult coho salmon and downstream migrating juveniles; (2) estimate marine and freshwater survival rates; (3) track abundance of juveniles coincident with habitat modifications, and (4) calibrate the spawning ground surveys used to estimate adult abundance, based on observations of live adults, redds, or carcasses. LCM stations should be located and designed for complete counts of smolts and adults from the entire basin or a defined portion of the basin using weirs, fences, traps, live mark/recapture techniques, sonar, or other techniques. At least one LCM station should be monitored in each diversity stratum (see Table 5-1) so that a regional estimate of freshwater survival is available for every diversity stratum, and a regional estimate of marine survival is available for every coastal diversity stratum.

Given the amount of data to be collected at LCM stations, they may serve as the focal point for evaluating the status of SONCC coho salmon populations and restoration efforts, as well as encouraging further research. LCM stations in close proximity to the ocean can be used to determine marine survival. Large rivers may not be appropriate or feasible locations for LCM stations if all coho salmon adults cannot be counted, smolt trapping efficiencies are low, or flows are too high or unsafe for operation. Alternatively, an LCM station could be established on a tributary of a large river. LCM stations are likely to be located opportunistically and at existing counting stations within each stratum.

Table 5-1. Population viability monitoring needs by population role.

Population Role	Monitoring Goal	Purpose and Methods
Core and Non-Core 1	Annually estimate number of adults	Track abundance of spawners relative to spawner targets. **Methods**: Carry out total counts, mark/recapture, or spawner surveys [Adams et al. (2011) (for California) and Stevens (2002) (for Oregon)]. Monitoring entities should strive for adult spawner data with a coefficient of variation on average of 15 percent or less per population (Crawford and Rumsey 2011).
Core and Non-Core 1	Annually monitor the spatial distribution of coho salmon adults spawning in the wild	If fish spawn and rear in a variety of freshwater habitats in a sub-basin, the population will be buffered against year-to-year environmental variations.
	Annually estimate the distribution of juvenile coho salmon	Track population productivity and spatial distribution. **Methods**: Carry out snorkel surveys [following Rodgers (2000 and 2001) in Oregon and Adams et al. (2011) in California] to determine juvenile occupancy (% area occupied) and density using GRTS technique (Stevens and Olsen 2004, Adams et al. 2011).
	Annually estimate the proportion of adults of hatchery origin	Determine extent of hatchery influence on spawners in order to assess possible impacts of domestication/hatchery selection on non-hatchery origin fish. **Methods**: During spawner counts, note whether specimen has internal or external hatchery mark.
	Periodically monitor key life-history characteristics	Document life-history diversity, which is important to understanding the long-term resilience and adaptability of SONCC coho salmon populations. **Methods**: Track characteristics such as spawner run timing, age at maturation, spawn timing, outmigration timing, smoltification timing, developmental rate, egg size, fecundity, freshwater and ocean distribution, size at maturation, and timing of ascension to natal stream.
Core with LCM station	Annually estimate the number of adults in area sampled by LCM station	Track abundance of spawners over time and, with smolt numbers, determine survival rate. **Methods**: Carry out total counts, mark/recapture, or spawner surveys [Adams et al. (2011) (for California) and Stevens (2002) (for Oregon)]. Monitoring entities should strive for adult spawner data with a coefficient of variation on average of 15 percent or less per population (Crawford and Rumsey 2011).
	Annually estimate smolt abundance in areas sampled by LCM station	Assess population productivity, and, with adult numbers, determine survival rate. **Methods**: Compare adult and smolt numbers to determine survival rate; in coastal LCMs, compare adult and smolt numbers to determine marine survival rate.
	Annually estimate marine survival	Assess influence of marine survival on abundance of coastal populations. Methods: Divide smolt abundance by spawner abundance for each coastal LCM station.
Dependent and Non-Core 2	Annually estimate juvenile occupancy	Track population productivity and spatial distribution. **Methods**: Juvenile occupancy surveys (% area occupied) and density in a spatially balanced random sampling design.

Table 5-2. Population viability monitoring actions for each population.

Stratum	Population	Population Role	Adult	Juvenile	LCM Eligible*
Northern Coastal	Elk River	Core	X	X	X
	Brush Creek	Dependent		X	
	Mussel Creek	Dependent		X	
	Lower Rogue River	Non-Core 1	X	X	
	Hunter Creek	Dependent		X	
	Pistol River	Dependent		X	
	Chetco River	Core	X	X	X
	Winchuck River	Non-Core 1	X	X	
Interior Rogue	Illinois River	Core	X	X	X

	North Fork Eel	Non-Core 2		X	
	Middle Mainstem Eel	Core	X	X	X
	Upper Mainstem Eel	Non-Core 2		X	

* LCM stations should be established in at least one core population in each diversity stratum.

5.4 Research

Numerous questions remain about the best means to collect and interpret population viability and habitat data. Table 5-3 describes research needs. These research needs correspond to recovery actions listed in Table 5-9.

Table 5-3. Research needs and methods.

Research Need	Purpose and Methods
Obtain better information on the extent and distribution of spawning in each Core and Non-Core 1 population area.	Accurate expansion of survey data to population estimates requires accurate information on current population range.
Develop efficient survey designs for assessing patchily-distributed populations	Understanding factors that influence distribution will aid in the design of more precise and efficient surveys.
Consider carrying out abundance surveys in consistently occupied, higher abundance patches and spatial structure surveys outside these patches	The appropriate survey method could differ based on the distribution of the animals to be surveyed.
Further develop the spatial structure monitoring protocol outlined in Adams et al. (2011) for California	Standard protocol for documenting spatial structure should be fully developed and followed by plan implementers to ensure consistent data collection.
Determine how juvenile distribution is influenced by streamflow, temperature, and sediment barriers	Annually monitor streamflow, temperature, and sediment barriers/extent of dry areas along with juvenile spatial structure to allow formal hypothesis testing of influence of one on another.
Develop cost-effective survey designs and methods for assessing spawning populations in streams where conditions (stream size, turbidity, cover) reduce the efficacy of traditional visual survey methods	Some parts of the SONCC coho salmon ESU's range are not amenable to traditional visual spawning survey protocols due to site-specific conditions.
Develop estimator for number of redds within a sample reach.	Adult abundance is sometimes estimated based on redd observations. Redds may be obscured from view over the course of the spawning season. Estimates of the number of redds deposited over the spawning survey must account for redds that cannot be observed during the periodic surveys. **Methods**: Model the redd deposition/ obscurement process as an open population mark-recapture problem. Use flagged redd recaptures on successive surveys to estimate rate at which existing redds cannot be detected in subsequent surveys. Adjust the number of new redds observed on new survey by survival rate since last survey. Use a non-parametric bootstrap routine to estimate within-reach uncertainty in number of redds.

Research Need	Purpose and Methods
Estimate total redd construction over regional space, incorporating within- and between-sample uncertainty.	Use of a Simple Random Sample Estimator is documented in Adams et al. (2011). However, small population sample frames are likely to lead to poor estimates of uncertainty using large sample variance equations. **Methods**: Use a bootstrap routine over large sample variance estimators for small frame and sample sizes. Using the outcome of estimator for number of redds within a sample reach (see Item 7 in this table, above), develop an algorithm for generating estimates of the number of redds over a sample space including the variance at the within-reach and between reach (sample error) levels.
Estimate the number of fish from estimates of redds.	At LCM stations, immigrating adults can be intercepted and either counted directly or marked for later recapture to create a spawner population estimate. Redds can also be directly counted or a number can be estimated using mark-recapture. The number of redds can be used to estimate the number of spawners. The relationship between the number of redds and the “true” number of spawners is used to adjust regional estimates of redds for reporting of the number of spawners. This approach assumes that the LCM station relationship between redds and spawners is the same as the regional relationship. Preliminary analysis suggests large variability between LCM redd to fish relationships in California.
Determine the number of reaches that should be sampled within a population to achieve a target coefficient of variation in annual status, and determine over what time period a trend of a specified magnitude can be detected at what spatial scale given specified sample rates.	NMFS’ evaluation of salmonid viability uses the population as the fundamental unit, building up to Diversity Strata. The status of the ESU is therefore based on the status of its component populations. Based on sample frames previously constructed in California, most independent populations have between 40 and 120 stream reaches. Crawford and Rumsey (2011) recommend that spawner abundance estimates achieve a CV of 15% or less at the population level. The number of reaches to be sampled to obtain that CV in each population is unknown. **Methods**: Conduct a power analysis to determine: 1. the number of reaches that should be sampled to achieve the target CV in each population, and 2. over what time period a trend of specified magnitude can be detected at what spatial scale given specific sample rates.
Develop techniques to estimate spawner abundance in remote areas.	Some remote areas of the ESU (e.g., in the Rogue and Eel River basins) cannot be sampled using traditional methods.
Evaluate the potential to restore extirpated populations.	Several populations in the ESU appear to be extirpated or nearly so. These populations may have less potential for recovery than those that currently support coho salmon.
Research supplemental or alternative means to develop population targets.	Methods other than those used in Williams *et al.* (2008) could be effectively used to delineate populations.

Research Need	Purpose and Methods
Determine whether the abundance targets for independent populations could be decreased if other VSP parameters are well-estimated.	Williams et al. (2008) did not include criteria for spatial structure and diversity, rather abundance served as a proxy for these parameters: "The high-risk thresholds [which define the low end of the spawner density criteria] identify densities at which populations are at a heightened risk of a reduction in per capita growth rate (i.e., depensation). Populations exceeding the low-risk density thresholds [which define the high end of the spawner density criteria] are expected to inhabit a substantial portion of their historical range, which serves as a proxy indicator that resultant spatial structure and diversity will reasonably represent historical conditions (Williams et al. 2008)". This recovery plan includes criteria that explicitly measure spatial structure and diversity. If these criteria are met, the number of spawners needed could be less than that identified in Williams *et al.* (2008).
Determine how to differentiate salmonid species observed using DIDSON[11].	DIDSON is an acoustic camera which uses sonar and so is not affected by turbidity (Adams et al. 2011). DIDSON is a recommended method for counting steelhead in Southern California, but not in Northern California because when two or more salmonid species inhabit a stream, it is difficult to reliably distinguish them based on the DIDSON images (Adams et al. 2011). If salmonid species could be reliably distinguished, the DIDSON camera could be a powerful tool for tracking adult coho salmon abundance in the SONCC coho salmon ESU.
Determine whether chosen LCM locations capture existing spatial differences in marine survival due to different "marine environments".	One reason to have at least one LCM in each coastal diversity stratum is to capture the conditions in different "marine environments" across the marine range of SONCC coho salmon. The assumption that one LCM in each diversity stratum will adequately describe the effects of these "marine environments" remains untested.
Refine understanding of the accuracy of field protocols to detect juvenile occupancy.	Presence of juveniles in samples is proof of occupancy, but absence cannot be proven although the probability of absence can be determined. The frequency of "false" absences depends on the abundance and distribution of individuals, the sampling method and intensity, and the scale of sampling. This can be particularly problematic for species that are rare or patchily distributed, or as species and populations decline in abundance and distribution leading to errors in estimates that vary with habitat and environmental conditions and species abundance. **Methods**: Develop a juvenile spatial structure protocol that estimates detection probability.

[11] Dual-Frequency Identification Sonar.

Research Need	Purpose and Methods
Develop a quantitative limiting factors life cycle model.	Integrate information about the ecology of the salmon life cycle, the factors that may limit the survival of key life stages and the effects of human activities such as landscape management, habitat rehabilitation, and exploitation. Results of the model can be used to reprioritize recovery actions or identify additional actions needed to achieve SONCC coho salmon recovery.
Track ocean productivity	Compile data obtained from ocean net surveys, hatchery returns, and oceanic data collected by satellite and buoy arrays throughout the northeastern Pacific ocean.
Determine which life-history traits or other diversity parameters are the most meaningful measures of diversity, particularly in the context of future climate change impacts.	Development of meaningful measures of diversity is difficult largely because of the lack of understanding of the expression of individual life-history traits (the genetic and environmental effects) and the degree of correlation between these traits, survival, and reproduction.
Determine best approach to conduct effectiveness and validation monitoring.	Determine whether goals of effectiveness and validation monitoring can be achieved by measuring a subset of restoration actions, rather than all of them. Determine appropriate subset.

5.5 Stress and Threat Monitoring

In order to achieve recovery, the stresses and threats faced by coho salmon populations in the ESU must be sufficiently abated to facilitate the long term sustainability. The objectives for abatement of stresses and threats are as follows: (1) the stresses currently affecting SONCC coho salmon have been sufficiently reduced and (2) the threats identified at the time of listing, as well as any new threats, have been sufficiently removed or reduced.

Monitoring is needed to gauge progress toward meeting the stress and threat objectives. Monitoring needs for stresses and threats are described for each population in Table 5-4, Table 5-5, Table 5-6, and Table 5-7. Table 5-10 through Table 5-49 describe the recovery actions necessary to obtain information on these stresses and threats for each population.

An initial, comprehensive field-based habitat survey should be carried out for all populations as soon as possible (1; Table 5-6 and Table 5-7). The purpose of these surveys is to describe the current habitat conditions in each population area to inform restoration actions and for future statistical sampling of the area to support the GRTS approach. The surveys should be followed by monitoring of indicators related to those stresses ranked high or very high for each population. Such indicators should be monitored every 5 years beginning as soon as possible (3; Table 5-6 and Table 5-7). For those stresses ranked medium or low for each population, indicators should be monitored every 10 years beginning as soon as possible (4; Table 5-6 and Table 5-7). Monitoring needs for stresses are described for each population in Table 5-5 (for coastal diversity strata) and Table 5-6 (for interior diversity strata). Some stresses can cause habitat to worsen rapidly, and some of these changes in habitat could be fatal to coho salmon. For this reason, indicators for water temperature, barriers (due to sediment or dry areas), altered hydrologic function, adverse fishery-related effects, increased disease, predation, and competition, and adverse hatchery-related effects should be monitored annually for populations that rated high or very high for these stresses (2; Table 5-5 and Table 5-6). Threat monitoring is described in Table 5-7. NMFS will describe the status and trends of stresses related to particular threats, along with other identified information, as part of the status review to be completed every five years.

Table 5-4. Recommended monitoring to assess stresses associated with listing factors.

Listing Factor	Stress	Monitoring[1]
A: Habitat Destruction, Modification or Curtailment	Lack of Floodplain and Channel Structure	Habitat indicators[2] for the stresses rated *high* or *very high* should be monitored[3] every 5 years.
	Altered Sediment Supply	
	Impaired Water Quality	
	Degraded Riparian Forest Condition	
	Impaired Estuarine Function[4]	
	Barriers (due to sediment, dry areas, or high temperature)	Annually monitor the extent of barriers due to sediment or seasonally dry areas in independent populations where such barriers are identified as a *high* or *very high* stress.
	Altered Hydrologic Function	Annually monitor the hydrograph, where appropriate, in independent populations where altered hydrologic function is identified as a *high* or *very high* stress.
B: Overutilization for commercial, recreational, scientific, or educational purposes	Adverse Fishery-Related Effects	Annually estimate the commercial and recreational ocean fisheries bycatch and mortality rate for wild SONCC coho salmon. Annually estimate the in-river bycatch and tribal harvest for all rivers and streams in the SONCC recovery domain.
C: Disease or predation	Increased Disease/Predation/ Competition	Annually estimate the infection and mortality rate of juvenile coho salmon from pathogens, such as *Ceratonova shasta*, in the mainstem Klamath River at Beaver Creek during May and June
C: Disease or predation	Increased Disease/Predation/ Competition	Annually estimate the density of non-native predators, such as the Sacramento pikeminnow in the Eel River basin, in independent populations where predation is identified as a *high* or *very high* stress.
D: The inadequacy of existing regulatory mechanisms	All	Monitor changes in adequacy of existing regulatory mechanisms.
E: Other natural or manmade factors affecting the species' continued existence	Climate Change	Refer to monitoring associated with Impaired Hydrologic Function and Water Quality.
	Adverse Hatchery-Related Effects	Annually determine the percent of hatchery origin spawners (PHOS) in independent populations where hatchery effects are a *high* or *very high* stress.

[1]The first habitat monitoring should be comprehensive and occur as soon as possible in both freshwater and estuarine (if applicable) habitat, in order to inform restoration activities and statistical sampling of population area.
[2] A list of habitat indicators is presented in Table 4-6.
[3] Habitat monitoring will be based on GRTS (use of this method for habitat monitoring is described in Rodgers et al. (2005)).
[4] NMFS has no recommendation regarding the habitat parameters to be measured in estuaries. A recovery action to identify the appropriate estuarine parameters is included for each population where such monitoring is needed.

Table 5-5. Monitoring actions to assess stresses for each population in the coastal diversity strata.

Monitoring Action: Track indicators related to:	Northern Coastal Basins					Central Coastal Basins						Southern Coastal Basins

3 = Monitor applicable habitat or population indicators every five years, to begin as soon as possible.
4= Monitor applicable habitat or population indicators every 10 years, to begin after initial comprehensive habitat survey completed.

C = core population

NC1 = non-core 1 population

NC2 = non-core 2 population

Table 5-7. Monitoring for threats rated high or very high, with associated listing factors.

Listing Factor[1]	**Threat**	**Monitoring**[2]
A: The present or threatened destruction, modification, or curtailment of the species' habitat or range	Roads	Describe the status and trend of related stresses[3]. Describe status and trends of road treatments and road density.
	Timber Harvest	Describe the status and trend of related stresses[3].
	Dams/Diversion	Describe the status and trend of related stresses[3].
	Road-Stream Crossing Barriers	Describe status and trends of identified fish passage barriers[3].
	High Intensity Fire	Describe trends in occurrence of high-intensity fire as well as trends in change of related stresses[3].
	Agricultural Practices	Describe the status and trend of related stresses[3].
	Channelization/ Diking	Evaluate the status and trend of related stresses[3]. Describe new channelization/diking and changes to existing channelization/diking.
	Urban/Residential /Industrial Development	Evaluate the status and trend of related stresses[3]. Describe new development and changes to existing development.
	Mining/Gravel Extraction	Evaluate the status and trend of related stresses[3]. Describe any new mining or gravel extraction.
B: Over-utilization for commercial, recreational, scientific or educational purposes	Fishing and Collecting	Annually estimate the commercial and recreational fisheries bycatch and mortality rate for wild SONCC coho salmon. Recreational fishing in freshwater and marine habitats should be assessed through development of Fisheries Monitoring and Evaluation Plans specifically designed to monitor and track catch and mortality of wild and hatchery coho salmon. Annually estimate the in-river bycatch and tribal harvest for all rivers and streams in SONCC recovery domain.
D: The inadequacy of existing regulatory mechanisms[4]	All	Monitor changes in adequacy of existing regulatory mechanisms.
E: Other natural or manmade factors affecting the species' continued existence	Climate Change	Evaluate the status and trend of related stresses[3].
	Hatcheries	Evaluate the status and trend of related stresses[3]. Describe status of HGMP development and implementation.
	Invasive Non-Native Alien Species	Evaluate the status and trend of abundance and occurrence of invasive, non-predatory species that may adversely affect SONCC coho salmon.

[1] Listing Factor C is not included in this table because disease and predation are considered stresses, and the preceding three tables describe monitoring actions to assess stresses.
[2] For each population with this threat rated as high or very high (Chapters 7 to 46), describe status at least once every five years during NMFS' status review of the SONCC coho salmon ESU.
[3] See Table 3-2 to determine related stresses for each threat.
[4] Timber harvest and dams/diversions should also be evaluated under this listing factor.

5.6 Limiting Factors Modeling

A quantitative limiting factors life cycle model is designed to integrate information about the ecology of the salmon life cycle, the factors that may limit the survival of key life stages, and human activities such as landscape management, habitat rehabilitation, and exploitation. Modeling limiting factors may provide insight into what elements of the habitat, or which life stages of coho salmon, are acting as roadblocks to recovery. Models can validate assumptions on which recovery actions are most essential to achieve recovery as well as identify factors which may have been overlooked. As recovery actions are implemented, limiting factors may change. Periodic use of and updates to the limiting factors models that are validated with habitat surveys may help recovery practitioners redirect efforts where they are most needed.

Typically these models associate fish abundance (density) and survival with each habitat type at important life stages. Both carrying capacity and density-independent survival are affected by habitat quantity and quality. Limiting habitat analyses at the basin-level are conducted using this life-stage specific approach. Two potential approaches are simplified limiting factor models and dynamic life cycle models. Both approaches are based on the salmon life cycle, and assess current and historical habitat conditions in a basin to estimate how habitat changes may have altered salmon abundance or survival at different life stages. However, the approaches differ in two main respects. First, each approach emphasizes different parameters driving life stage-to-life stage survivorship. Simplified limiting factors models focus on changes in capacity at each freshwater life stage and treat density-independent stage-to-stage survival as constants. The dynamic life cycle model incorporates both capacity and survival through the use of stage to stage stock-recruitment relationships, and estimates population abundance or other VSP parameters via iterative simulations.

An example of a simplified limiting factors model for coho salmon in Oregon coastal streams is the Habitat Limiting Factors Model (HLFM v7; Nickelson 1998). This model relies upon habitat typing information to determine total area of the various habitat types. The analyst then multiplies the area of each habitat by habitat-specific coho salmon density to estimate potential abundance. This process is done for each life stage/season using life-history-specific density values.

An example of a dynamic life cycle model is RIPPLE developed by Stillwater Sciences and UC Berkley (Dietrich and Ligon 2009). RIPPLE couples geomorphic information with biological and aquatic habitat data. Analysts are expected to ask questions such as “what is the expected population response to increasing the capacity or productivity (survival) of habitat in ‘X’ portion of the stream?” Additionally, the analyst could compare the abundance of fish at any given stage to the intrinsic potential of the basin and the current status of the habitat within the basin.

Such modeling efforts have implications for identifying habitats that may limit recovery of populations. They can provide a transparent framework to: (1) relate habitat to capacity and survival; (2) estimate stage specific abundance from a basin’s intrinsic potential; (3) apply knowledge of the current state of the habitat to stage specific capacity, survival and abundance; (4) identify model assumptions and parameters that can dramatically alter predictions of population responses to habitat changes; (5) indicate which life stages may be most sensitive to habitat change regardless of the assumptions about density dependence and therefore shift the focus of restoration efforts; and (6) identify parameter and model uncertainties that substantially alter conclusions about which habitats limit recovery. Such analyses motivate critical research to identify and characterize poorly understood habitats, their effects on salmon abundance and survival, and the extent to which they have been modified.

Development of a limiting factors model in one or more SONCC coho salmon populations is identified as a research need (Table 5-3).

5.7 Assessing Restoration Actions

The restoration of physical habitat is one of the fundamental strategies used to achieve recovery. Therefore, the effectiveness of certain habitat restoration activities in achieving the desired habitat improvements should be identified, as well as the change or response in coho salmon populations. Three types of monitoring can be employed to evaluate restoration actions: implementation, effectiveness, and validation. Each type serves a unique purpose.

5.7.1 Implementation Monitoring

Implementation monitoring is designed to assess whether restoration projects are carried out as planned (MacDonald et al. 1991), according to the intended purpose and design. For example, implementation monitoring would be used to determine whether a barrier replacement was carried out according to the planned design.

5.7.2 Effectiveness Monitoring

Effectiveness monitoring is used to determine whether restoration actions result in the expected physical effect. For instance, effectiveness monitoring could be used to assess the short-term structural integrity (e.g., instream structure anchoring) and physical objectives (e.g., scouring due to instream structure placement) of implemented restoration actions. Much of this can be done through on-site observations. Effectiveness monitoring of restoration actions has two parts: (1) pre-treatment site characterization for establishing the conditions prior to restoration and (2) post-treatment monitoring to determine if the restoration is having the intended effects.

5.7.3 Validation Monitoring

Validation monitoring is designed to assess whether an anticipated biological response actually occurred. Validation monitoring can range from measuring short-term response (1 to 3 years) of coho salmon to restoration actions implemented at the project level (e.g., successful passage through a former barrier). In addition, validation monitoring may evaluate the long term response of coho salmon populations to the cumulative basin restoration.

Implementation monitoring should occur in conjunction with restoration actions, while effectiveness and validation monitoring are appropriate for a subset of restoration actions[12]. Many effectiveness or validation monitoring efforts should be undertaken in the same area where intense biological sampling occurs. Careful planning and implementation of restoration

[12] Chapter 5 contains a research recovery action to accomplish this.

activities within the same areas as LCMs will allow for these analyses to be conducted with little additional costs for status or biological information.

An accurate evaluation of the effectiveness of a restoration action requires a clear statement of the desired effect of the project on the environment. Restoration objectives should be expressed as quantifiable changes in environmental conditions. For example, if installation of an in-stream structure is intended to improve rearing habitat, the desired changes could be expressed in terms of pool frequency, in-stream cover, or some other measurable environmental characteristic. The objectives should be stated as desired outcomes (e.g., 50 percent of reach length in pools). If objectives are vague, it will be difficult to evaluate effectiveness (Harris et. al 2005).

It may be difficult or impossible to detect how much of a biological response is due to a restoration action, as opposed to other influences. Validation monitoring may be confounded by other potentially limiting factors or variables that are not addressed by the restoration action. Similarly, single project restoration actions may not have enough impact to see a measurable response at the basin scale (MacDonald et al. 1991). Therefore, validation monitoring may be best for restoration actions that result in a quick response to the quality of instream salmonid habitat, such as instream habitat and fish passage improvement projects. Validation monitoring of other restoration actions should occur as part of an intensively monitored watershed, or IMW. IMWs are intensive watershed-scale research and monitoring efforts. A project level effectiveness monitoring study might include a single restoration action implemented in one location. In contrast, an IMW would look at an entire suite of restoration actions at a larger watershed scale and attempt to determine how these combined restoration actions would affect physical and biological conditions (OWEB 2014). IMWs are used to evaluate assumptions about what should be done to improve habitat and resulting fish response. IMWs also allow evaluation of critical uncertainties for the limiting factors models. Monitoring efforts conducted in IMW may find that using the Before-After-Control-Impact (BACI) approach (Stewart-Oaten et al. 1986) will provide the most useful information to evaluate biological and physical response to restoration activities. BACI study designs are often used to determine if a restoration action had the intended effect. The spatial and temporal scale of both the treatment and response must be carefully considered for this type of design to be informative. For example, a large road decommissioning project may not reduce sediment delivery for a number of years after project implementation. Road decommissioning may have a short term negative effect on sediment delivery. The spatial scale might be considered a reach, stream, or basin while the temporal scale of response might be 10 years or more.

5.8 Database Management

As research and monitoring actions are carried out, a great deal of data will be generated. Data on the VSP parameters, stresses and threats, restoration actions, and other pertinent monitoring and adaptive management elements are expected to be collected into one or more electronic databases that will be accessible to conservation partners. Standards for data collection methods and calculations (for example, population estimates) should be developed with resource agencies and tribes to ensure data quality and consistency.

Table 5-8. Population names and associated Population ID codes to be used in conjunction with Table 5-9 to describe population-specific research actions.

Population Name	**Population ID**		**Population Name**	**Population ID**
Bear River	BeaR		Middle Mainstem Eel River	MMER
Brush Creek	BruC		Middle Rogue/Applegate R.	MRAR
Chetco River	CheR		Mussel Creek	MusC
Elk Creek	ElkC		North Fork Eel River	NFER
Elk River	ElkR		Norton/Widow White Creek	NWWC
Guthrie Creek	GutC		Pistol River	PisR
Humboldt Bay Tribs.	HBT		Redwood Creek	RedC
Hunter Creek	HunC		Salmon River	SalR
Illinois River	IllR		Scott River	ScoR
Lower Eel/Van Duzen R.	LEVR		South Fork Eel River	SFER
Little River	LitR		South Fork Trinity River	SFTR
Lower Klamath River	LKR		Shasta River	ShaR
Lower Rogue River	LRR		Smith River	SmiR
Lower Trinity River	LTR		Strawberry Creek	StrC
Mad River	MadR		Upper Klamath River	UKR
Maple Creek	MapC		Upper Mainstem Eel River	UMER
Mattole River	MatR		Upper Rogue River	URR
Mainstem Eel River	MER		Upper Trinity River	UTR
Middle Fork Eel River	MFER		Wilson Creek	WilC
Middle Klamath River	MKR		Winchuck River	WinR

Table 5-9. Implementation schedule for research-related recovery actions. Use in conjunction with Table 5-8 to determine appropriate Action ID and Step ID. For example, if use of SONCC.Exam.27.1.1 is desired in the Chetco River, the code to use would be SONCC.CheR.27.1.1. Priority is described in Section 6.6.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-Exam.29.2.17	Research	No	Determine best means to collect and interpret habitat data	Collect data using standard, consistent protocols	All	3d
SONCC-Exam.29.2.17.1	*Develop standards for data collection methods and calculations*					
SONCC-Exam.29.2.17.2	*Apply standards for data collection and calculations*					
SONCC-Exam.29.2.25	Research	No	Determine best means to collect and interpret habitat data	Determine best approach to conduct effectiveness and validation monitoring	All	3d
SONCC-Exam.29.2.25.1	*Determine whether goals of effectiveness and validation monitoring can be achieved by measuring a subset of restoration actions, rather than all of them. Determine appropriate subset.*					
SONCC-Exam.29.2.24	Research	No	Determine best means to collect and interpret habitat data	Track ocean productivity	All	3d
SONCC-Exam.29.2.24.1	*Compile data obtained from ocean net surveys, hatchery returns, and oceanic data collected by satellite and buoy arrays throughout the northeastern Pacific ocean.*					
SONCC-Exam.29.1.1	Research	No	Determine best means to collect and interpret population viability data	Assess patchily-distributed populations	All	3d
SONCC-Exam.29.1.1.1	*Understand factors that influence distribution of coho salmon*					
SONCC-Exam.29.1.1.2	*Develop survey design which considers factors that influence distribution of coho salmon to best assess patchily-distributed populations. Consider carrying out abundance surveys in consistently occupied, higher abundance patches and spatial structures*					
SONCC-Exam.29.1.18	Research	No	Determine best means to collect and interpret population viability data	Compile monitoring data into common databases	All	3d
SONCC-Exam.29.1.18.1	*Collect monitoring data into one or more electronic databases accessible to conservation partners*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID		*Step Description*				
SONCC-Exam.29.1.5	Research	No	Determine best means to collect and interpret population viability data	Determine accuracy of field protocols to detect juvenile occupancy and refine if needed	All	3d
SONCC-Exam.29.1.5.1		*Develop a juvenile spatial structure protocol that estimates detection probability*				
SONCC-Exam.29.1.5.2		*If detection probability is too low, refine protocol to obtain higher probability of detection*				
SONCC-Exam.29.1.4	Research	No	Determine best means to collect and interpret population viability data	Determine how to differentiate salmonid species observed using DIDSON.	Anywhere that DIDSON units are used to count salmonids	3d
SONCC-Exam.29.1.4.1		*Obtain data from DIDSON in areas where more than one species of salmonid are present*				
SONCC-Exam.29.1.4.2		*Develop method to differentiate different salmonid species using DIDSON images*				
SONCC-Exam.29.1.11	Research	No	Determine best means to collect and interpret population viability data	Determine needed number of reaches to sample, and needed time period over which to sample, to obtain target coefficient of variation and magnitude of trend	All	3d
SONCC-Exam.29.1.11.1		*Conduct a power analysis to determine the number of reaches that should be sampled to achieve the target coefficient of variation in each population*				
SONCC-Exam.29.1.11.2		*Conduct a power analysis to determine, given specified sample rates, over what time period a trend of specified magnitude can be detected and at what spatial scale*				
SONCC-Exam.29.1.2	Research	No	Determine best means to collect and interpret population viability data	Determine potential for recovery of populations	Populations which are extirpated or nearly extirpated	3d
SONCC-Exam.29.1.2.1		*Develop analytical tool to determine probability of recovery populations at different population sizes*				
SONCC-Exam.29.1.13	Research	No	Determine best means to collect and interpret population viability data	Determine whether chosen LCM locations capture existing spatial differences in marine survival due to different "marine environments"	Coastal LCM stations and adjacent ocean habitat	3d
SONCC-Exam.29.1.13.1		*Determine marine survival rates at coastal LCMs*				
SONCC-Exam.29.1.13.2		*Identify different "marine environments" which affect coho salmon survival*				
SONCC-Exam.29.1.13.3		*Determine whether chosen LCM locations capture different "marine environments"*				
SONCC-Exam.29.1.3	Research	No	Determine best means to collect and interpret population viability data	Determine whether the abundance targets for independent populations could be decreased if other parameters (spatial structure, diversity, productivity) were well-estimated	All	3d
SONCC-Exam.29.1.3.1		*Apply measures of spatial structure, diversity, and productivity to populations in the SONCC coho salmon ESU*				
SONCC-Exam.29.1.3.2		*Determine whether abundance targets for populations could be reduced*				

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID		*Step Description*				
SONCC-Exam.29.1.10	Research	No	Determine best means to collect and interpret population viability data	Determine whether the relationship between the number of redds and number of spawners is the same at Life Cycle Monitoring stations compared to elsewhere in the ESU.	All	3d
SONCC-Exam.29.1.10.1		*Determine the relationship between the number of redds and number of spawners at locations other than where LCMs are located*				
SONCC-Exam.29.1.10.2		*Compare the relationship between the number of redds and number of spawners at these alternative locations to the relationship found at LCMs*				
SONCC-Exam.29.1.8	Research	No	Determine best means to collect and interpret population viability data	Develop estimator for number of redds within a sample reach by modeling the redd deposition/obscurement process as an open population mark-recapture problem	All	3d
SONCC-Exam.29.1.8.1		*Use flagged redd recaptures on successive surveys to estimate rate at which existing redds cannot be detected in subsequent surveys*				
SONCC-Exam.29.1.8.2		*Adjust the number of new redds observed on new survey by survival rate since last survey*				
SONCC-Exam.29.1.8.3		*Use a non-parametric bootstrap routine to estimate within-reach uncertainty in number of redds*				
SONCC-Exam.29.1.6	Research	No	Determine best means to collect and interpret population viability data	Develop protocol for monitoring spatial structure	All areas in California	3d
SONCC-Exam.29.1.6.1		*Further develop the protocol for spatial structure described in Adams et al. 2011*				
SONCC-Exam.29.1.7	Research	No	Determine best means to collect and interpret population viability data	Develop survey designs and methods for assessing populations	Streams where traditional visual survey methods are not effective due to factors such as stream size, turbidity, and cover	3d
SONCC-Exam.29.1.7.1		*Identify factors (such as stream size, turbidity, and cover) which reduce efficacy of traditional visual survey methods*				
SONCC-Exam.29.1.7.2		*Develop survey designs and methods which account for identified factors*				
SONCC-Exam.29.1.7.3		*Carry out both new survey designs and methods, and traditional visual survey methods, in the same stream*				
SONCC-Exam.29.1.12	Research	No	Determine best means to collect and interpret population viability data	Estimate spawner abundance in remote areas	All	3d
SONCC-Exam.29.1.12.1		*Develop techniques to estimate spawner abundance in remote areas*				
SONCC-Exam.29.1.12.2		*Identify remote areas for which new techniques should be used*				
SONCC-Exam.29.1.12.3		*Estimate spawner abundance in remote areas using new techniques*

SONCC-Exam.29.3.21.1	*Develop a quantitative limiting factors life cycle model*					
SONCC-Exam.29.3.21.2	*Utilize quantitative limiting factors life cycle model to better understand factors limiting SONCC coho salmon in particular populations.*					
SONCC-Exam.29.3.19	Research	No	Improve understanding of SONCC coho salmon	Understand how juvenile distribution is influenced by environmental factors	All	3d
SONCC-Exam.29.3.19.1	*Determine how juvenile distribution is influenced by streamflow, temperature, and sediment barriers*					
SONCC-Exam.29.3.19.2	*Incorporate understanding into juvenile distribution survey methods.*					

Table 5-10. Monitoring-related recovery actions for Bear River.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-BeaR.27.2.17	Monitor	No	Track habitat condition	Track habitat indicators related to spawning, rearing, and migration	Population wide	3d
SONCC-BeaR.27.2.17.1	*Measure indicators for spawning and rearing habitat. Conduct a comprehensive survey*					
SONCC-BeaR.27.2.17.2	*Measure indicators for spawning and rearing habitat once every 15 years, sub-sampling using GRTS technique*					
SONCC-BeaR.27.2.18	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Lack of Floodplain and Channel Structure'	All IP habitat	3d
SONCC-BeaR.27.2.18.1	*Measure the indicators, pool depth, pool frequency, D50, and LWD*					
SONCC-BeaR.27.2.19	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Degraded Riparian Forest Condition'	All IP habitat	3d
SONCC-BeaR.27.2.19.1	*Measure the indicators, canopy cover, canopy type, and riparian condition*					
SONCC-BeaR.27.2.21	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Impaired Water Quality'	All IP habitat	3d
SONCC-BeaR.27.2.21.1	*Measure the indicators, pH, D.O., temperature, and aquatic insects*					
SONCC-BeaR.27.2.22	Monitor	No	Track habitat condition	Monitor stream temperature	Population wide	3d
SONCC-BeaR.27.2.22.1	*Continue stream temperature monitoring at established locations*					
SONCC-BeaR.27.2.24	Monitor	No	Track habitat condition	Determine best indicators of estuarine condition	Estuary	3d
SONCC-BeaR.27.2.24.1	*Determine best indicators of estuarine condition*					
SONCC-BeaR.27.2.29	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Altered Sediment Supply'	All IP habitat	3d
SONCC-BeaR.27.2.29.1	*Measure the indicators, % sand, % fines, V Star, silt/sand surface, turbidity, embeddedness*					
SONCC-BeaR.27.2.30	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Impaired Estuarine Function'	Estuary	3d
SONCC-BeaR.27.2.30.1	*Identify habitat condition of the estuary*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-BeaR.27.2.35	Monitor	No	Track habitat condition	Track water temperature	All IP habitat	3d
SONCC-BeaR.27.2.35.1	*Measure water temperature continuously during the summer period*					
SONCC-BeaR.27.1.15	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Estimate juvenile spatial distribution	Population wide	3d
SONCC-BeaR.27.1.15.1	*Conduct presence/absence surveys for juveniles*					
SONCC-BeaR.27.1.16	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track indicators related to the stress 'Fishing and Collecting'	Population wide	3d
SONCC-BeaR.27.1.16.1	*Annually estimate the commercial and recreational fisheries bycatch and mortality rate for wild SONCC coho salmon.*					
SONCC-BeaR.27.1.23	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Refine methods for setting population types and targets	Population wide	3d
SONCC-BeaR.27.1.23.1	*Develop supplemental or alternate means to set population types and targets*					
SONCC-BeaR.27.1.23.2	*If appropriate, modify population types and targets using revised methodology*					
SONCC-BeaR.27.4.34	Monitor	No	Track threat	Describe road threat	Population wide	3d
SONCC-BeaR.27.4.34.1	*Describe the status and trends of road treatments and road density at least once every five years*

SONCC-LRR.27.1.18.1		*Annually estimate the commercial and recreational fisheries bycatch and mortality rate for wild SONCC coho salmon.*				
SONCC-LRR.27.1.28	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track life-history diversity	Population wide	3d
SONCC-LRR.27.1.28.1		*Describe annual variation in migration timing, age structure, habitat occupied, and behavior*				
SONCC-LRR.27.1.30	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Refine methods for setting population types and targets	Population wide	3d
SONCC-LRR.27.1.30.1		*Develop supplemental or alternate means to set population types and targets*				
SONCC-LRR.27.1.30.2		*If appropriate, modify population types and targets using revised methodology*				
SONCC-LRR.27.4.39	Monitor	No	Track threat	Describe road threat	Population wide	3d
SONCC-LRR.27.4.39.1		*Describe the status and trends of road treatments and road density at least once every five years*				
SONCC-LRR.27.4.40	Monitor	No	Track threat	Describe channelization/diking threat	Population wide	3d
SONCC-LRR.27.4.40.1		*Describe new channelization/diking and changes to channelization/diking at least once every five years*				
SONCC-LRR.27.4.41	Monitor	No	Track threat	Describe threat of development	Population wide	3d
SONCC-LRR.27.4.41.1		*Describe new urban/residential/industrial development and changes to development at least once every five years*				
SONCC-LRR.27.4.43	Monitor	No	Track threat	Track indicators related to the threat 'Barriers'	Population wide	3d
SONCC-LRR.27.4.43.1		*Annually monitor the extent of barriers due to sediment or seasonally dry areas*				

Table 5-23. Monitoring-related recovery actions for Lower Trinity River.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-LTR.27.2.24	Monitor	No	Track habitat condition	Track habitat indicators related to spawning, rearing, and migration	Population wide	3d
SONCC-LTR.27.2.24.1	*Measure indicators for spawning and rearing habitat. Conduct a comprehensive survey*					
SONCC-LTR.27.2.24.2	*Measure indicators for spawning and rearing habitat once every 10 years, sub-sampling using GRTS technique*					
SONCC-LTR.27.2.25	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Lack of Floodplain and Channel Structure'	All IP habitat	3d
SONCC-LTR.27.2.25.1	*Measure the indicators, pool depth, pool frequency, D50, and LWD*					
SONCC-LTR.27.2.26	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Altered Sediment Supply'	All IP habitat	3d
SONCC-LTR.27.2.26.1	*Measure the indicators, % sand, % fines, V Star, silt/sand surface, turbidity, embeddedness*					
SONCC-LTR.27.2.27	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Impaired Hydrologic Function'	All IP habitat	3d
SONCC-LTR.27.2.27.1	*Continuously measure the hydrograph*					
SONCC-LTR.27.2.27.2	*Identify instream flow needs for coho salmon*					
SONCC-LTR.27.1.20	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Estimate abundance	Population wide	3d
SONCC-LTR.27.1.20.1	*Determine annual abundance of adult coho salmon*					
SONCC-LTR.27.1.21	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Develop survival estimates	Site to be determined	3d
SONCC-LTR.27.1.21.1	*Install and annually operate a life cycle monitoring (LCM) station*					
SONCC-LTR.27.1.22	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track life-history diversity	Population wide	3d
SONCC-LTR.27.1.22.1	*Describe annual variation in migration timing, age structure, habitat occupied, and behavior*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-LTR.27.1.23	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track indicators related to the stress 'Fishing and Collecting'	Population wide	3d
SONCC-LTR.27.1.23.1	*Annually estimate the commercial and recreational fisheries bycatch and mortality rate for wild SONCC coho salmon.*					
SONCC-LTR.27.1.23.2	*Annually estimate the in-river tribal harvest of wild/natural SONCC coho salmon*					
SONCC-LTR.27.1.34	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Refine methods for setting population types and targets	Population wide	3d
SONCC-LTR.27.1.34.1	*Develop supplemental or alternate means to set population types and targets*					
SONCC-LTR.27.1.34.2	*If appropriate, modify population types and targets using revised methodology*					
SONCC-LTR.27.1.41	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track indicators related to the stress 'Hatchery Management'	All IP habitat	3d
SONCC-LTR.27.1.41.1	*Annually determine the percent of hatchery origin spawners (PHOS), percent of natural origin spawners (PNOS), and the proportion of natural influence (PNI)*					
SONCC-LTR.27.1.45	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Estimate juvenile spatial distribution	Population wide	3d
SONCC-LTR.27.1.45.1	*Conduct presence/absence surveys for juveniles*					
SONCC-LTR.27.4.42	Monitor	No	Track threat	Describe road threat	Population wide	3d
SONCC-LTR.27.4.42.1	*Describe the status and trends of road treatments and road density at least once every five years*					
SONCC-LTR.27.4.43	Monitor	No	Track threat	Describe channelization/diking threat	Population wide	3d
SONCC-LTR.27.4.43.1	*Describe new channelization/diking and changes to channelization/diking at least once every five years*					
SONCC-LTR.27.4.44	Monitor	No	Track threat	Describe threat of hatcheries	Population wide	3d
SONCC-LTR.27.4.44.1	*Describe status of development and implementation of applicable HGMPs at least one every five years*					

Table 5-24. Monitoring-related recovery actions for Mad River.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-MadR.27.2.30	Monitor	No	Track habitat condition	Track habitat indicators related to spawning, rearing, and migration	Population wide	3d
SONCC-MadR.27.2.30.1	*Measure indicators for spawning and rearing habitat. Conduct a comprehensive survey*					
SONCC-MadR.27.2.30.2	*Measure indicators for spawning and rearing habitat once every 10 years, sub-sampling using GRTS technique*					
SONCC-MadR.27.2.31	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Lack of Floodplain and Channel Structure'	All IP habitat	3d
SONCC-MadR.27.2.31.1	*Measure the indicators, pool depth, pool frequency, D50, and LWD*					
SONCC-MadR.27.2.32	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Degraded Riparian Forest Condition'	All IP habitat	3d
SONCC-MadR.27.2.32.1	*Measure the indicators, canopy cover, canopy type, and riparian condition*					
SONCC-MadR.27.2.33	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Altered Sediment Supply'	All IP habitat	3d
SONCC-MadR.27.2.33.1	*Measure the indicators, % sand, % fines, V Star, silt/sand surface, turbidity, embeddedness*					
SONCC-MadR.27.2.34	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Impaired Water Quality'	All IP habitat	3d
SONCC-MadR.27.2.34.1	*Measure the indicators, pH, D.O., temperature, and aquatic insects*					
SONCC-MadR.27.2.35	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Impaired Estuarine Function'	All IP habitat	3d
SONCC-MadR.27.2.35.1	*Identify habitat condition of the estuary*					
SONCC-MadR.27.2.40	Monitor	No	Track habitat condition	Determine best indicators of estuarine condition	Estuary	3d
SONCC-MadR.27.2.40.1	*Determine best indicators of estuarine condition*					
SONCC-MadR.27.2.45	Monitor	No	Track habitat condition	Track water temperature	All IP habitat	3d
SONCC-MadR.27.2.45.1	*Measure water temperature continuously during the summer period*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID		*Step Description*				
SONCC-MadR.27.1.25	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Estimate abundance	Population wide	3d
SONCC-MadR.27.1.25.1		*Determine annual abundance of adult coho salmon*				
SONCC-MadR.27.1.26	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track life-history diversity	Population wide	3d
SONCC-MadR.27.1.26.1		*Describe annual variation in migration timing, age structure, habitat occupied, and behavior*				
SONCC-MadR.27.1.27	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track surrogate for genetic diversity	Mad River Hatchery	3d
SONCC-MadR.27.1.27.1		*Describe annual ratio of naturally-produced fish to hatchery-produced fish spawned for hatchery production*				
SONCC-MadR.27.1.28	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track indicators related to the stress 'Fishing and Collecting'	Population wide	3d
SONCC-MadR.27.1.28.1		*Annually estimate the commercial and recreational fisheries bycatch and mortality rate for wild SONCC coho salmon.*				
SONCC-MadR.27.1.29	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track indicators related to the stress 'Hatchery Management'	Population wide	3d
SONCC-MadR.27.1.29.1		*Annually determine the percent of hatchery origin spawners (PHOS), percent of natural origin spawners (PNOS), and the proportion of natural influence (PNI)*				
SONCC-MadR.27.1.38	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Estimate juvenile spatial distribution	Population wide	3d
SONCC-MadR.27.1.38.1		*Conduct presence/absence surveys for juveniles*				
SONCC-MadR.27.1.39	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Refine methods for setting population types and targets	Population wide	3d
SONCC-MadR.27.1.39.1		*Develop supplemental or alternate means to set population types and targets*				
SONCC-MadR.27.1.39.2		*If appropriate, modify population types and targets using revised methodology*				

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority

Step ID		*Step Description*				
SONCC-NFER.27.2.16	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Lack of Floodplain and Channel Structure'	All IP habitat	3d
SONCC-NFER.27.2.16.1		*Measure the indicators, pool depth, pool frequency, D50, and LWD*				
SONCC-NFER.27.2.28	Monitor	No	Track habitat condition	Track ocean productivity	Population wide	3d
SONCC-NFER.27.2.28.1		*Compile and analyze data obtained from ocean net surveys, hatchery returns, satellites and buoy arrays in the ocean*				
SONCC-NFER.27.2.26	Monitor	No	Track habitat condition	Track water temperature	All IP habitat	3d
SONCC-NFER.27.2.26.1		*Measure water temperature continuously during the summer period*				
SONCC-NFER.27.1.25	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Estimate juvenile spatial distribution	Population wide	3d
SONCC-NFER.27.1.25.1		*Conduct presence/absence surveys for juveniles*				
SONCC-NFER.27.1.23	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track indicators related to the stress 'Fishing and Collecting'	Population wide	3d
SONCC-NFER.27.1.23.1		*Annually estimate the commercial and recreational fisheries bycatch and mortality rate for wild SONCC coho salmon*				
SONCC-NFER.27.1.14	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track indicators related to the threat 'Invasive Species'	Population wide	3d
SONCC-NFER.27.1.14.1		*Identify the status and trend of invasive species*				
SONCC-NFER.27.4.20	Monitor	No	Track threat	Describe road threat	Population wide	3d
SONCC-NFER.27.4.20.1		*Describe the status and trends of road treatments and road density at least once every five years*				
SONCC-NFER.27.4.21	Monitor	No	Track threat	Describe threat of high intensity fire	Population wide	3d
SONCC-NFER.27.4.21.1		*Describe trends in occurrence of high severity fire at least once every five years*				
SONCC-NFER.27.4.22	Monitor	No	Track threat	Describe threat of invasive species	Population wide	3d
SONCC-NFER.27.4.22.1		*Describe status and trend of abundance and distribution of invasive species annually*				

Table 5-34. Monitoring-related recovery actions for Norton/Widow White Creeks.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-NWWC.27.2.6	Monitor	No	Track habitat condition	Track habitat indicators related to spawning, rearing, and migration	Population wide	3d
SONCC-NWWC.27.2.6.1	*Measure indicators for spawning and rearing habitat. Conduct a comprehensive survey*					
SONCC-NWWC.27.2.6.2	*Measure indicators for spawning and rearing habitat once every 15 years, sub-sampling using GRTS technique*					
SONCC-NWWC.27.2.11	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Lack of Floodplain and Channel Structure'	All IP habitat	3d
SONCC-NWWC.27.2.11.1	*Measure the indicators, pool depth, pool frequency, D50, and LWD*					
SONCC-NWWC.27.2.12	Monitor	No	Track habitat condition	Track habitat indicators related to the stress 'Degraded Riparian Forest Condition'	All IP habitat	3d
SONCC-NWWC.27.2.12.1	*Measure the indicators, canopy cover, canopy type, and riparian condition*					
SONCC-NWWC.27.1.10	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Estimate juvenile spatial distribution	Population wide	3d
SONCC-NWWC.27.1.10.1	*Conduct presence/absence surveys for juveniles*					
SONCC-NWWC.27.1.13	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Refine methods for setting population types and targets	Population wide	3d
SONCC-NWWC.27.1.13.1	*Develop supplemental or alternate means to set population types and targets*					
SONCC-NWWC.27.1.13.2	*If appropriate, modify population types and targets using revised methodology*					
SONCC-NWWC.27.1.21	Monitor	No	Track population abundance, spatial structure, productivity, or diversity	Track indicators related to the stress 'Fishing and Collecting'	Population wide	3d
SONCC-NWWC.27.1.21.1	*Annually estimate the commercial and recreational fisheries bycatch and mortality rate for wild SONCC coho salmon.*					
SONCC-NWWC.27.4.17	Monitor	No	Track threat	Describe road threat	Population wide	3d
SONCC-NWWC.27.4.17.1	*Describe the status and trends of road treatments and road density at least once every five years*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-NWWC.27.4.18	Monitor	No	Track threat	Describe channelization/diking threat	Population wide	3d
SONCC-NWWC.27.4.18.1	*Describe new channelization/diking and changes to channelization/diking at least once every five years*					
SONCC-NWWC.27.4.19	Monitor	No	Track threat	Describe threat of development	Population wide	3d
SONCC-NWWC.27.4.19.1	*Describe new urban/residential/industrial development and changes to development at least once every five years*					
SONCC-NWWC.27.4.20	Monitor	No	Track threat	Describe threat of road-stream crossing barriers	Population wide	3d
SONCC-NWWC.27.4.20.1	*Describe any new road-stream crossing barriers and any changes to existing road-stream crossing barriers at least once every five years*

6. Implementation Program

6.1 Phased Approach to Recovery

Recovery of the SONCC coho salmon ESU will occur by rebuilding each population so that it can eventually serve its needed role. The recovery strategy, to be applied on a population-by-population basis, has two phases. In Phase I, the goal for Core and Non-Core 1 populations is to prevent extinction by rebuilding spawner numbers to above depensation, and the goal for Dependent and Non-Core 2 populations is to build capacity to support strays by restoring habitat to support all life stages. Once a population achieves the goal for Phase I, its goal changes to that for Phase II. In Phase II, the goal for each independent population is to rebuild the number of spawners to those levels needed for a recovered ESU. The goal for each dependent and Non-Core 2 population in Phase II is to build juvenile occupancy to needed levels. **Table 6-1**shows each population's current phase of recovery and status relative to depensation or habitat.

Table 6-1. Current phase of recovery and status of each population.

Population	Phase of Recovery	
	Current Phase of Recovery	Status
Elk River	Extinction prevention	Likely below depensation
Brush Creek	Building capacity	Insufficient habitat to support all life stages
Mussel Creek	Building capacity	Insufficient habitat to support all life stages
Lower Rogue River	Extinction prevention	Likely below depensation
Hunter Creek	Building capacity	Insufficient habitat to support all life stages
Pistol Creek	Building capacity	Insufficient habitat to support all life stages
Chetco River	Extinction prevention	Likely below depensation
Winchuck River	Extinction prevention	Likely below depensation
Smith River	Extinction prevention	Likely below depensation
Elk Creek	Building capacity	Insufficient habitat to support all life stages
Wilson Creek	Building capacity	Insufficient habitat to support all life stages
Lower Klamath River	Extinction prevention	Likely below depensation
Redwood Creek	Extinction prevention	Likely below depensation
Maple Creek/Big Lagoon	Building capacity	Insufficient habitat to support all life stages
Little River	Rebuilding	Likely above depensation
Strawberry Creek	Building capacity	Insufficient habitat to support all life stages
Norton/Widow White Creek	Building capacity	Insufficient habitat to support all life stages
Mad River	Extinction prevention	Likely below depensation
Humboldt Bay tributaries	Rebuilding	Likely above depensation
Lower Eel/Van Duzen Rivers	Extinction prevention	Likely below depensation
Guthrie Creek	Building capacity	Insufficient habitat to support all life stages
Bear River	Building capacity	Insufficient habitat to support all life stages
Mattole River	Extinction prevention	Likely below depensation
Illinois River	Rebuilding	Likely above depensation
Middle Rogue/Applegate Rivers	Rebuilding	Likely above depensation
Upper Rogue River	Rebuilding	Likely above depensation
Middle Klamath River	Rebuilding	Likely above depensation

Population	Phase of Recovery	
Upper Klamath River	Extinction prevention	Likely below depensation
Shasta River	Extinction prevention	Likely below depensation
Scott River	Rebuilding	Likely above depensation
Salmon River	Extinction prevention	Likely below depensation
Lower Trinity River	Extinction prevention	Likely below depensation
South Fork Trinity River	Extinction prevention	Likely below depensation
Upper Trinity River	Rebuilding	Likely above depensation
Mainstem Eel River	Extinction prevention	Likely below depensation
North Fork Eel River	Building capacity	Insufficient habitat to support all life stages
Middle Mainstem Eel River	Extinction prevention	Likely below depensation
Upper Mainstem Eel River	Building capacity	Insufficient habitat to support all life stages
Middle Fork Eel River	Building capacity	Insufficient habitat to support all life stages
South Fork Eel River	Rebuilding	Likely above depensation

6.2 Recovery Action Themes

The seven diversity strata in the SONCC Coho Salmon ESU share stresses and threats which must be reduced to allow for SONCC coho salmon to recover. Many of the stresses and threats can be addressed with recovery actions. Recovery actions are designed to both address acute issues and restore processes which create and maintain coho salmon habitat. Recovery actions should focus on areas where coho salmon currently persist, and on unoccupied areas of suitable habitat, to maximize the chance of preserving existing coho salmon. The best available information on coho salmon distribution is described in Chapters 7 through 46. Recovery actions that are common to multiple coho salmon populations are organized into the following themes. See the recovery actions at the end of Chapters 7 through 46 to determine which themes apply to particular populations of interest.

6.2.1 Flow

Stream flow quantity, quality, and timing are insufficient across much of the ESU. Insufficient flows contribute to problems with water quality in many populations. Instream flow criteria should be established. Flows should be restored, through actions such as reducing the number of unpermitted diversions, encouraging water conservation, streamlining water leasing and instream dedication processes, and improving timber, grazing, and irrigation practices. The current timing and volume of flow should be assessed in the Eel, Klamath, Trinity, and Rogue Rivers, and dams and diversions should be operated so that the timing and volume of flow better approximates natural conditions.

6.2.2 Floodplain and Channel Structure

Floodplain and channel structure is insufficient for all populations. Habitat should be reconnected and restored. Large wood or other structure should be added to streams. Off-channel ponds, wetlands, and side channels should be restored or connected to the channel, possibly by reintroducing beavers. Levees and dikes should be removed, set back, or reconfigured and the natural channel form and floodplain connectivity re-established. Mature forests should be established along streams to increase the potential for large woody debris by improving timber harvest practices, planting conifers, releasing conifers from competition with hardwoods, and establishing a healthy fire regime.

6.2.3 Estuaries

In coastal basins, estuaries have been disconnected from their floodplains by major highways or levees, drained or filled, or converted to freshwater. Restoration of the hydrologic function of estuaries is necessary to provide tidal habitat used by rearing juvenile coho salmon, and to restore passage to needed habitat upstream of the estuary. The tidal exchange of water should be increased by setting back or removing levees and improving or removing tide gates. Tidal channels, wetlands, sloughs, and the estuary should be connected. Channelized reaches should be restored by restoring passage and habitat complexity. Remaining estuarine habitat needed for recovery should be protected from development, dredging, or filling.

6.2.4 Dams

In the Klamath and Trinity rivers, dams block access to large amounts of habitat needed to produce coho salmon. Dams also disrupt ecosystem functions in these rivers by impeding sediment transport and degrading water quality. For the Upper Klamath River, the recovery strategy and actions include removing four Klamath Hydroelectric Project (Project) dams on the mainstem of the Klamath River as provided in the Klamath Hydroelectric Settlement Agreement or constructing and operating fishways prescribed by NMFS for Project relicensing. On the Trinity River, recovery actions include studying the feasibility of fish passage at Lewiston and Trinity dams and providing fish passage accordingly. If habitat above dams becomes accessible, it should be restored.

6.2.5 Hatcheries

The ecological and genetic impacts of fish produced by the Trinity River Hatchery and Iron Gate Hatchery should be reduced. Hatchery and genetic management plans should be developed for every hatchery in the ESU.

Some populations of coho salmon are so small that they suffer from effects of low population size which increase the possibility of population extirpation. Enhancement programs such as captive broodstock, rescue rearing, or conservation hatcheries should be considered and, if appropriate, employed to support coho salmon populations in the Mainstem Eel River, Middle Mainstem Eel River, Mattole River, and Shasta River.

6.2.6 Disease and Non-Native Species

An assessment of all means possible to disrupt the life cycle of the *C. shasta* parasite should be completed and a plan developed and implemented in the Upper Klamath River based on the results of the assessment. A plan should be developed and implemented to reduce the number of warm-water non-native fish in the Interior Rogue and Interior Klamath basins. In the Interior Trinity stratum, brown trout should be eradicated. Throughout the Eel River, Sacramento pikeminnow abundance should be substantially reduced.

6.2.7 Fishing

Fisheries should be managed such that they do not limit attainment of population-specific viability criteria for the SONCC coho salmon ESU.

6.2.8 Altered Sediment Supply

To reduce fine sediment delivery to streams, roads should be upgraded, maintained, or decommissioned, slopes stabilized, and timber harvest and grazing practices improved.

6.3 Benefits of Recovery

Healthy salmon and steelhead populations provide significant economic, societal, and environmental benefits. Communities, businesses, jobs, and cultures have been built around salmonids on the West Coast.

Monetary investments in watershed restoration projects can promote the economic vitality in a myriad of ways. The largest economic returns resulting from recovered salmon and steelhead populations are associated with sport and commercial fishing. For example, the California commercial and recreational salmon fisheries are estimated to generate a total of $118-279 million in income annually (University of the Pacific 2010), and provide roughly two to three thousand jobs. These figures will increase as salmon runs increase, providing both economic gains and more commercial and recreational fishing opportunities. With a revived sport and commercial fishery, these substantial economic gains and the creation of jobs would be realized across the SONCC coho salmon ESU range, most notably for river communities and coastal counties.

The economy also will be stimulated through the employment of workers needed to implement recovery projects. Habitat restoration projects stimulate job creation at a level comparable to traditional infrastructure investments such as mass transit, roads, or water projects (Nielsen-Pincus and Moseley 2010). Every dollar invested in watershed restoration projects travels through the state's economy. Design, implementation, and maintenance of habitat restoration projects require hiring consultants, contractors, employees, and field crews, and purchasing equipment, goods and services. People hired to carry out such projects spend their wages on goods and services in their local communities. In Oregon, 90% of investments in habitat restoration have been shown to stay in the state (Nielsen-Pincus and Moseley 2010).

Based on studies that examined streams in Colorado and salmonid restoration in the Columbia River Basin (Washington, Oregon and Idaho), the San Joaquin River (California), and the Elwha River (Washington), the value of salmonid recovery could be significantly larger than the fiscal or socioeconomic costs of recovery (CDFG 2004a). Importantly, the general model for viewing cost versus benefits should be viewed in terms of long-term benefits derived from short-term costs. Recovery actions taken for a particular listed salmonid are likely to also benefit other listed salmonids that occur in the same area, thus increasing the cost effectiveness of the actions.

Habitats restored to properly functioning conditions offer enhanced resource values and provide substantial non-monetary benefits for human communities. These benefits include: improving and protecting the quality of important surface and ground water supplies, reducing damage from flooding resulting from floodplain development, reducing expenditures on bank stabilization and flood control actions, and reducing the incidence of high severity fire. Restoring and maintaining healthy watersheds also enhances important human uses of aquatic habitats, including outdoor recreation, ecological education, field-based research, aesthetic benefits, and the preservation of tribal and cultural heritage.

Salmonid recovery is an investment and opportunity to diversify and strengthen the economy while enhancing the quality of life for present and future generations. The dollars necessary to recover salmonids should be made available without delay such that the suite of benefits can begin to accrue as soon as possible.

6.4 Achieving Recovery

Even with NMFS and other Federal agencies doing all within their authority and resources to achieve recovery of SONCC coho salmon, recovery will likely not occur without involvement by other entities. Federal agencies have neither the funds nor the authority to bring about all the actions necessary to sufficiently improve the condition of this species. Partnerships are a critical component of SONCC coho salmon recovery: partnerships between private landowners, tribes, and local, state, and federal government agencies; between non-governmental organizations and landowners; and between federal, state, and local agencies. A recovered ESU can provide ecosystem, recreation, and economic benefits to communities. All of these entities have a common interest in bringing healthy coho salmon populations and their ecosystems back to California and Oregon's coasts. Anyone who has an interest in the recovery of a listed species is a conservation partner. Conservation Partners Conservation partners are essential to the implementation and success of the recovery plan. NMFS looks forward to working with our conservation partners to recover the SONCC coho salmon ESU. Conservation partners may be individuals, groups, government or non-government organizations, industry, or tribes. A list of known conservation partners can be found in Appendix E.

6.5 Implementation Schedule

The last tables in Chapters 7 through 46 list the population-specific recovery actions that make up the SONCC coho salmon Recovery Program, including the recovery action number, recovery action step number, target, strategy, recovery action, action step, area, priority, and whether the action addresses a key limiting stress or threat. Appendix F lists the recovery action step number, potential lead agency and estimated cost for each action. Together, the tables in Chapters 7 through 46 and Appendix F make up the implementation schedule. A portion of an example implementation schedule is shown in Figure 6-1.

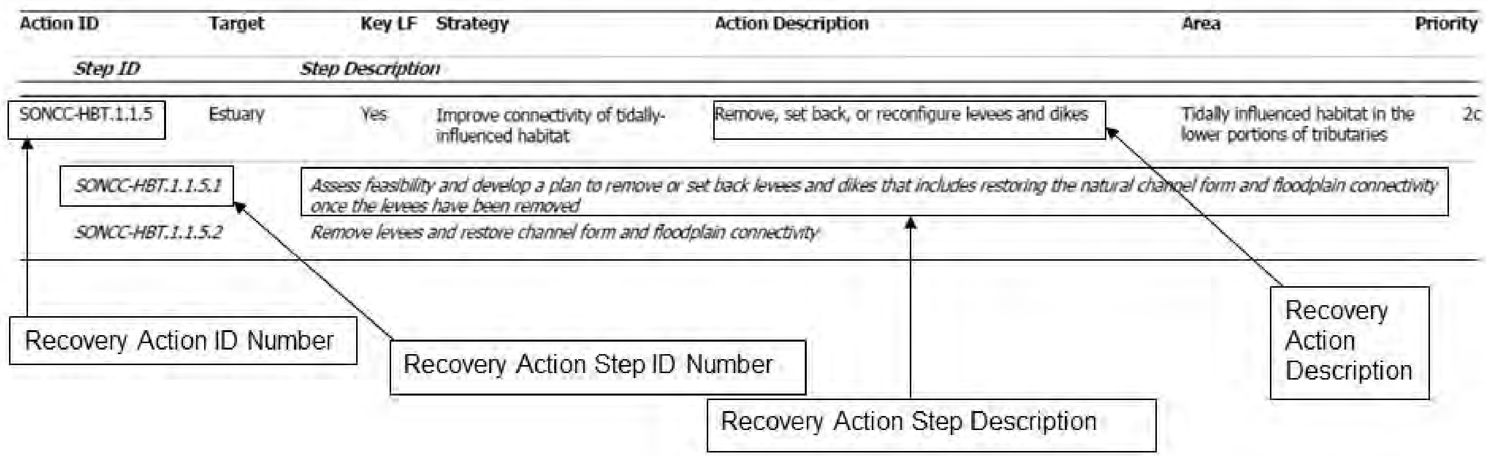

Figure 6-1. Example implementation schedule with selected elements labeled.

The fields in the recovery action tables found at the end of each population profile (Chapters 7 to 46) provides a unique ID number for each recovery action and recovery action step, information about which stress or threat each is meant to address, the purpose of the action, the particular action to be completed and the steps needed to complete it, the location where the action should be completed, the priority assigned to each action, and whether the action addresses a key limiting stress or threat. Additional fields, including cost and potential lead, are shown in Appendix F.

6.5.1 Recovery Action ID Number

A unique recovery action number is assigned to every recovery action to facilitate reference to the recovery action. For example, in the recovery action number SONCC-HBT.2.2, “SONCC” refers to the ESU, “HBT” refers to the population (in this case "Humboldt Bay Tributaries"), the first “2” is the strategy ID number (see Table 6-2), and the second “2” refers to the recovery action.

6.5.2 Recovery Action Step ID Number

The recovery action step ID number is a unique identifier assigned to each step of a particular recovery action to facilitate reference to a particular recovery action step number. It consists of the Recovery Action Number, with an additional number which refers to the sequential order of the action step (i.e., 1, 2, 3, or 4). For example, in SONCC-HBT.2.2.1, the “1” refers to the action step, in this case the first in a sequence of steps.

6.5.3 Target

The target is the primary stress or threat the recovery action is designed to address (e.g., the strategy “Sediment” is meant to address the stress “Altered sediment supply”).

shows the target ID number, the target, and the stress or threat addressed by that target. For example, in SONCC-HBT-2.2.1, the target is Floodplain and Channel Structure. Note that a recovery action may address more than one stress or threat, and therefore more than one target. However, only one target is associated with each recovery action in the implementation schedule.

Table 6-2. Stress or threat addressed by each target.

Strategy ID Number*	Target	Stress or Threat Addressed
1	Estuary	Impaired Estuarine Function
2	Floodplain and Channel Structure	Lack of Floodplain and Channel Structure
3	Hydrology	Impaired Hydrologic Function
5	Passage	Barriers
7	Riparian	Degraded Riparian Forest Conditions
8	Sediment	Altered Sediment Supply
10	Water Quality	Impaired Water Quality
12	Agricultural Practices	Agricultural Practices
13	Channelization/Diking	Channelization/Diking
14	Invasive, Non-native Species	Invasive, Non-native Species
16	Fishing/Collecting	Adverse Fishery-Related Effects
17	Hatcheries	Adverse Hatchery-Related Effects
19	Timber Harvest	Timber Harvest
22	Urban, Residential, Industrial Development	Urban, Residential, Industrial Development
23	Road-Stream Crossing Barriers	Road-Stream Crossing Barriers
26	Low Population Dynamics	Not applicable
27	Monitor	Not applicable
28	Roads	Roads
29	Research	Not applicable
30	Disease, Predation, Competition	Disease, Predation, Competition
*Gaps in strategy ID numbers reflect categories not used for SONCC plan but used for other recovery plans in California.		

6.5.4 Strategy

The strategy describes the purpose of the recovery action: To increase, reduce, or maintain particular characteristics of the stress (e.g., reduce delivery of sediment to streams).

6.5.5 Recovery Action

Action to be completed (e.g., reduce road-stream hydrologic connection).

6.5.6 Action Step

Steps to accomplish action (e.g., assess and prioritize road-stream connection, and identify appropriate treatments to meet strategy; decommission roads, guided by assessment). The action steps describe the actions to be taken to accomplish the recovery action and strategy.

6.5.7 Area

Location where action should be completed (e.g., all tributaries of the alluvial coastal plain downstream of Rock Creek, Indian Creek, and Bagley Creek, especially the Butler Creek watershed). Complementary actions were often created for recovery actions that had area identified as "population wide." The complementary actions will describe the area as, "area where fish would benefit immediately." Complementary actions that benefit fish immediately will have a higher priority than those described as population wide.

6.5.8 Priority

Each recovery action has been assigned a priority number, which is explained in Section 6.7.

6.5.9 Key Limiting Stress or Key Limiting Threat

Some recovery actions address key limiting stresses or key limiting threats - those stresses and threats that have the greatest impact on current population viability. Key limiting stresses and threats are explained in Section 6.5.9, and are identified for each population in its respective population profile (Chapters 7 through 46). If a recovery action addresses a key limiting stress or key limiting threat for a given population, this field will read "Yes". If not, it will read "No". Whether or not an action addresses a key limiting stress or threat factors in to the priority assigned to that action.

6.6 Developing Conservation Plans for Recovery Action Implementation

In general, the SONCC Coho Recovery Plan avoids describing overly prescriptive actions within individual watersheds so that conservation partners can develop the best strategies to obtain the associated objectives. Typically, a multi-stepped process is described to help managers achieve these goals. First, a proper assessment will help identify and prioritize locations for restoration. Second, an implementation or conservation plan will determine a strategy for abating the stress or threat through recovery actions. Third, actions can be implemented under the guidance of the plan. In some cases, a simplified assessment or plan may suffice in instances where effects and treatment are obvious (e.g., cows are walking in the stream, action is to build fences).

Below is an example of a multi-stepped action found in the Smith River population profile:

Strategy: Improve wood recruitment, bank stability, shading, and food subsidies
Action: Improve grazing practices

Action Steps:

SONCC-SmiR.7.1.7.1	Assess grazing impact on sediment delivery and riparian condition, identifying opportunities for improvement
SONCC-SmiR.7.1.7.2	Develop grazing management plan to meet objective
SONCC-SmiR.7.1.7.3	Plant vegetation to stabilize stream bank
SONCC-SmiR.7.1.7.4	Fence livestock out of riparian zones
SONCC-SmiR.7.1.7.5	Remove instream livestock watering sources

The development of a conservation plan or restoration strategy is a critical phase of restoration and when done correctly, will help ensure goals are met and desired conditions are attained. The following provides guidelines for developing conservation/restoration plans for some of the most frequently described recovery actions:

Strategy: Reduce delivery of sediment to streams
Action: Reduce road-stream hydrologic connection

A road assessment for a watershed should identify which roads are primary sources for sediment in the stream network. Assessments should include the identification of road surfaces (native material, gravel, paved, etc.), condition of the road and drainage features, and potential for sediment delivery (distance to the stream, eroding cut slopes, etc.).

If possible, the treatment plan should first prioritize the restoration of those roads delivering the most sediment to streams, and identify the actions necessary to reduce sediment delivery. Roads may need to be decommissioned by pulling out culverts or locking gates, or could be completely removed by re-contouring the hill slope to mimic a natural state. In other cases, roads may only need to be upgraded to solve the majority of sediment delivery problems. Roads surfaced with native materials typically contribute the majority of fines (USFS 2004). An assessment may find that it is only necessary to surface native roads with gravel, crown the road surfaces to discourage erosion of the surface, or improve drainage features. Treatment plans should include a long term maintenance schedule and monitoring plan if necessary. The California Department of Fish and Game's California Salmonid Stream Habitat Restoration Manual (CDFG 2010a) includes instructions for how to carry out an upslope erosion inventory and how to control sediment inputs.

Strategy: Improve wood recruitment, bank stability, shading, and food subsidies
(or) Reduce sediment delivery to streams
Action: Improve grazing practices

After an assessment is completed, which evaluates the contribution of livestock to sediment delivery and riparian degradation, a grazing management plan can be developed to reduce the stresses to SONCC coho salmon. Actions included in a plan may include fencing livestock outside of the riparian corridor, moving water sources upslope so animals are not in the stream, and planting new vegetation alongside the stream. The Natural Resources Conservation Service (NRCS) can provide resources for plan development including appropriate BMPs. For example, NRCS (2013) describes specifications for sustainable grazing practices, how to improve conditions of riparian forests and water resources, and how to develop a monitoring plan.

Strategy: Increase channel complexity
Action: Increase LWD, boulders, or other instream structure
(or) Construct off-channel ponds, alcoves, backwater habitat, or old stream oxbows

Instream structure

An assessment of channel complexity may consider such factors as amount and size of LWD present, depth of pools, and frequency of pools. A plan to increase instream structure may describe locations where addition of instream structure/habitat would be most beneficial, and ideally would prioritize those locations. The plan could also describe, for each location, how the instream structure would be added and the type and size of structural material (e.g., wood, boulders). For coastal California, the preferred wood type is redwood or Douglas fir which have a life expectancy of 25-50 years once fallen from the tree. Deciduous trees have a higher rate of decay and may only last 5-10 years. A LWD plan should consider adding wood with a root wad attached to add stability and complexity to the structure. Log structures may range from a single log to very complex engineered log structures. Log structures may be unanchored and allowed to move with high stream flows or be anchored in place. Consideration should be given to downstream infrastructure such as roads and homes. In addition, the plan should consider opportunities for obtaining wood or other structural material, and whether the available wood or other structural material is sized appropriately for the watershed. "Section 5.1.2 Side Channel/Off Channel Habitat Restoration" in the Washington Department of Fish and Wildlife Stream Habitat Restoration Guidelines 2004 (Saldi-Caromile et al. 2004) provides additional details regarding large wood construction projects.

Off-channel habitat

An assessment of a watershed may note opportunities for improved connection of the channel to the floodplain. A preliminary look at aerial photographs will help identify old or abandoned channel features such as oxbows and side channels that can be reconnected. Types of side-channel or off-channel restoration may include:

- Connection of abandoned side channel or pond habitats to restore fish access.
- Connection of adjacent ponds, remnants from aggregate excavation.
- Connection of oxbow lakes on floodplains that have been isolated from the meandering channel by river management schemes, or channel incision.
- Creation or re-connection of side channel or off-channel habitat with self-sustaining channels.
- Improvement of hydrologic connection between floodplains and main channels.

Restoration projects in this category may require removal or breaching of levees and dikes, channel and pond excavation, creating temporary access roads, constructing wood or rock tailwater control structures, and construction of LWD habitat features.

A plan for creating off channel habitat may consider water supply (channel flow/overland flow/groundwater), water quality and reliability, risk of channel change, and channel and hydraulic grade. Ideally, a project will not require regular maintenance. Anticipated maintenance should be described and planned for. The use of appropriately designed LWD structures may function as water level control structures or could redirect flow to help maintain channel features. Additionally, a plan may consider details such as site constraints and project limits, risk to infrastructure or other properties due to increased flow through a project channel, and descriptions of how the off-channel feature is anticipated to change and adjust over time. Saldi-Caromile et al. 2004 is a good reference document for designing off channel habitat features.

Strategy: Improve flow timing or volume
Action: Improve irrigation practices

**(or)	Improve water management techniques**
**(or)	Increase instream flows**
**(or)	Reduce diversions**
**(or)	Store water under a forbearance agreement for flow augmentation**

An assessment of flow may consider factors such as the extent of current illegal diversions, an evaluation of current instream flows, and a description of current water management techniques. An assessment should also consider the coho salmon life stage that will benefit from additional flow and how it will benefit (e.g., lower temperature for rearing, improve spawning habitat, improve migration corridor) as well as what length of stream reach will be affected by the increased flow. A plan to increase instream flows or reduce diversions would identify the means by which such changes would be accomplished, possibly with a prioritized list of the areas most in need of increased flow, or the illegal diversions having the most impact on flow. Water conservation projects should provide for a more efficient use of water extracted from the stream and result in increased flows that benefit aquatic species. Water conservation measures may include off-channel water storage, changes in the timing or source of water supply, moving points of diversion, irrigation ditch lining, piping, stock-water systems, and agricultural tailwater recovery/management systems.

Water conservation projects that use water storage tanks may consider filling them through rainwater catchment or by surface or groundwater flow. A project plan may consider establishment of water storage tanks using a forbearance agreement for at least 10 years, which will provide temporal and quantitative assurances for pumping activities that result in less water withdrawal during the summer low flow period. Water storage capacity for the water diversion forbearance period should be of sufficient capacity to provide for all water needs during that time period. For example, if the no-pump period is 105 days (August to November), the diverters must have enough storage to cover any domestic, irrigation, or livestock needs during that time.

Strategy: Improve access
Action: Remove structural barrier

Structural barriers may include permanent, flash board, or seasonal push up dams. An assessment of a structural barrier should identify the life stages of coho salmon which are blocked by the barrier and characteristics of the barrier (e.g., height, size of jump pool, gradient). An assessment may also include amount and characteristics of the sediment that will be released by removing the dam.

A small dam removal plan may include engineered designs for the upstream channel that minimizes negative effects (e.g., scour, down cutting) to downstream habitat. The plan may include excavation of sediment, diversion of water during dam removal, and seasonal timing windows for construction. CDFW's Habitat Restoration Manual (CDFG 2010a) provides additional information about how to remove small dams.

Strategy: Improve wood recruitment, bank stability, shading, and food subsidies
Action: Increase conifer riparian vegetation

An assessment of riparian forests should identify regions where the most degraded conditions occur such as those areas with little or no vegetation, limited conifer abundance, and regions of small sized or crowded conifers. A silvicultural prescription should prioritize regions with the most degraded forests conditions and those immediately adjacent to fish habitat. Prescriptions may include planting conifers, protecting riparian zones with the use of buffers, thinning small conifers to encourage faster growth in others, or removing exotic species such as Himalayan blackberries that prevent the establishment of new conifers. The NRCS can provide resources about how to manage riparian forests, including suggestions for buffer sizes which may be variable depending on the size of the stream (NRCS 2013). Additionally, NRCS and other resources such as Fischer and Fischenich (2000)'s Design Recommendations for Riparian Corridors and Vegetated Buffer Strips can provide information about how to successfully plant vegetation, exclude foraging animals, and control competing vegetation. CDFG (2010a) describes how to manage forests to improve wood recruitment, stabilize banks, and manage for shade.

Strategy: Increase channel complexity
Action: Increase beaver abundance

A beaver conservation plan could significantly enhance coho habitat in watersheds, but must consider issues associated with relocation of beavers and landowner conflicts. It is preferable for a plan to follow an "Educate-Mitigate-Relocate" type strategy. A conservation plan should first focus on education and outreach to landowners, detailing the benefits of beaver to the health of our ecosystems (see Chapter 3, Lack of Floodplain and Channel Structure and Climate Change). Because it is preferable to encourage beavers to stay in their chosen habitats, mitigation and technical assistance to landowners dealing with beavers should be a strong focus in any conservation plan. Tools such as tree cages, sand painting for trees, piping through dams to control flooding, and culvert exclusion devices such as beaver deceivers can help restoration groups assist landowners in beaver conflicts prior to removal of the beaver. Finally, relocation or reintroduction of beaver may be considered as a last resort. If no beavers are currently present in a watershed, a feasibility study should be carried out to determine whether beavers could be successful. A ranking scheme for watersheds and stream reaches should be developed to guide relocation efforts and may include factors such as stream gradient, food resources, protective cover, and landownership. Strong guidelines and methods should be developed prior to relocating or reintroducing beaver to an area. The Methow Beaver Project in Washington State provides extensive detail regarding relocation methods for beavers and meeting restoration objectives (Woodruff 2013), while Swales and Pollock (in review) provides a review of California regulations for trapping and relocating beaver.

Conservation plans may also include restoration projects that utilize beaver engineering skills to create coho salmon habitat and restore hydrologic function to streams. A restoration project may include techniques for construction of beaver dam analogues that will simulate the effects of beaver dams both for the purposes of creating habitat suitable for beaver and for creating the beneficial effects of beaver dams in locations that beaver are unlikely to occupy in the near future. Pollock et al. (2012) details methods and monitoring protocols in one example of this type of restoration.

Strategy: Improve water quality
Action: Reduce contaminants

When developing a watershed scale pesticide management plan, it's important to start with an inventory of potential pesticide use in the watershed. Determine if pesticides come from urban development such as lawn care and gardening, if they are associated with agriculture, or both. Pesticide use and selection often differs depending upon the area treated, although similar pesticide classes (e.g. pyrethroid insecticides) or active ingredients (e.g. glyphosate) may be used in both urban and agricultural uses. After areas of potential pesticide use and discharge into local waterbodies have been identified, management objectives can be defined. Pesticide management plans should have an educational and technical assistance component that assists landowners in preventing or minimizing their chemical input to streams.

There are numerous resources available on-line for use when developing a watershed scale or site specific pesticide management plan. For urban areas or rural developments (e.g. housing or infrastructure development in a rural area), a manual that gives development techniques and practices considered to be "low impact development" for storm water quality should also be consulted. Typical best management practices for these urban areas, in addition to careful pesticide selection and application techniques, include installation of vegetated filter strips and grassy swales for filtering storm water that may carry pesticide residues from a site. Maintaining, improving or expanding buffer zones between pesticide application areas and streams is also a common practice. Infiltration of storm water or site drainage is often useful for preventing the discharge of non-mobile products to water bodies. More developed areas can often use detention basins to settle out sediments contaminated with pesticide residues, or infrastructure-specific areas such as inlet filters or wet vaults.

NMFS encourages the development of smaller scale pesticide management plans at the stream reach or even individual ownership level. In many cases, it may be impracticable to wait for or to rely upon the development of a watershed-wide plan. The principals and most BMPs expressed in the preceding paragraphs are valid for site-specific planning. Many municipalities in California are covered under State-issued discharge permits which require the organizations to work with their citizens to reduce pesticide discharges. Local jurisdictions (e.g. cities, counties) should be consulted to see if they have developed, or can access, programs or materials that will aid in this process. There are also many existing programs for agricultural landowners. The University of California Cooperative Extension system has organized and conducts many programs targeted to reducing nonpoint source pollution from agriculture, including pesticide pollution, with many geared toward particular cropping systems. There are additional, non-profit based programs freely available as well, such as Fish Friendly Farming and Fish Friendly Ranching programs.

6.7 Recovery Action Priority

Conservation partners should consider the priority of a recovery action when choosing recovery actions to implement. Table 6-3 describes the prioritization system NMFS used to assign priorities to recovery actions for Core and Non-Core 1 populations. Table 6-4 is the system used for recovery actions for Dependent and Non-Core 2 populations. The numeric parts of the priorities (i.e., 1, 2, and 3) are defined by Conditions 1, 2, and 3 in Table 6-3 and Conditions 1 and 2 in Table 6-4. These conditions are based on language from NMFS guidelines (NMFS 1990), which is designed to prioritize those actions that are necessary to prevent extinction of the ESU, or to prevent a significant negative impact to the ESU short of extinction, over all other actions needed to achieve ESU recovery. Condition 7 in Table 6.3, and Condition 5 in Table 6-4, are based on Oregon's "broad-sense recovery goals". Actions meeting either of these conditions would contribute to broad-sense recovery goals but are not necessary to provide for ESA recovery of the ESU. The a, b, c and d parts of the priorities are defined by Conditions 6, 5, and 4, respectively, in Table 6-3 and Conditions 3 and 4 in Table 6-4. Priorities with the letter d are defined by meeting Condition 2 or 3 but not 4, 5 and 6 in Table 6-2 or meeting Condition 1 or 2 but not 3 or 4 in Table 6-3. NMFS used these conditions to consider several important factors: 1. If an action addresses a key limiting stress or threat and so would help resolve an identified population bottleneck; 2. If an action will benefit coho salmon immediately because they are already present in or near the action area; and 3. If the number of spawners in a population is below the depensation threshold.

Table 6-3. Prioritization system for Core and Non-Core 1 populations.

Condition		Priority[1]									
		1	2a	2b	2c	2d	3a	3b	3c	3d	BR
1	Action needed to prevent extinction of ESU by 1. Preventing extirpation of one or more independent populations or 2. Making a significant difference to multiple limiting factors in many of the populations in the ESU, meaningfully decreasing the extinction risk for much of the ESU.	x									
2	Action needed to prevent significant decline[2] in habitat or population in any population.		x	x	x	x					
3	Action needed to achieve recovery of the ESU but does not meet Condition 1 or 2.						x	x	x	x	
4	Action addresses key limiting stress or key limiting threat OR benefits[3] coho salmon immediately[4].			x	x			x	x		
5	Population below depensation based on the lowest three consecutive years from 2001 to 2012.		x	x			x	x			
6	Action addresses key limiting stress or key limiting threat AND benefits[3] coho immediately[4].		x				x				
7	Action not needed to achieve ESA recovery but would contribute to broad-sense recovery (BR) goals.										x

[1]To qualify for a priority, an action must meet all the conditions marked for the priority.
[2]Examples of "prevent significant decline": Prevent loss of one or more year classes; prevent abundance from falling below the depensation threshold; prevent direct mortality of coho salmon; make habitat available which is necessary for population to build above depensation threshold; prevent loss of a critical life-history requirement (e.g., summer rearing habitat, migratory habitat); and prevent the loss of occupied habitat.
[3] "Benefit" means the action will significantly improve likelihood of survival of coho salmon. Improvement in likelihood in survival may occur at any life-history stage (e.g., increased growth leads to fish being larger when enters ocean, improving likelihood of survival in ocean).
[4] "Immediately" means coho salmon from the subject population will benefit from the action within three years of completing the action. Three years accounts for all three year classes of coho salmon.

Table 6-4. Prioritization system for Dependent and Non-Core 2 populations.

Condition		Priority[1]						
		2b	2c	2d	3b	3c	3d	BR
1	Action needed to prevent significant decline[2] in habitat or population in any population.	x	x	x				
2	Action needed to achieve recovery of the ESU but does not meet Criterion 1.				x	x	x	
3	Action addresses key limiting stress or threat OR benefits[3] coho salmon immediately[4].		x			x		
4	Action addresses key limiting stress or threat AND benefits[3] coho immediately[4].	x			x			
5	Action not needed to achieve ESA recovery but would contribute to broad-sense recovery goals (BR).							x

[1]To qualify for a given priority, an action must meet all the conditions marked for that priority.
[2]Examples of “prevent significant decline”: Prevent loss of one or more year classes; prevent abundance from falling below the depensation threshold; prevent direct take of coho salmon; make habitat available which is necessary for population to build above depensation threshold; prevent loss of a critical life-history requirement (e.g., summer rearing habitat, migratory habitat); and prevent the loss of occupied habitat.
[3] “Benefit” means the action will significantly improve likelihood of survival of coho salmon. Improvement in likelihood in survival may occur at any life-history stage (e.g., increased growth leads to fish being larger when enters ocean, improving likelihood of survival in ocean).
[4] “Immediately” means coho salmon from the subject population will benefit from the action within three years of completing the action. Three years accounts for all three year classes of coho salmon.

6.8 Time to Achieve Phase I of Recovery for Any Population

In order for a population to be at moderate (not high) risk of extinction, it needs to consistently support more adults than the depensation threshold – usually in the tens to hundreds of adults, depending on the size of the population area. Phase I of recovery for independent populations, is to prevent extinction (Section 6.1) by rebuilding to above the depensation threshold and so achieve a moderate risk of extinction. Recovery actions which increase the amount of summer or winter rearing habitat by adding in-channel structure or off-channel ponds, or by ensuring enough water remains in the river in the summer months, can be effective almost immediately in increasing production and survival of the juveniles which will come back as adults. Barrier removal can provide access to dozens of kilometers of habitat in very little time. When these types of actions are implemented, fish response can be very rapid. Phase I of recovery, could therefore be accomplished in less than 10 years in some cases. The priority NMFS has assigned to each recovery action, which is described in Section 6.7, helps conservation partners identify which actions would most benefit coho salmon, either by benefiting them immediately or by addressing the key limiting stresses or key limiting threats which are causing bottlenecks in a population. If conservation partners focus on implementing the highest priority recovery actions, they have the greatest likelihood of helping the population avoid extinction by building to a level above the depensation threshold.

6.9 Time to Achieve Phase II of Recovery for All Populations

The minimum time to recover all populations in the SONCC coho salmon ESU and delist the species is determined by the following: 1) the time to complete all recovery actions, 2) the time for the habitat to respond to the recovery actions, 3) the time for the salmon populations to respond to the habitat improvements by attaining target levels; and 4) continued attainment of recovery criteria objectives described in Chapter 4 (i.e., population recovery targets, habitat condition) for at least 12 years (the time needed for determination of status of population (Williams et al. 2011) (Table 4-1).

Most actions consist of multiple steps and require time for planning and implementation; therefore, under ideal circumstances (e.g., assuming unlimited funding for recovery actions, planning is comprehensive and fast, and implementation is unimpeded) all actions could be completed in ten years. The environmental response to those actions will take in some cases many additional years. Actions such as increasing stream flows will result in an immediate positive benefit for coho salmon. However, other actions such as those associated with tree planting and the maturation of a riparian forest may take up to 80 years to reach the desired condition (Beschta et al. 1987, Keeton et al. 2007, Meleason et al. 2002). Because all recovery actions are necessary for the recovery of the species, and assuming actions will be implemented within ten years, 90 years will be the minimum time required for the improvement of environmental conditions necessary to rebuild coho populations and meet recovery criteria.

Coho salmon populations will likely start to recover immediately as a result of recovery action implementation. However, because that habitat is not expected to be fully recovered until 90 years have passed, and that habitat is expected to be needed to support target population sizes, the population targets cannot be fully realized until after that time. It is expected that another four generations (12 years) must pass before the population can build to a level consistent with final recovery after the habitat is fully restored (Bryant et al. 1999, Kiffney et al. 2007, Pess et al. 2008). At approximately year 102, populations may reach levels of viability. The final monitoring phase will take a minimum of 12 years (Williams et al. 2008; Table 4-1), resulting in delisting as early as year 114 if all recovery criteria are met and maintained during that final phase of monitoring.

The assumption that all recovery actions will be implemented within the first 10 years is likely unrealistic due to available funding, but it is used as a basis for recovery under ideal circumstances. If the actions are not completely implemented until year 30, delisting may not occur until year 134. Other assumptions used for this estimate may also be unrealistic. The time to recovery may be many times greater if any of the following occurs: 1) freshwater habitat conditions degrade further, 2) poor ocean conditions limit adult population size, 3) populations continue to decline, 4) recovery actions are not implemented immediately, or 5) adequate monitoring has not occurred to document improved conditions and populations.

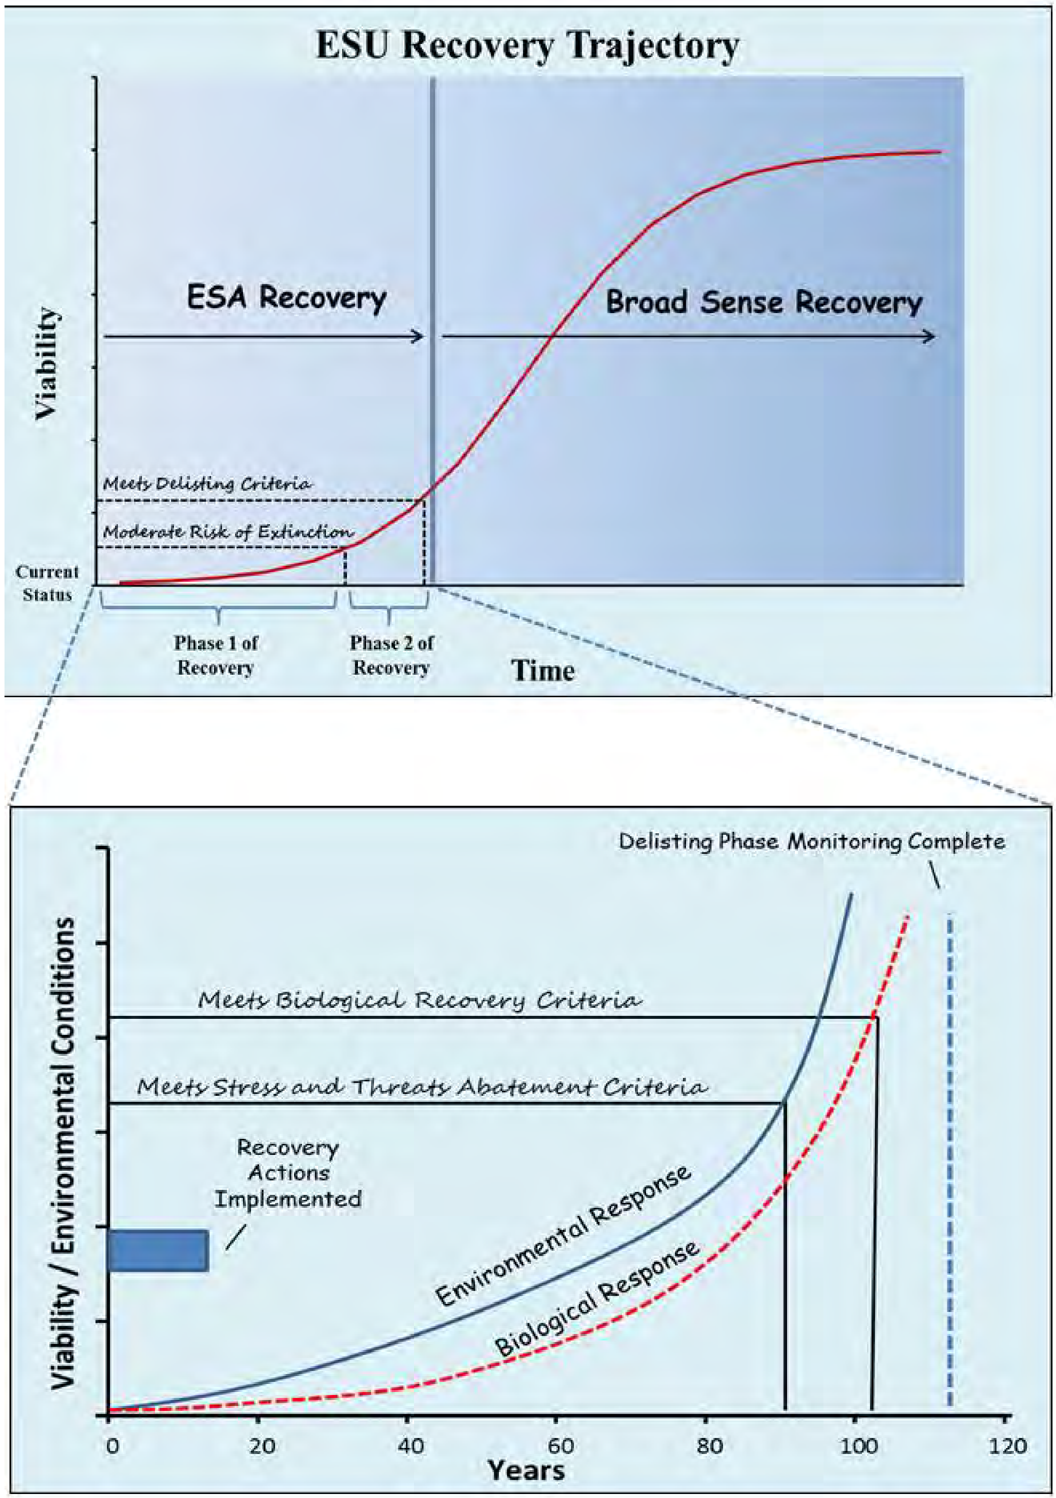

Figure 6-2. Minimum time to recovery displayed in context of long term trajectory and immediate goals.

6.10 Tracking Recovery

NMFS will track implementation of SONCC coho salmon recovery actions using an online database and associated mapping tool. This database and mapping tool, which is currently in final development, will track the implementation of recovery actions for Pacific salmon and steelhead listed under the Endangered Species Act. It is a web application that provides the following functions:

- Maps actions in a Geographic Information System (GIS);
- Tracks recovery action implementation;
- Fulfills NMFS' reporting requirements, specifically related to the Government Performance and Results Act; and
- Enables the public and stakeholders to access real-time data on recovery actions via an interactive web tool.

The Recovery Action Mapping Tool will be available here: www.westcoast.fisheries.noaa.gov/

6.10.1 Review of Recovery Progress

NMFS will regularly review the recovery actions accomplished and actions still in need of implementation, in order to track implementation status and identify any additional recovery needs. NMFS is required to review the status of listed species at least once every five years (ESA Section 4(c)(2)(A)). As part of each status review, NMFS will compare the status of the ESU, stresses, and threats to the delisting criteria. All available monitoring data will be used to determine the status of the ESU, describe progress made toward delisting, and identify any needed changes to the recovery program.

6.11 Changing the Recovery Plan

The recovery plan may be changed at any time. There are three types of plan modifications: update, revision, and addendum.

6.11.1 Update

An update to a recovery plan involves relatively minor changes. An update may identify specific actions that have been initiated since the plan was completed, as well as changes in species status or background information that do not alter the overall direction of the recovery effort. An update cannot suffice if substantive changes are made in the recovery criteria or if any changes in the recovery strategy, criteria, or recovery actions indicate a shift in the overall direction of planned recovery. In this case, a revision would be required.

6.11.2 Addendum

An addendum can be added to a plan after a recovery plan has been finalized. Types of addenda can range from implementation strategies or participation plans, to minor information updates. Addenda that represent significant additions to the recovery plan should undergo public review and comment before being attached to the recovery plan. An example of a significant addendum is one that adds a species to a plan.

6.11.3 Revision

A revision is a substantial rewrite of at least a portion of a recovery plan and is usually required if major changes are required in the recovery strategy, objectives, criteria, or actions. A revision may be required when new threats to the species are identified, when research identifies new life-history traits or threats that have significant recovery ramifications, or when the current plan is not achieving its objectives.

Notification, Review, and Approval of Plan Modifications

Updates to recovery plans and minor addenda represent minor changes and do not require formal public comment. These changes will be made to the latest recovery plan posted on NMFS regional and national internet sites.

Because plan revisions represent a significant change to the recovery plan, they go through the same review and clearance procedures as a draft and final recovery plan. If plan revisions or major addenda are planned, NMFS will publish a Federal Register Notice of Intent at the beginning of the process. This Notice will solicit data, provide information about public review and comment, and state the purpose of the revision.

6.12 How to Recommend Changes to the Recovery Plan

NMFS will accept suggestions for changes to the plan, or new information to be considered in the plan, at any time. Such changes or information can be provided by emailing the following address: SONCC.recovery@noaa.gov.

Disclaimer

Recovery plans delineate such reasonable actions as may be necessary, based upon the best scientific and commercial data available, for the conservation and survival of listed species. Plans are published by the National Marine Fisheries Service (NMFS), sometimes prepared with the assistance of recovery teams, contractors, State agencies and others. Recovery plans do not necessarily represent the views, official positions or approval of any individuals or agencies involved in the plan formulation, other than NMFS. They represent the official position of NMFS only after they have been signed by the Assistant Administrator. Recovery plans are guidance and planning documents only; identification of an action to be implemented by any public or private party does not create a legal obligation beyond existing legal requirements. Nothing in this plan should be construed as a commitment or requirement that any General agency obligate or pay funds in any one fiscal year in excess of appropriations made by Congress for that fiscal year in contravention of the Anti-Deficiency Act, 31 U.S.C 1341, or any other law or regulation. Approved recovery plans are subject to modification as dictated by new findings, changes in species status, and the completion of recovery actions.

Appendix A. Population Designation

The number of kilometers of habitat with Intrinsic Potential (IP-km) identified for some populations was updated from those values provided in Williams et al. (2008), due to previously unaccounted for natural barriers and other habitat-based information. Some of these updates resulted in changes to population classifications (i.e., functionally independent, potentially independent, dependent). Note that the updated IP-km values do not account for manmade barriers such as dams, which in some cases were considered when developing population spawner targets.

The amount of IP-km has been updated in nine of the populations since the public draft. The old and revised IP-km amounts are described in Table A-1, and the rationale for each change is explained in Section A.2.

Table A-1. Population-specific changes to IP-km due to natural barriers and population classification

A.1 Rationale for population-specific IP-km and classification changes

Northern Coastal Diversity Stratum

Mill Creek

A previously unaccounted for natural barrier at Garrison Lake excludes coho salmon from the watershed. Garrison Lake has a natural historic pattern of connection and disconnection to the ocean by a large sand bar. The watershed has been isolated from the ocean since sand dunes naturally migrated and filled the outlet stream in the mid-1900's (Maguire 2001). Anadromous fish do not currently occur in the Mill Creek watershed (Maguire 2001) and during periods of saltwater intrusion Garrison Lake likely has unsuitable conditions for juvenile rearing. Williams et al. (2006) determined that dependent populations must have at least 5 IP-km. After removing the IP-km in the lake and above it, the Mill Creek population has no IP-km and therefore does not meet the criterion for dependent populations.

Central Coastal Diversity Stratum

Smith River

Lake Earl and its associated stream network were removed from the Smith River IP calculations because the IP model was not intended for open water habitat. Williams et al. (2006) determined that independent populations must have at least 34 IP-km. After removing the IP habitat that occurs in Lake Earl and its associated stream network, the total amount of IP-km for the Smith River population remains high enough for it to qualify as an independent population.

McDonald Creek

Stone Lagoon was removed from the McDonald Creek IP-km calculations because the IP model was not intended for open water habitat. Williams et al. (2006) determined that dependent populations must have at least 5 IP-km. When the lagoon was accounted for, the amount of IP-km in the McDonald Creek population was reduced and did not meet the criteria for a dependent population.

Maple Creek/Big Lagoon

A previously unaccounted for natural barrier occurs 8,000 feet below the M-Line road crossing. A series of boulder rough falls form a 10-15% gradient and extend for 1,000 feet. No coho salmon have been found above the falls (Ryan Bourque, Green Diamond Resource Company, pers. comm. 9/26/13). When the IP-km for Maple Creek/Big Lagoon was decreased, the total amount of IP-km remained high enough for it to qualify as a dependent population.

Strawberry Creek

IP-km which should have been attributed to Strawberry Creek was previously attributed to the Mad River. Williams et al. (2006) determined that independent populations must have at least 34 IP-km. When the IP-km for Strawberry Creek was increased, it did not meet this criterion and so remained a dependent population.

Norton/Widow White Creek

IP-km which should have been attributed to Norton/Widow White Creek was previously attributed to the Mad River. Williams et al. (2006) determined that independent populations must have at least 34 IP-km. When the IP-km for Norton/Widow White Creek was increased, it did not meet this criterion and so remained a dependent population.

Mad River

IP-km which should have been attributed to Strawberry Creek and Norton/Widow White Creek was previously attributed to the Mad River. Williams et al. (2006) determined that independent populations must have at least 34 IP-km. When the IP-km for the Mad River was reduced, the total amount of IP-km for the Mad River population remains high enough for it to qualify as an independent population.

Southern Coastal Diversity Stratum

Guthrie Creek

Due to mapping errors the amount of IP-km originally attributed to Guthrie Creek was too high. Williams et al. (2006) determined that dependent populations must have at least 5 IP-km. When the IP-km for Guthrie Creek was decreased, the total amount of IP-km remained high enough for it to qualify as a dependent population.

McNutt Gulch

A previously unaccounted for 15-foot waterfall with bedrock canyon walls occurs 1.98 km upstream from the mouth of McNutt Gulch. The waterfall is the natural limit to anadromy (CalFish 2009) and is assumed to be the upstream limit of historic coho salmon occurrence in McNutt Gulch. When this natural barrier was accounted for, the amount of IP-km in the Middle McNutt Gulch population was reduced and did not meet the criterion for a dependent population.

Interior Rogue Diversity Stratum

Middle Rogue/Applegate Rivers

A previously unaccounted for waterfall occurs 1.7 miles upstream from the Applegate River at Little Applegate Falls. The falls appear to function as a complete barrier to adult coho salmon (Maiyo 2011). Williams et al. (2006) determined that independent populations must have at least 34 IP-km. When the IP-km for the Middle Rogue/Applegate Rivers population was reduced, the total amount of IP-km remained high enough for it to qualify as an independent population.

Upper Rogue River

IP-km previously attributed to the Upper Rogue River population area was removed because it occurred outside of the population boundary. Williams et al. (2006) determined that independent populations must have at least 34 IP-km. When the IP-km for the Upper Rogue River was reduced, the total amount of IP-km remained high enough for it to qualify as an independent population.

Interior Trinity Diversity Stratum

Lower Trinity River

A previously unaccounted for boulder-roughs barrier occurs upstream of the Boise Creek confluence with Willow Creek. The barrier functions as a complete barrier to adult coho salmon (A. Collins, USFS, pers. comm.). Williams et al. (2006) determined that independent populations must have at least 34 IP-km. When the IP-km for the Lower Trinity River population was reduced, the total amount of IP-km remained high enough for it to qualify as an independent population.

Upper Trinity River

IP-km in the Upper Trinity River population was changed for two reasons: to account for the gradient of the stream under reservoirs, and because the temperature mask was not appropriate.

The IP model used the surface elevations of the reservoirs as the gradient for those areas of the basin, which artificially inflates the low risk spawner threshold. The historic channel gradient of the Upper Trinity was estimated, and revised IP-km was calculated for the area under the reservoirs. Williams et al. (2006) determined that independent populations must have at least 34 IP-km. After reducing the IP-km as a result of this reservoir analysis, the total amount of IP-km for the Upper Trinity River remained high enough for it to qualify as an independent population.

Because the temperature mask is based on air temperature, it does not account for snowmelt and other sources of cold water within the basin, including releases from Lewiston Dam. Numerous streams which are documented to presently support rearing coho salmon rearing occur under the temperature mask. Williams et al. (2006) recognized the potential limitations of the temperature mask approach in the Upper Trinity. The temperature mask was removed from the Upper Trinity River population, which increased the amount of IP-km in the Upper Trinity River population.

Interior Eel Diversity Stratum

South Fork Eel River and Mainstem Eel River

In response to co-manager comments submitted during the public comment period, NMFS considered 20 proposed natural barriers in the South Fork Eel River and 11 proposed natural barriers in the Mainstem Eel River. NMFS analyzed each proposed natural barrier and determined 24 of the 31 proposed natural barriers met NMFS' criteria. Williams et al. (2006) determined that independent populations must have at least 34 IP-km. After reducing the IP-km as a result of this analysis, the total amount of IP-km for the South Fork Eel River and the Mainstem Eel River population areas remained high enough for each to qualify as an independent population.

Upper Mainstem Eel River, Middle Mainstem Eel River, and Mainstem Eel River

In response to public comments regarding the intrinsic unsuitability of mainstem Eel River habitat for coho salmon, NMFS considered multiple factors that may have resulted in the prior inclusion of IP habitat that may be intrinsically unsuitable due to summer temperature. Factors considered included: 1) mean August air temperature data from Alderpoint, California; 2) the range of potential temperature masks considered in Williams et al. (2006); 3) solar heating due to river orientation; 4) natural valley width; 5) natural lack of riparian shade; 6) measured stream temperatures; and 7) lack of coho salmon presence in summer surveys. Based on the information provided, NMFS excluded the reach of the mainstem Eel River (excluding tributaries) extending from Cape Horn Dam to the westernmost extent of the 21.0 °C temperature mask identified in Williams et al. (2006) from spawner target calculations for each population.

Interior Klamath Diversity Stratum

Salmon River

In response to co-manager comments submitted during the public comment period, NMFS considered and accepted one previously unaccounted for natural barrier. Williams et al. (2006) determined that independent populations must have at least 34 IP-km. After reducing the IP-km as a result of this analysis, the total amount of IP-km for the Salmon River remained high enough for it to qualify as an independent population.

Scott River and Shasta River

In response to numerous comments regarding IP in the Scott River and Shasta River basins, NMFS evaluated IP designations for these populations on a reach-scale. NMFS followed three steps to evaluate IP in the Scott River and Shasta River basins: 1) compare reach-scale National Hydrography Dataset (NHD) stream locations to IP model results; 2) examine reference materials and the California Department of Fish and Wildlife's Calfish database to determine the current reach-scale distribution of anadromous salmonids (including coho salmon) and their habitat within the Shasta and Scott rivers; and, 3) visit sites in the field in these basins where IP has been questioned. The evaluation resulted in considerable changes to IP-km in both populations.

Step One: Comparing NHD and IP results

To compare the NHD dataset with IP model outputs, NMFS used the high-resolution version of the NHD dataset, and assumed that if the IP stream network output and NHD stream locations overlapped, or were found to be within 100-feet of each other, that they were in fact the same stream. This exercise identified areas in the IP stream network output that were inconsistent with stream locations described in the National Hydrography Dataset. Comparison between the NHD stream layers and IP stream network outputs found that, with the exception of the Shasta and Scott River, Independent Populations were consistent (overlapped) 94% on average (**Figure A-1**). The IP stream network output overlapped with the NHD stream layer well in confined areas, and tended to deviate more over the flat, low gradient areas that commonly provide high-quality rearing habitat for juvenile coho salmon. However, the overlap in the Shasta and Scott River basins was 53% and 69%, respectively. This low overlap between the NHD and IP occurred, in part, because these two basins have large low gradient valleys, often with multiple braiding channels, and these channels were difficult to capture consistently between the two modeling exercises. The extent to which human alteration of historic stream channels is responsible for this deviation is difficult to discern.

Steps Two and Three: Considering references and field investigations

Once the degree of overlap between NHD and IP in the Scott River and Shasta River basins was identified (Figure A-2 and Figure A-3), NMFS evaluated whether to exclude certain stream reaches from IP based on whether a previously unidentified natural barrier exists. NMFS' analysis considered that natural barriers can exist due to a steep gradient, a physical blockage such as a boulder or gradient change, or the natural lack of sufficient flow in a reach. The latter may be caused not only by a lack of precipitation, but also by porous geology (Crandell 1989), volcanism, or major debris flows. As part of the evaluation of potential natural barriers, NMFS investigated the current distribution of coho salmon and their habitat (as an indicator of potential condition), as well as the degree of watershed disturbance influencing the reach, which is relevant to whether a barrier is of natural origin. Ultimately, NMFS' recommendation to remove some IP-km was based on evaluation of the best available scientific information, which includes NMFS' professional judgment.

NMFS' evaluation of these sources of information produced one of three outcomes at a reach scale:

- Complete or nearly complete alignment between IP and NHD;
- Lack of agreement between IP and NHD, based on small discrepancies that could be resolved with additional resources.
- Lack of agreement between IP and NHD that could not be resolved. In some cases, streams/stream reaches could not be resolved with a defensible determination of how IP should be adjusted. In those cases, NMFS removed IP where additional resources provided compelling justification to do so.

Examples of the first outcome include the eastside drainages in the Scott River, and the southeast and eastside drainages in the Shasta River. In these areas, there is neither the geology nor residual riparian habitat to sustain surface flow. In some instances, human activities have exacerbated such conditions (*e.g.*, eastside drainages of the Scott Basin). Where geologic and associated hydrologic limitations pose a natural barrier to coho salmon, NMFS removed these reaches from the IP stream network.

Examples of the second outcome are Moffett Creek in the Scott River and Parks Creek in the Shasta River. Though Moffett Creek is not currently considered a coho salmon stream, there is no physical evidence suggesting why it did not previously support coho salmon, and why it could not do so in the future. NMFS used available information to remove IP at a reach-scale in the upper Moffet Creek Basin. In Parks Creek, coho salmon have not recently been observed greater than a mile or two upstream from the I-5 crossing. However, as there is no natural barrier precluding coho salmon presence, NMFS elected to retain these areas within IP.

An example of the third outcome is Willow Creek (near Grenada) in the southwest portion of the Shasta River Basin. Irrigation infrastructure has rendered Willow Creek's drainage network almost unrecognizable compared to historic conditions, though it's late fall/winter surface flow is still occasionally considerable. NMFS removed a portion of IP in Willow Creek where agreement between IP and NHD diverged repeatedly.

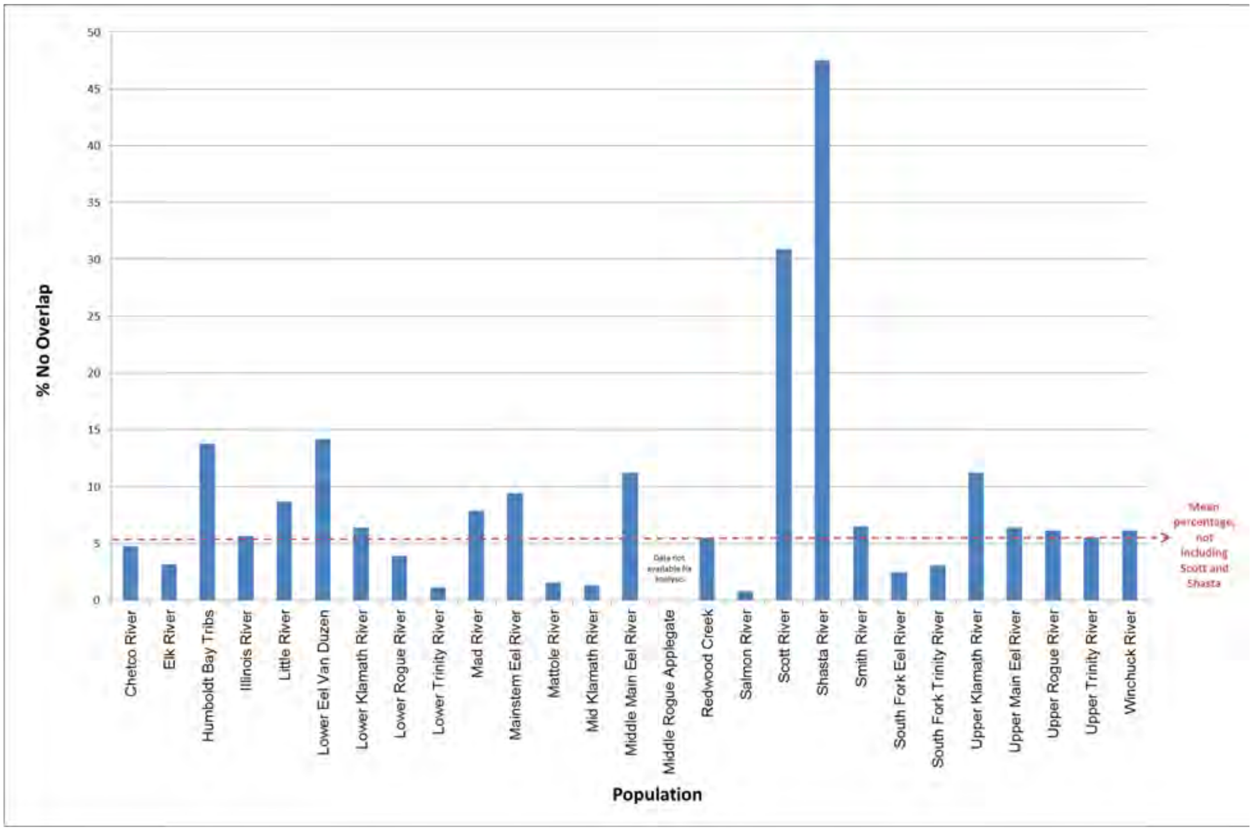

Figure A-1. Percentage of stream lengths for independent populations within the SONCC coho salmon evolutionarily significant unit (ESU) where the National Hydrography Dataset (NHD) of stream layers and Intrinsic Potential (IP) model outputs deviate from each other, indicating potential errors in the IP model output.

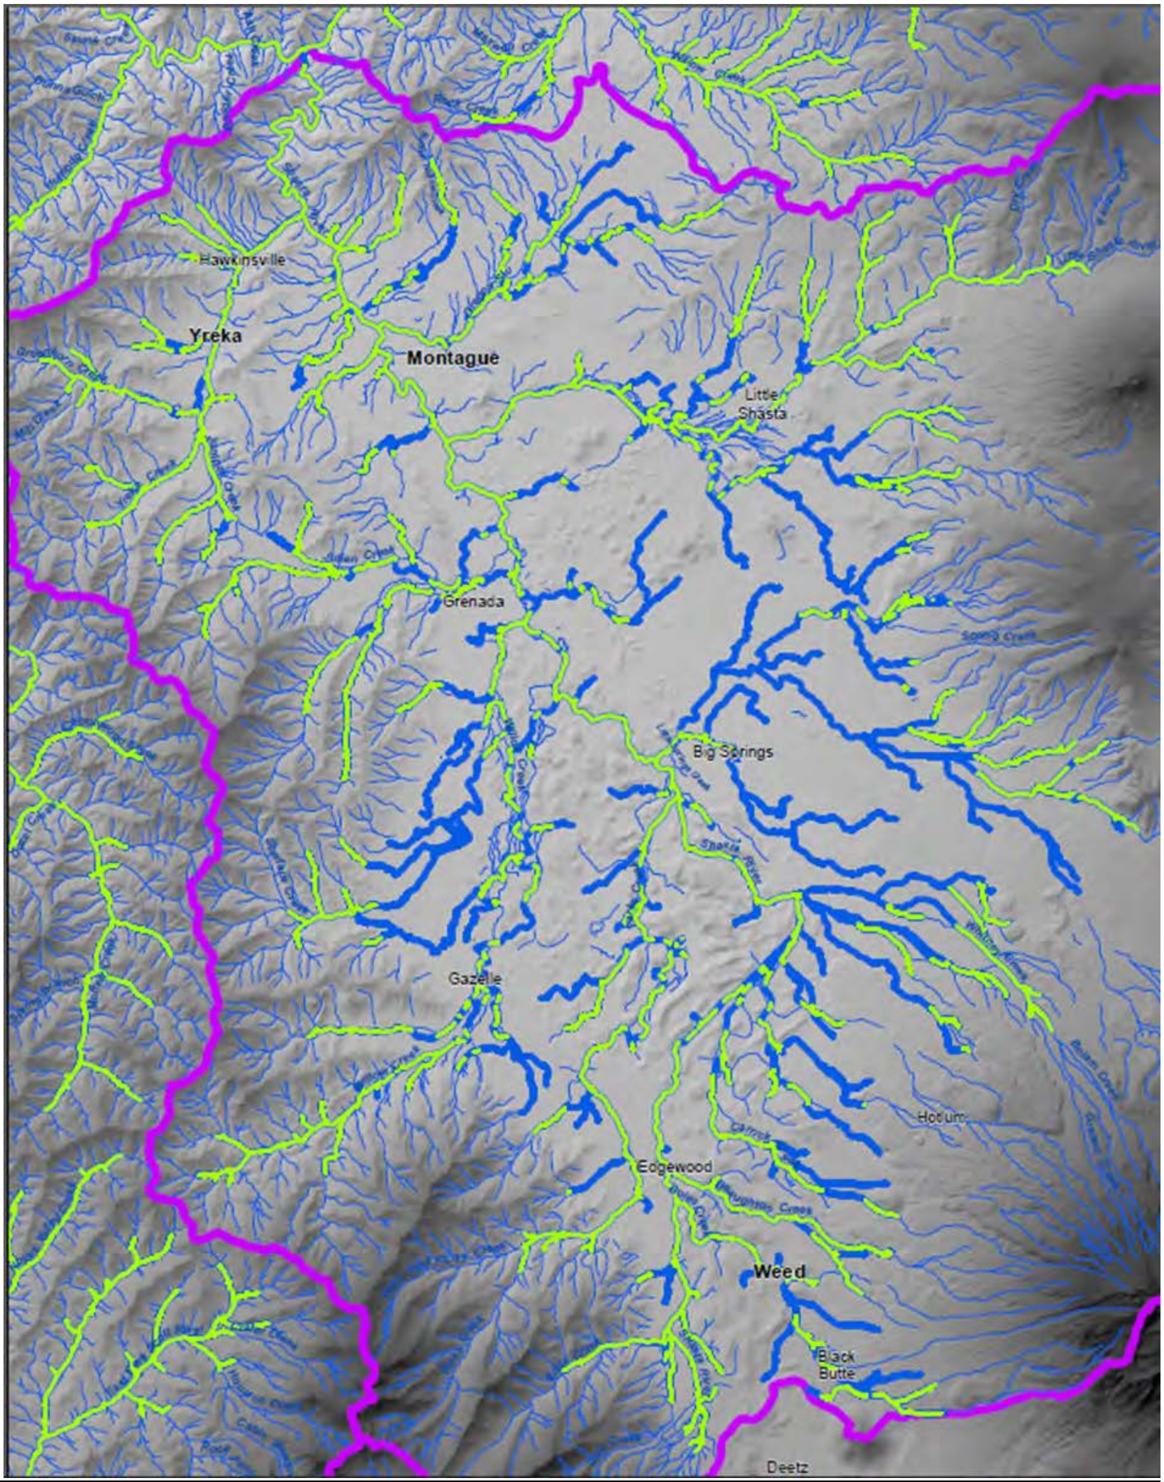

Figure A-2. Map of the Shasta River watershed depicting the results of the comparison between the NHD stream layers and Intrinsic Potential (IP) outputs for coho salmon. Green highlights show areas where IP outputs overlap, or are consistent with the NHD stream layer. Blue highlights depict areas where IP and NHD are inconsistent.

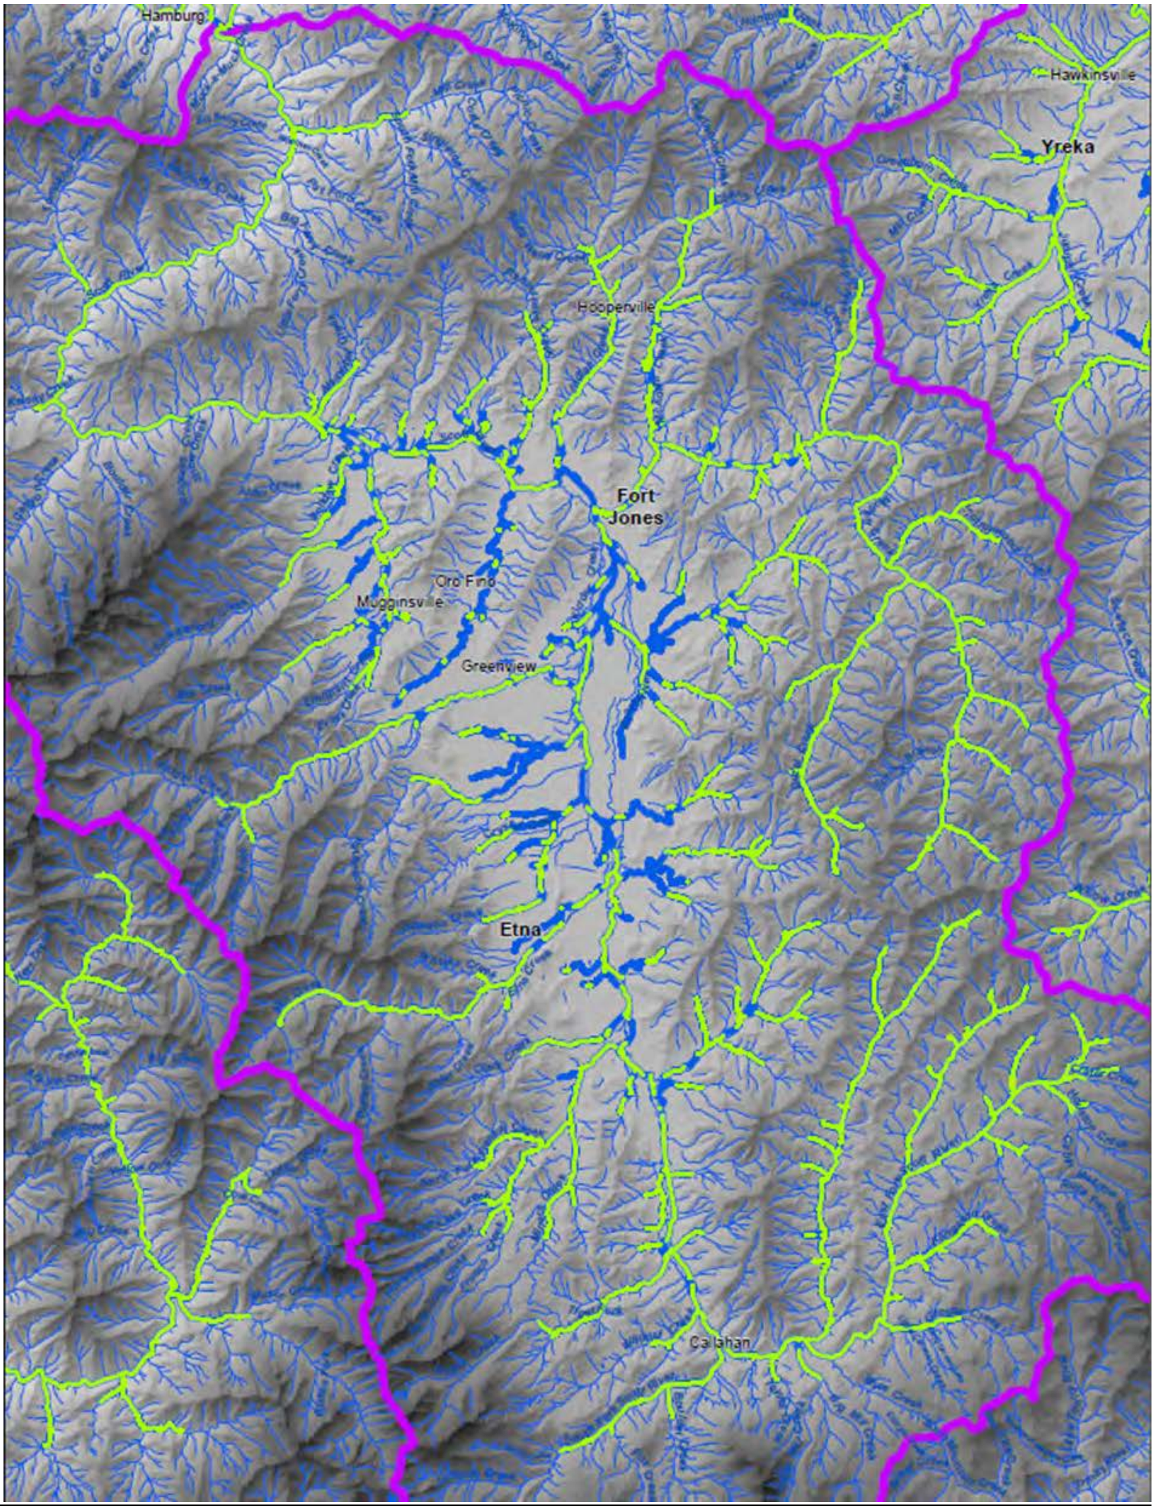

Figure A-3. Map of the Scott River watershed depicting the results of the comparison between the NHD stream layers and Intrinsic Potential (IP) outputs for coho salmon. Green highlights show areas where IP outputs overlap, or are consistent with the NHD stream layer. Blue highlights depict areas where IP and NHD are inconsistent.

Appendix B. Stress and Threat Analysis Methodology

NMFS used several tools to develop and perform a threat and stress assessment, and to develop methods to score additional threat and stress categories. These tools included The Nature Conservancy's Conservation Action Planning (CAP) process, best professional judgment, climate change models and predictions, and empirical data. NMFS used these tools to ascertain current watershed condition, identify severity and scope of stresses, assess the contribution and irreversibility of identified threats, create additional threat and stress categories, and develop population profiles for each population in the SONCC coho salmon ESU. NMFS used the CAP process as a conceptual framework for the threats assessment. The threats assessment process spanned four years and the methodology evolved over time in response to new information, to incorporate new stresses and threats, and in recognition of the limitations of the initial tools (Table B-1).

The use of best professional judgment, in consideration of available data, underlies the entire threat and stress assessment process. Empirical data were acquired, compiled into a database, summarized, and then entered into an initial set of CAP workbooks. Stress and threat ratings in the CAP workbooks were then revised to include professional judgment for additional stresses and threats. NMFS then utilized best professional judgment to assess the accuracy and reliability of the resulting CAP summary tables, produce a comprehensive stress and threat assessment, and develop individual population profiles that detail the current condition of each population area.

The following sections summarize the components of the stress and threats methodology, including the development of the initial CAP workbooks, revision of the CAP workbooks, creation of GIS maps, refinement of the stress and threat summary tables, additional analyses conducted in response to public comment, and the development of additional stress and threat categories (climate change, estuary/mainstem condition, and fishing/collecting).

B.1 Background Information about the CAP Process

As part of the assessment of the viability and condition of SONCC coho salmon populations and their habitat in the SONCC ESU, NMFS performed a series of conservation planning and assessment exercises based upon the Nature Conservancy's Conservation by Design concept (TNC 2006). This concept utilizes Conservation Action Planning (CAP) tools and workbooks to develop a threat and stress assessment. The CAP process is designed to recognize the shifting nature of knowledge and the challenges that causes, by allowing for a regular, iterative process of successive approximations (TNC 2006). The CAP process provided NMFS with a tool to capture the best understanding of the current situation, and develop a set of recovery actions built on that understanding. This understanding included the use of NMFS' best professional judgment and other tools. NMFS utilized this process to identify conservation targets, assess the current status of the selected targets, identify critical threats and stresses occurring in the landscape, and develop a threat and stress assessment that described current population and environmental conditions across the landscape.

NMFS completed the following planning and assessment activities:

1. Identified conservation targets
2. Assessed the current status of conservation targets
3. Determined potential stresses and threats
4. Compiled available literature, empirical data, and best professional knowledge on the condition of the landscape
5. Rated these stresses and threats across the landscape
6. Developed recovery actions to decrease or eliminate the stresses and threats.

The first step in the process was to identify the conservation targets, which were the life stages of coho salmon in the SONCC coho salmon ESU. Next, NMFS assessed the current status of conservation targets by reviewing all available monitoring data on coho salmon population trends.

NMFS then used the best available information to identify the stresses affecting coho salmon populations and the sources of the stresses, also known as threats. Most stresses are caused by incompatible human uses of land, water and natural resources. Stresses destroy, degrade or impair conservation targets by impacting a key ecological attribute relating to their size, condition or landscape context (TNC 2006). Natural factors such as rainfall and marine productivity (ocean conditions, El Niño) were identified as factors for the decline of the SONCC coho salmon ESU (62 FR 24588; May 6, 1997). NMFS elected to not describe these natural factors as threats in this recovery plan for two reasons. First, SONCC ESU coho salmon evolved to live with natural variation in rainfall and marine productivity, and it was likely a combination of these factors with habitat degradation, fishing, and other human-caused threats that led to their decline. Populations that are fragmented or reduced in size and range are more vulnerable to extinction by natural events (62 FR 24588, May 6, 1997), and NMFS chose to focus on the causes of population fragmentation and reduced size rather than natural factors. Second, there is little that recovery actions can do to affect change in natural factors such as rainfall or marine productivity. NMFS developed recovery actions to reduce the detrimental effects of the result of that rainfall (e.g., droughts and floods). For example, water resources can be managed to ensure sufficient water remains in waterways when coho salmon need it even during drought conditions, and land can be managed to promote bank stability and reduce the likelihood that floods will release large amounts of sediment into coho salmon habitat. Similarly, in years when marine productivity is expected to be poor, fishing effort can be moderated to allow sufficient spawner escapement, as described in the current management of ocean salmon fisheries (Sharr et al. 2000). In short, the recovery plan addresses the causes of population fragmentation and decline that can be improved by human actions. Therefore, stresses are the destruction, degradation or impairment of SONCC ESU coho salmon habitats and ecosystem processes caused directly or indirectly by human sources. A threat is the proximate cause of a stress. The stresses and threats considered are either current or have high potential to occur in the next ten years[13] under current circumstances and management (TNC 2006). Ten years was chosen to capture reasonably foreseeable events in the near future. The threats and stresses selected for inclusion in the CAP workbooks are the same as those identified at the time of listing. Eight stresses and 11 threats were identified and analyzed using the CAP toolbox (Table B-1 and Table B-2). After completing the CAP exercises, three additional categories were created and assessed using the other tools available. More information on these additional threats and stresses are explained later.

After threats and stresses were selected, a large amount of data, literature, and other information were acquired to inform the assessment of stresses and threats. The CAP process uses a simple grading scale to assess the current status of threats and stresses –Very High, High, Medium, Low. This four-part ranking scale is based on over 20 years of similar application by natural heritage inventory programs throughout the United States (TNC 2003). It provides a sufficient degree of distinction among the four scores and allows for a reasonable confidence level, while recognizing the lack of the information that would be needed to provide more precise rankings (TNC 2003).The final step was to develop a list of recovery actions designed to decrease or eliminate the stresses and threats. These actions were prioritized to address the most important stresses and threats and to focus effort on the coho salmon populations with the most promising prospects for recovery.

B.2 Development of Initial CAP Workbooks Based on Data

The initial CAP workbooks were produced using only empirical data , with the exception of inclusion of pre-existing USFS and ODFW professional judgments.

For the six stresses included in the initial set of CAP workbooks, one or more indicators of aquatic habitat suitability were used to quantitatively assess each stress. To minimize data gaps, the list of indicators was tailored to match the specific data metrics widely available for populations in the SONCC coho salmon ESU, rather than a comprehensive list which would

[13] 50 years was used for climate change given the longer-term nature of changes in its effects.

include indicators only available for some populations. For each indicator, NMFS developed a set of benchmarks for rating habitat suitability for coho salmon on a four-category scale (poor, fair, good, very good) based on the best available scientific literature (Kier Associates and NMFS 2008)(Table B-3). A few of the indicators reflect previous professional judgments by USFS and ODFW and so are not quantitative. In addition, some threats were quantitatively assessed using GIS analyses (Table B-4).

Table B-3. Indicators of aquatic habitat suitability for coho salmon, with reference values. Table adapted from Kier Associates and NMFS (2008).

Stress	Indicator	Poor	Fair	Good	Very Good
Altered Hydrologic Function	Flow Restoration Needs (ODFW judgment)	3.5-4	2.5-3.5	1.5-2.5	1-1.5
Altered Hydrologic Function	Water Quantity/Flow Regime (USFS judgment)	Altered	Partially Altered		Unaltered
Altered Sediment Supply	Embeddedness (%)	>45%	30.1-45%	25.1-30%	<=25 %
Altered Sediment Supply	Fines (Dry Sample) (% <1 mm)	>12.6%	11.1-12.6%	8.9-11.1%	<8.9%
Altered Sediment Supply	Fines (Wet Sample) (% <1 mm)	>17%	15-17%	12-15%	<12%
Altered Sediment Supply	Sand (Dry Sample) (% <6.4 mm)	>25.8%	21.5-25.8%	12.9-21.5%	<12.9%
Altered Sediment Supply	Sand (Wet Sample) (% <6.4 mm)	>30%	25-30%	15-25%	<15%
Altered Sediment Supply	Silt/Sand Surface (% riffle area)	>17	15-17	12-15	<12
Altered Sediment Supply	Turbidity (hours/year >25 FNU)	>720	361-720	120-360	<120
Altered Sediment Supply	VStar	>0.25	0.21-0.25	0.15 - 0.21	<0.15
Barriers	Fish Passage (% of Dry Habitat Types)	>5%	1-5%	<1%	0%
Degraded Riparian Forest Conditions	Canopy Cover (% Shade)	<60% shade	60-70% shade	70.1-80% shade	>80% shade
Degraded Riparian Forest Conditions	Canopy Type (% Open + Hardwood)	>40%	30-40%	20-30%	<20%
Degraded Riparian Forest Conditions	Riparian Condition (conifers >36" dbh / 1000ft)	<75	75.0-125	125-200	>200
Degraded Riparian Forest Conditions	Stream Corridor Vegetation (USFS judgment)	Impaired	Functioning At-risk		Properly Functioning
Impaired Water Quality	Aquatic Invertebrates (B-IBI NorCal)	<40	40-60	60.1-80	>80
Impaired Water Quality	Aquatic Invertebrates (EPT)	<=12	12.1-17.9	18-2523	>23

Stress	Indicator	Poor	Fair	Good	Very Good
Impaired Water Quality	Aquatic Invertebrates (Rich)	<25	25-30	30-40	>40
Impaired Water Quality	D.O. (COLD) (mg/l 7-DAMin)	<6.0 mg/l	6-6.5 mg/l	6.5-7.0 mg/l	>7.0 mg/L
Impaired Water Quality	D.O. (SPAWN) (mg/l 7-DAMin)	<9 mg/l	9-10 mg/l	10-11 mg/l	>11.0 mg/l
Impaired Water Quality	pH	>8.75	8.5-8.75	8.25-8.5	<8.25
Impaired Water Quality	pH (annual maximum)	>8.75	8.5-8.75	8.25-8.5	<8.25
Impaired Water Quality	Temperature (MWAT) (C)	>17ºC	16-17ºC	15-16ºC	<15ºC
Impaired Water Quality	Temperature (MWMT) (C)	>18.3ºC	17-18.3ºC	16-17ºC	<16ºC
Lack of Floodplain and Channel Structure	D50 (median particle size) (mm)	<38 or >128	38-50 or 110-128	50-60 or 95-110	60-95 mm
Lack of Floodplain and Channel Structure	Floodplain Connectivity (USFS judgment)	Impaired	Functioning At-risk		Properly Functioning
Lack of Floodplain and Channel Structure	Pool Depth (Ave. in Feet)	<2 Ft	2-3 ft	3-3.3 ft	> 3.3 ft.
Lack of Floodplain and Channel Structure	Pool Frequency (% by Area)	<10%	10-20%	20-35%	>35%
Lack of Floodplain and Channel Structure	Pool Frequency (% by Length)	<35%	35-40%	40-50%	>50
Lack of Floodplain and Channel Structure	Wood Frequency ODFW (key pieces/100m)	>1	1-2	2-3	>3
Lack of Floodplain and Channel Structure	Wood Frequency USFS: streams <20 ft. wide	>35 pieces/mi	35-53	54-84	<85
Lack of Floodplain and Channel Structure	Wood Frequency USFS: streams >30 ft. wide	>16 pieces/mi	16-33	33-60	<60
Lack of Floodplain and Channel Structure	Wood Frequency USFS: streams 20-30 ft	>25 pieces/mi	26-36	37-64	<65

Table B-4. Quantitative metrics used to assess threats. Table from Kier Associates and NMFS (2008).

Threat	Metric	Low	Medium	High	Very High
Timber Harvest	Harvested area, as percent of watershed	<10%	10-25%	25-35%	>35%
Agricultural Practices	Pasture/hay and cultivated crops, as a percent of watershed	<2%	2-5%	5-10%	>10%
Roads	Road Density (mi/sq. mi)	<1.6	1.6-2.5	2.5-3.0	>3.0
Urban/Residential/ Industrial	Total impervious area, as a percent of watershed	<5%	5-10%	10-25%	>25%

Indicator and threat data were acquired, reformatted, and compiled into a Microsoft Access database. Data were tagged with stream name and either spatial coordinates or GIS-linked stream reach codes (LLID), so that summaries for SONCC CAP populations or other spatial units could be produced as needed.

Data were gathered from all available sources including grey literature, peer reviewed literature, monitoring and research efforts, and county and state planning efforts. Data contributors include the California Department of Fish and Wildlife (CDFW), Oregon Department of Fish and Wildlife (ODFW), U.S. Forest Service (USFS) Region 5 (R5) and Region 6 (R6), California State Water Resources Control Board (SWRCB), Oregon Department of Environmental Quality (ODEQ), California Department of Forestry and Fire Protection (CAL-FIRE), U.S. Environmental Protection Agency (EPA), the Bureau of Reclamation (Reclamation), the Bureau of Land Management (BLM), the U.S. Fish and Wildlife Service (USFWS), the Yurok Tribe, Karuk Tribe, Hoopa Valley Tribe, Resource Conservation Districts (RCDs), Utah State University's (USU) Bug Lab, Klamath Resource Information System (KRIS), the Conservation Biology Institute, South Coast and Lower Rogue Watershed Councils, Mattole Restoration Council, Mattole Salmon Group, and other contributors. A complete list of datasets is included in Appendix C.

A master CAP workbook template was created. Then a set of custom Python computer programs was used to summarize information from the database to the population level and transfer the summaries into a separate CAP workbook for each population.   This methodology ensured that all workbooks used the same criteria and setup, and avoided labor-intensive and error-prone manual data entry. The initial set of CAP workbooks for each population was created in June 2007.

B.3   Revised CAP workbooks Incorporating Professional Judgment

Data were lacking for some indicators and threats that are recognized as affecting coho salmon or their habitats. NMFS staff conducted an extensive review of literature for SONCC coho salmon population watersheds to derive values for those factors. Documents included federal agency watershed analyses, TMDL reports, restoration plans and locally-driven watershed assessments. These supplementary data were then incorporated into the Microsoft Access database and a revised set of CAP workbooks was created in November 2008. This set of workbooks considered NMFS professional judgment in addition to available empirical data. If available empirical data were incomplete, e.g., from only one side of the watershed, NMFS applied its specialized knowledge of the area to determination the appropriate ratings for stresses and threats.

B.4 GIS Maps

NMFS also created GIS (Geographic Information System) maps using the instream monitoring and landscape data compiled for each population. These maps are available upon request from the SONCC recovery coordinator in Adobe Acrobat (PDF) format and are designed to be used as electronic documents, not printed. The many layers in the maps can be toggled on/off and users can zoom in to see more detail. There are two PDF maps included for each population. The main set of maps contains the stress and threat data, in addition to base layers such as coho IP and streams, and was completed in May 2010. The second set of maps was completed in December 2009 and includes canopy change over various time periods and tree size. These maps are described in Appendix I and were used to analyze and interpret habitat condition across the landscape. Additionally, boundary maps for each population unit showing land ownership, coho distribution, and IP habitat are included as the first figure in each population profile.

B.5 Creation of Stress and Threat Summary Tables for the 2012 Public Draft and Final Recovery Plan

The CAP workbooks produced summary tables that display the ranking for identified threats and stresses, the severity of the impact on each life stage (egg, juvenile, smolt, adult), and an overall ranking. One summary table for threats and one summary table for stresses are provided for each independent and dependent population (e.g., Table B-5 and Table B-6).

Table B-5. Example of summary table for identified stresses. Note: table contains ranks for stress Impaired Estuary/Mainstem Function that was not included in the CAP workbooks.

	Stresses	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Stress Rank
1	Lack of Floodplain and Channel Structure[1]	High	High	Very High[1]	Very High	Very High	Very High
2	Impaired Water Quality[1]		High	Very High[1]	High	Low	High
3	Degraded Riparian Forest Conditions	-	High	High	High	Medium	High
4	Impaired Estuary/Mainstem Function	-	Low	Medium	High	Low	Medium
5	Altered Hydrologic Function	Low	Low	High	Medium	Medium	Medium
6	Altered Sediment Supply	Medium	Medium	Medium	Low	Medium	Medium
7	Barriers	-	Medium	Medium	Low	Medium	Medium
8	Adverse Hatchery-Related Effects	Low	Low	Low	Low	Low	Low
9	Increased Disease/Predation/Competition	Low	Low	Low	Low	Low	Low
10	Adverse Fishery- and Collection-Related Effects	-	-	Low	Low	Low	Low

[1]Key limiting stresses and limited life stage.

Table B-6. Example of summary table for identified threats. Note: table contains ranks for the threats Fishing and Collecting and Climate Change that were not included in the CAP workbooks.

Threats		Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Threat Rank
1	Agricultural Practices[1]	High	Very High	Very High[1]	Very High	Very High	Very High
3	Channelization/Diking[1]	High	High	High[1]	Medium	Medium	High
2	Dams/Diversions	Low	Medium	High	High	Medium	High
4	Road/Stream Crossing Barriers	-	Low	High	Medium	High	High
5	Roads	Low	Medium	Medium	Medium	Medium	Medium
6	Timber Harvest	Medium	Medium	Medium	Medium	Low	Medium
7	Invasive/Non-Native Alien Species	-	Medium	Medium	Medium	Medium	Medium
8	Climate Change	-	-	Medium	Medium	Medium	Medium
9	High Severity Fire	Low	Low	Low	Low	Low	Low
10	Hatcheries	Low	Low	Low	Low	Low	Low
11	Mining/Gravel Extraction	Low	Low	Low	Low	Low	Low
12	Urban/Residential/Industrial Dev.	Low	Low	Low	Low	Low	Low
13	Fishing and Collecting	-	-	Low	Low	Low	Low

[1]Key limiting threats and limited life stage.

After the summary tables were developed, NMFS used best professional judgment to further assess the severity of the identified threats and stresses. Best professional judgment was employed to verify the CAP results, override results known to be erroneous, or include information where no current data are available. While empirical data are the preferred information with which to conduct population area condition assessments, develop indicator criteria, and evaluate threats and stresses in an area, these data are not always available or may be too old for current uses. This was the case in many areas in the SONCC coho salmon ESU. In such cases, NMFS used professional judgment to improve the accuracy of the threat and stress assessment. The summary tables were also revised in response to a subset of public comments.

B.5.1 Analyses of Stresses and Threats Added to Final Plan

To strengthen the technical basis for the recovery plan, and to respond to comments received on the public draft of the recovery plan, NMFS developed and implemented frameworks to re-evaluate several stresses and threats in a more quantitative and comprehensive fashion than had been conducted previously. These new analyses were performed on the stress of altered hydrologic function and the threats of dams/diversions and timber harvest. The following sections provide brief overviews of the analyses, with full details available in separate documents (Asarian 2014 and NMFS 2014).

Altered Hydrologic Function and Dams and Diversions

The stress of altered hydrologic function is strongly affected by the threat of dams and diversions; therefore, NMFS assessed them together in a combined analysis (Asarian 2014). The final products of the analysis were stress ranks for 'altered hydrologic function' and threat ranks for 'dams and diversions' for each coho salmon population and life stage. These ranks (i.e., very high, high, medium, or low) are professional judgments that are informed by a wide variety of information and detailed analyses, as summarized in Figure B-1. The resulting threat ranks were provided to NMFS staff for use in the recovery plan; however, NMFS allowed population profile authors to use professional judgment to over-ride these ranks, because the relatively coarse nature of this analysis does not take all relevant factors into account.

Various data sources were used to calculate indicators of the magnitude of the hydrologic alteration, as well as other effects of dams and diversions such as fish passage barriers. Some indicators were relatively simple to calculate while others required a series of complicated analytical steps. The diagram in Figure B-2 summarizes the data sources and calculation methods for each indicator. After indicators values were calculated, they were then rated on a four-category scale (very good, good, fair, poor), according to rules (i.e., category definitions) that were based on a combination of literature and professional judgment (Table B-7 and Table B-8). As an illustration of one example indicator, Figure B-3 maps the long-term (1953 to 2012) trend in minimum 30-day average streamflow. Besides the indicators listed in Figure B-2, supplemental analyses of streamflow and precipitation were also conducted and are presented in the report; however, these were only tangentially considered in the judgment process.

.

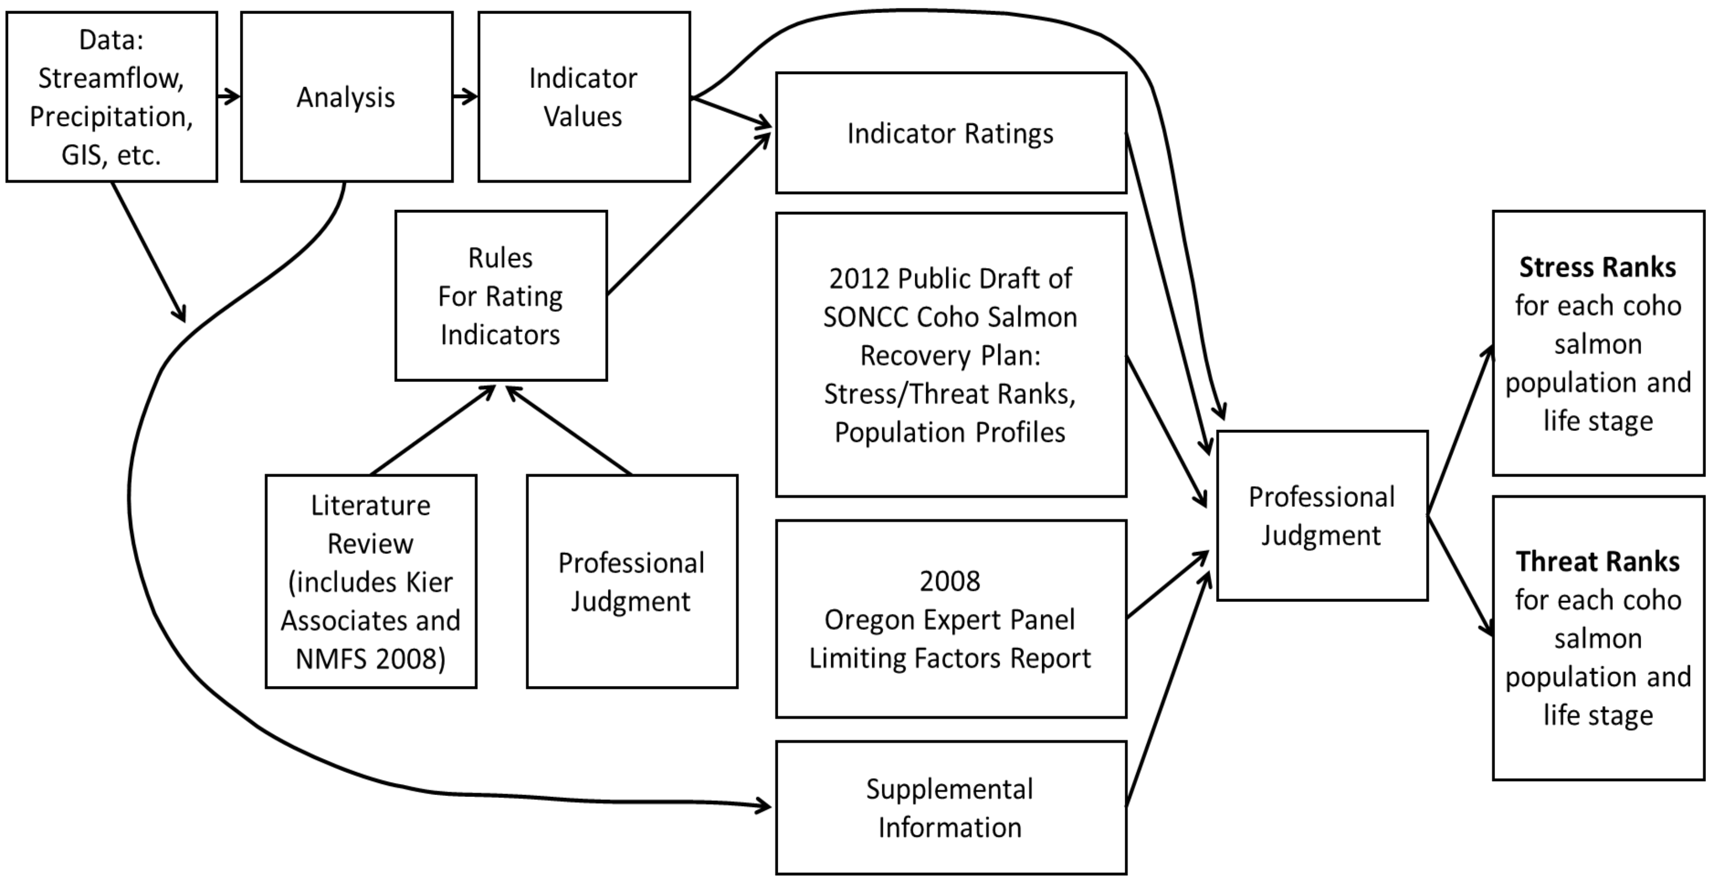

Figure B-1. Summary of process used to inform professional judgments and derive stress ranks for ‘altered hydrologic function’ and threat ranks for ‘dams and diversions’.

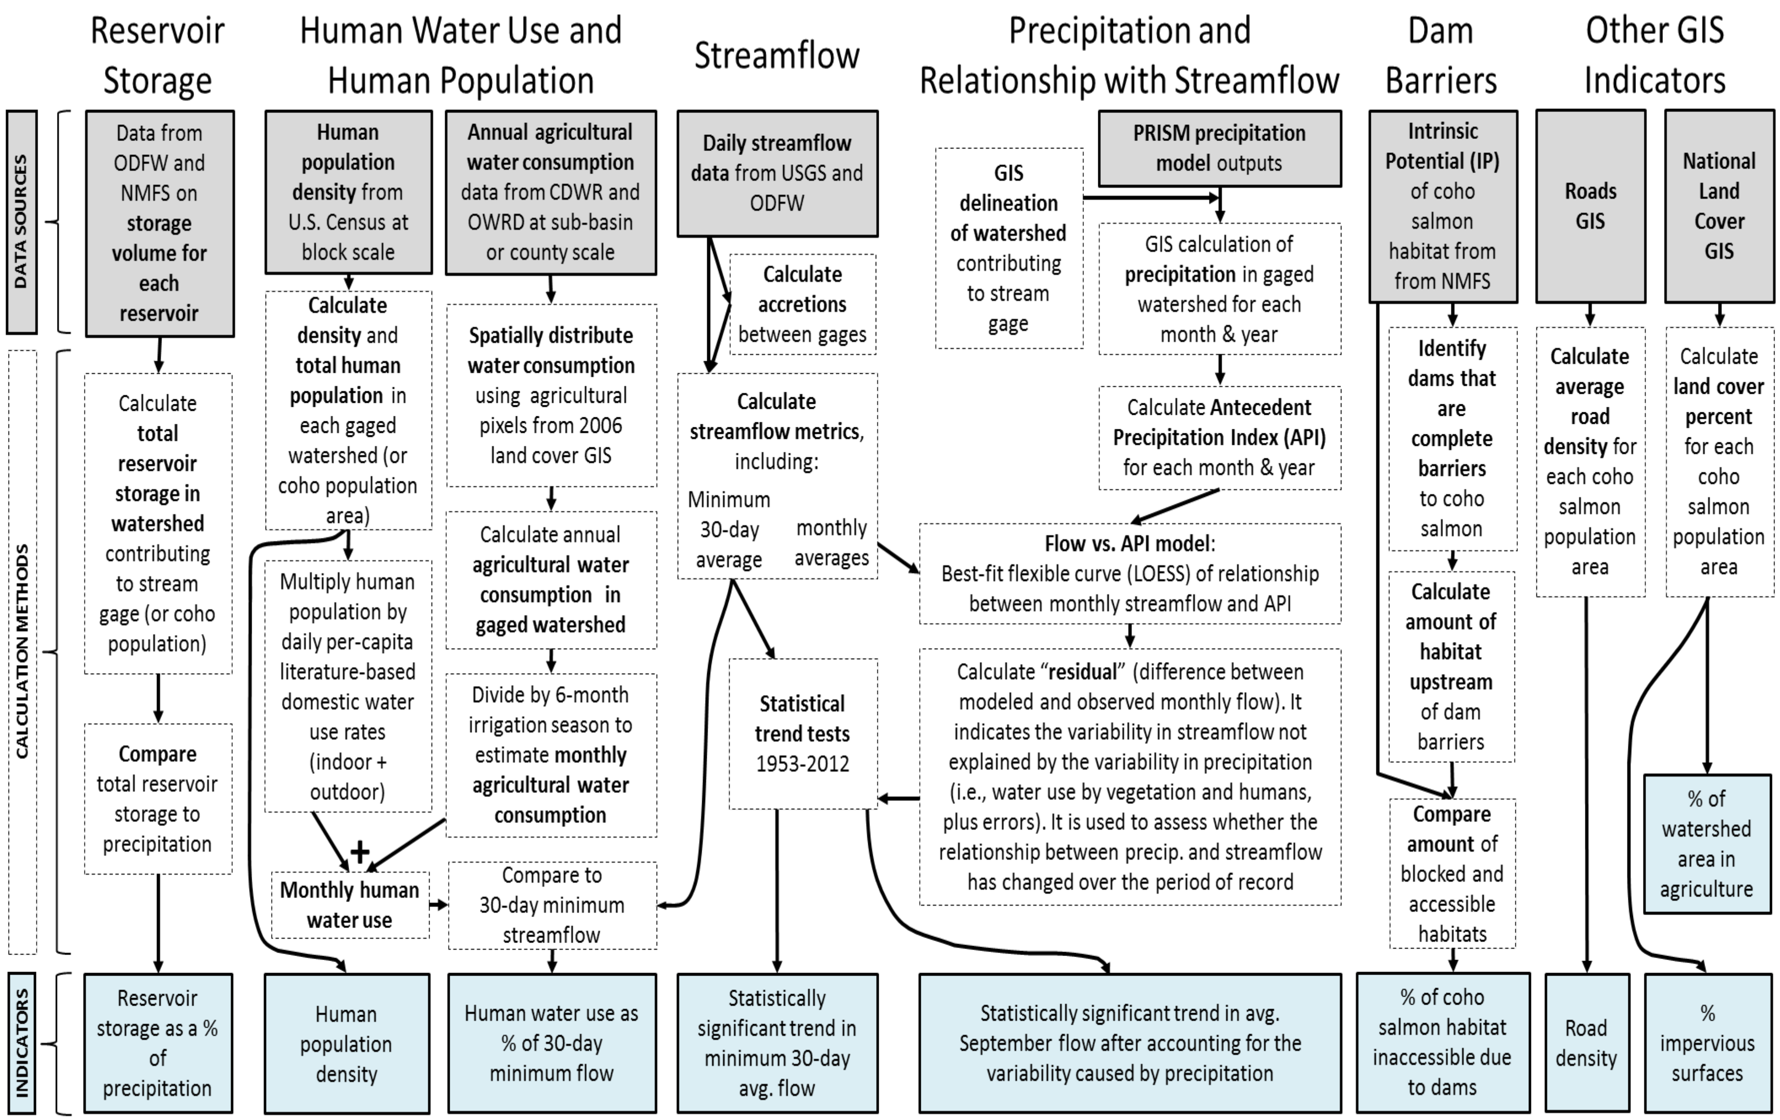

Figure B-2. Diagram summarizing the data sources (gray boxes at top) and calculation methods (hollow boxes in middle) used for each indicator (blue boxes at bottom).

Table B-7. Quantitative indicators for altered hydrologic function stress.

Indicator	Poor	Fair	Good	Very Good
Reservoir storage as a % of precipitation	>15%	>5-15%	0.5-5%	<0.5%
Statistically significant trend[*] in minimum 30-day average flow	>1%/yr decrease	>0.5-1.0%/yr decrease	0-0.5%/yr decrease	Increase or no significant trend
Statistically significant trend[*] in average September flow with the effect of precipitation accounted for	>1%/yr decrease	>0.5-1.0%/yr decrease	0-0.5%/yr decrease	Increase or no significant trend
Human water use (domestic plus agricultural) as a % of 30-day minimum flow	>50%	>20-50%	2-20%	<2%
Human population density	>25 persons/ km.^{2}	>5-25 persons/ km.^{2}	1-5 persons/ km.^{2}	<1 persons/ km.^{2}
% of watershed area in agriculture	>10%	>5-10%	2-5%	<2%
% impervious surfaces	>25%	>10-25%	5-10%	<5%
Road density	>3.0 mi/mi^2	>2.5-3.0 mi/mi^2	1.6-2.5 mi/mi^2	<1.6 mi/mi^2

* Trends evaluated for the period 1953-2012. Percent is relative to the median of the entire period, not the start of period, so total change for the period would be the per-year trend slope multiplied by 30 (half the 60-year period). Threshold of statistical significance is $p < 0.10$.

Table B-8. Quantitative indicators for dams/diversions threat.

Indicator	Poor	Fair	Good	Very Good
% of coho salmon habitat inaccessible due to dams	>40%	>15-40%	1-15%	<1%
Reservoir storage as a % of precipitation	>15%	>5-15%	0.5-5%	<0.5%
Domestic water use as a % of 30-day minimum flow	>50%	>20-50%	2-20%	<2%
Agricultural water use as a % of 30-day minimum flow				
Human population density	>25 persons/km.^{2}	>5-25 persons/km.^{2}	1-5 persons/km.^{2}	<1 persons/km.^{2}
% of watershed area in agriculture	>10%	>5-10%	2-5%	<2%

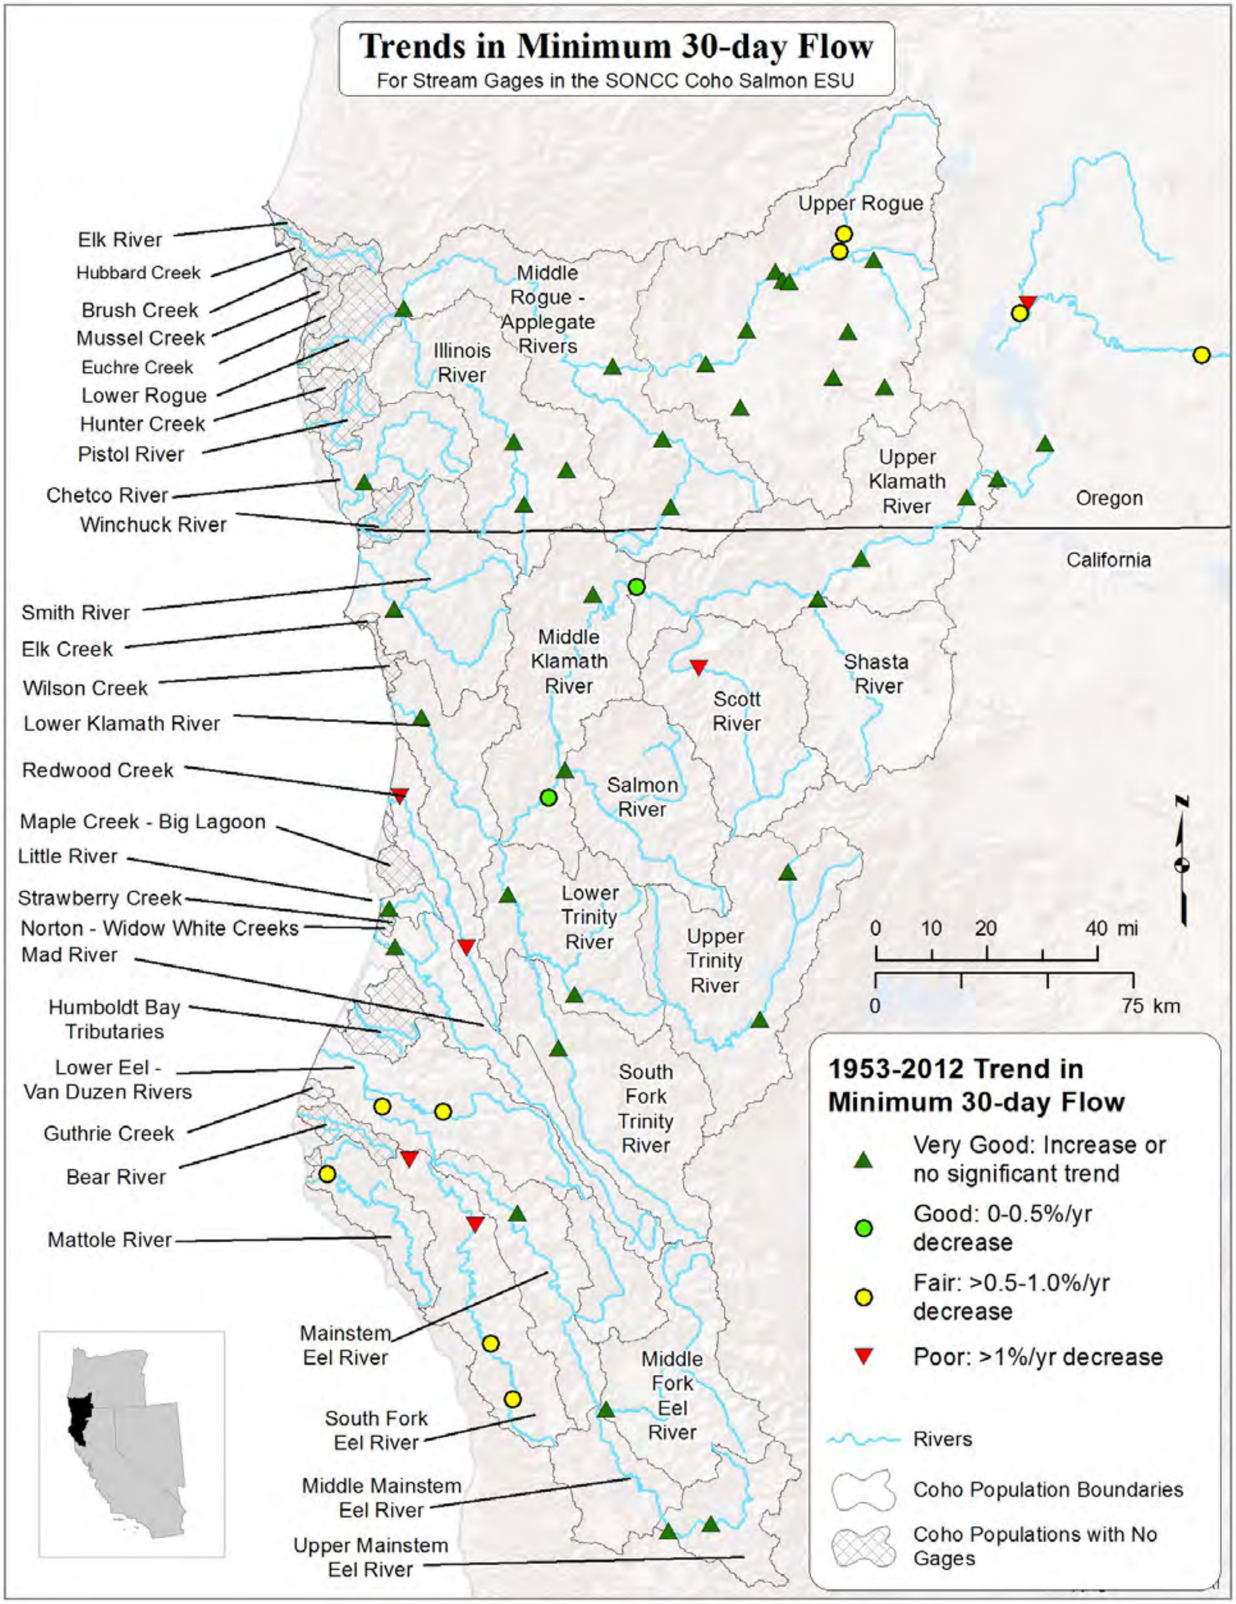

Figure B-3. Map of 1953-2012 trends in minimum 30-day streamflow. Gages are color-coded according to the rules in Table B-7.

Timber Harvest

NMFS evaluated the threat of 'Timber Harvest' within the next ten years (2014-2024) in the SONCC coho salmon ESU. Ten years was chosen to capture reasonably foreseeable events in the near future. The methods and results of the analysis are described in detail by NMFS (2014) and briefly described here. Three metrics are used in the assessment: 1) The Watercourse Management Area Index (WMAI) rates watercourse protection; 2) The Magnitude of Harvest (MH) rates the predicted harvest intensity; and 3) The Conservation Plan (CP) connotes whether timber harvest is guided by a conservation plan.

WMAI consists of four watercourse protection measures, each of which was assessed independently for Class I, Class II, and Class III streams: 1) Width of the Watercourse Management Area, 2) Width of the no-cut zone, 3) inner band canopy retention requirements, and 4) large tree retention requirements (Table B-9).

Rates of harvest were determined from ownership-specific management plans or monitoring reports, or from a literature review of harvest rates for ownership categories, and were then rated according to the rules in Table B-10.

Ownerships with an active conservation or restoration plan that has been approved by NMFS through applicable Endangered Species Act processes received points for the Conservation Plan (CP) metric, while ownerships that do not have a NMFS-approved conservation plan received no points.

The three metrics are summed together to obtain an 'ownership score' for each ownership (Table B-11). The overall threat score for each coho salmon population was determined by calculating an area-weighted average of the ownership scores, with the weight proportional to the percent of the forested area within a coho population area that an ownership covers. In populations with a low percentage (i.e., <75%) of forest area, to account for the reduced threat of timber harvest relative to other threats, an adjustment factor was applied based on the percent of forest area. Using a four-category scale (i.e., low, medium, high, and very high), a threat rank for timber harvest was then assigned according to the overall threat score.

The resulting threat ranks were provided to NMFS analysts for consideration in the recovery plan. However, the NMFS analysts contributing to the development of population profiles had an opportunity to consider other information that was not factored into the main assessment and apply professional judgment to "over-ride" these ranks.

Table B-9. Summary of the values used in the calculation of the Watercourse Management Area Index.

Class I Watercourse	Very Good (4)	Good (3)	Fair (2)	Poor (1)
Width of Watercourse Management Area (one side)	≥ 300’	150-299’	100-149’	< 100’
Width of No-Cut Zone (one side)	≥ 300	≥ 30’	15-29’	0-14’
Inner Band Overstory Canopy Retention (live trees, all species)	100%	70% (30-100’ width)	50-69%	None enforceable
Large Tree Retention	100%	13 largest TPA[1] (30-100 width’)	15 conifers/acre >16” dbh within RMA. Some large trees protected by canopy retention and LWD recruitment requirements	L: 40 live conifer trees per 1000’ >11” or M: 30 live conifer trees per 1000’ >8”
Class II Watercourse	**Very Good (4)**	**Good (3)**	**Fair (2)**	**Poor (1)**
Width of Watercourse Management Area	≥ 150’	100’-150’	76’-100’	< 75’
Width of No-Cut Zone	≥ 150’	≥ 30’	15-29’	0-14’
Inner Band Overstory Canopy Retention (live trees, all species)	100%	70% (25% conifer)	50-69%	None enforceable
Large Tree Retention	100%	13 largest TPA[1] (30-100 width’)	≥ 20’ no-cut buffer, plus L: 40 live conifer trees per 1000’ >11” or M: 30 live conifer trees per 1000’ >8”.	Canopy retention requirements likely protect some large trees
Class III Watercourse	**Very Good (4)**	**Good (3)**	**Fair (2)**	**Poor (1)**
Width of Watercourse Management Area	≥ 100’	≥ 50’ ELZ[2]	30’-49’ ELZ[2]	<30’ ELZ[2]
Width of No-Cut Zone	≥ 100’	≥50’	0-49’ and/or retain channel-stabilizing trees	None
Canopy Retention (live trees, all species)	100%	100% in inner zone, 50% in outer zone	Retain hardwoods, retain conifer to meet stocking, retain all trees in channel zone	Retain trees leaning over channel

[1] TPA = trees per acre.
[2] ELZ = equipment limitation zone with designated skid trail crossings.

Table B-10. Values used for rating Magnitude of Harvest (MH) metric, expressed as the percent of the forested area (as clear-cut equivalent) harvested annually, or as a percent of timber inventory volume harvested annually.

	Very High (1.5 point)	High (3.0 point)	Medium (4.5 points)	Low (6.0 points)	None (7.5 points)
Percent Harvest	>2%	1-2%	0.5-0.99%	0.01-0.49%	0%
Ownership category	Private industrial timberland	Private non-industrial timberland	Hoopa Tribe, BLM OR (unreserved)	USFS (unreserved), BLM CA (unreserved)	USFS (reserved), BLM (reserved), States of CA and OR, NPS, Other

Table B-11. Watercourse Management Area Index (WMAI), Magnitude of Harvest (MH), and Conservation Plan (CP) values used to calculate ownership scores, and resulting category scores.

Adverse Hatchery-Related Effects (Stress) and Hatcheries (threat)

The percent of observed adults of hatchery origin is used as an indicator of relative genetic risk to a coho salmon population. Use of less than 5 percent as the threshold for low risk is consistent with the approach described in Williams et al. (2008). Williams et al. (2008) does not provide guidance regarding the degree of risk above 5 percent. The status review for Oregon salmon and steelhead populations in the Willamette and Lower Columbia basins (McElhany et al. 2007) describes categories of genetic risk from hatcheries with break points at 10 percent and 30 percent, and this convention is adopted for all SONCC coho salmon life stages (Table B-12). Ecological effects of hatcheries are accounted for in the Medium stress and threat rank, which is assigned if there is a salmonid hatchery in the basin.

Table B-12. Criteria for ranking hatchery-related stress (Adverse Hatchery Effects) and threat (Hatcheries).

Rank	Definition
Low	Less than 5 percent of observed adults are of hatchery origin AND there is no salmonid hatchery is in the basin.
Medium	Greater than or equal to 5 percent and less than or equal to 10 percent of observed adults are of hatchery origin OR there is a salmonid hatchery in the basin.
High	Greater than 10 percent and less than 30 percent of observed adults are of hatchery origin.
Very High	Greater than or equal to 30 percent of observed adults are of hatchery origin.

B.5.2 Additional Threat and Stress Categories

NMFS developed categories for additional threats and stresses that are currently impacting the SONCC coho salmon ESU. Some were not identified at the time of listing, but are considered to be affecting SONCC coho salmon populations currently. These categories were developed for Climate Change, Impaired Estuary and Mainstem Function, fishing-related stress and threat ("Adverse Hatchery-Related Effects" and "Fishing and Collecting"), and hatchery-related stress and threat ("Adverse Fishery-Related Effects" and "Fishing and Collecting"). Since no empirical data are available for these categories, NMFS utilized additional tools to perform the threat and stress assessment and ranking. NMFS did not utilize the CAP workbooks to predict ratings for these new threat and stress categories. NMFS utilized professional judgment when ranking and assessing the severity for each life stage for the Estuary and Mainstem Condition category. For Climate Change, NMFS utilized climate change models and predictors that assessed future changes in a variety of environmental conditions. See below for environmental variables selected for the Climate Change category.

Climate Change

Climate change has the potential to dramatically alter the recovery landscape and must be considered in assessing current and future conditions. The impacts that are most likely to affect SONCC coho salmon populations include increasing temperatures, changes in quantity and quality of snowpack, changes in precipitation, and rising sea level. NMFS assessed the climate change threat for each individual population using current conditions along with modeled future conditions based on projections for future greenhouse gas emissions. Current climate was derived from PRISM (Parameter-elevation Regressions on Independent Slopes Model), an analytical tool that uses point data, a digital elevation model, and other spatial data sets to generate gridded estimates of monthly, yearly, and event-based climatic parameters, such as precipitation, temperature, and dew point. Future climate data were derived from climate projections produced using a statistical downscaling method (Vertenstein et al. 2004). These projections were derived from the Community Climate System Model (CCSM-3) (Vertenstein et al. 2004). We chose the A2 emission pathways, which uses one of the highest rates of greenhouse gas (GHG) emission predictions and the GFDL model, which has a relatively high sensitivity to emissions compared to other Intergovernmental Panel on Climate Change (IPCC) global climate models (California Environmental Protection Agency (CEPA) 2006). Since recent trends in GHG emission are thought to be well above those used in any of the IPCC (2007) models, it is likely that even the “high emission” scenario may underestimate actual emission in the future (Raupach et al. 2007). We chose the time period of 2030 to 2050 to reflect expected short-term changes in climate. For this recovery plan, ten years is the time period assumed for other stresses and threats in the stress and threats assessment. Ten years was chosen to capture reasonably foreseeable events in the near future. NMFS expects that effects of climate change may take longer to manifest than effects of other stresses, and so chose a longer time period (50 years) in which to detect its effects.

To develop threat rankings for the climate change threat, NMFS analyzed the assigned risks to populations from the various climate change indices and overlaid known life history requirements. Like other threats, the final threat level was based on application of NMFS' professional judgment in consideration of available data.

Current Minimum and Maximum Temperature

An assessment of current summer and winter temperatures provided insight into the vulnerability of populations to climate change. Those populations at or near the current thresholds for coho salmon are likely to have a greater threat from climate change based on the increases in temperature occurring. Current temperature regimes were assessed using PRISM data (PRISM Climate Group 2011) averaged for the time period from 1971 to 2000, which was the time period available through the PRISM Climate Group. The months of January and July were chosen for this analysis to represent winter and summer conditions.

Current Precipitation

Current summer and winter precipitation provided a baseline condition on which to assess future changes in climate. Low precipitation in the summer and high winter precipitation are factors which can increase the threat from climate change based on predicted and ongoing changes in climate (IPCC 2007) and on the environmental requirements of the SONCC coho salmon ESU during those time periods. Current precipitation regimes were assessed using PRISM data (PRISM Climate Group 2011) averaged for the time period from 1971 to 2000. The months of January and July were chosen for this analysis to represent winter and summer conditions. The average precipitation does not indicate the rates or types of precipitation, which is another climate factor that can influence coho salmon growth and survival.

Current snowpack

Changes in temperature and precipitation will ultimately affect the snowpack in Southern Oregon and Northern California. Areas that currently have little snowpack will likely have less in the future given the modeled changes in temperature and precipitation for the area (Gleick and Chalecki 1999, Lettenmeier and Gan 1990). Snowpack-driven systems are highly vulnerable to climate change and identification of these sensitive populations helps inform our assessment of the climate change threat. Information about current snowpack was derived from NRCS SNOTEL and Snow Course snow water equivalents for the month of January (NRCS 2011). These data are represented as a percentage of normal and averaged between 1971 and 2000. High risk was assigned to populations in areas that currently have a low snowpack and are snowpack dependent.

Modeled Future Temperature Change

Regional forecasts of temperature changes related to climate change were derived from the statistical downscaling method and Community Climate System Model (CCSM-3) (Vertenstein et al. 2004). The months of January and July are used to represent changes in the summer and winter in terms of mean daily temperature (Figure B-4 and Figure B-5). A high risk is assigned to populations where temperatures are already high and future increases in summer temperature are expected. High risk is also assigned to snowpack-dependent populations where increases in winter temperature are expected to decrease snowpack levels.

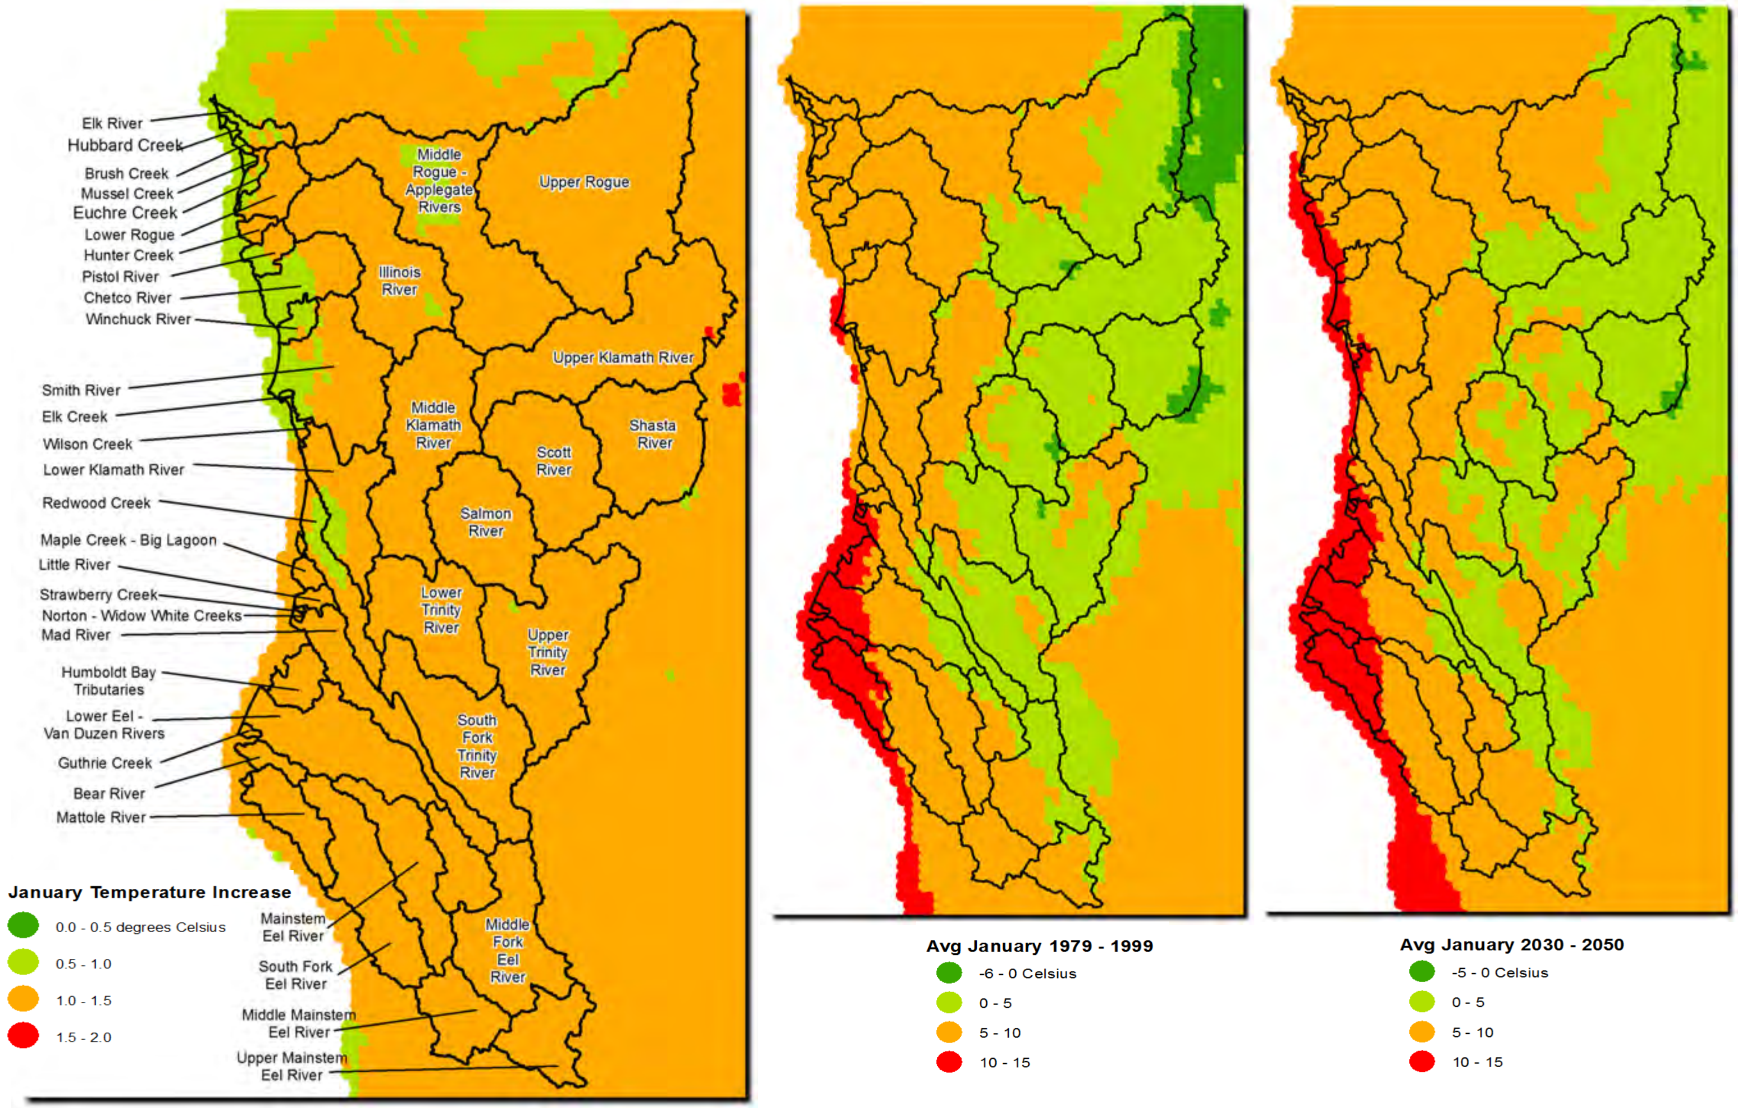

Figure B-4. Modeled average January temperatures for the years 1979 to 1999 (middle panel) and 2030 to 2050 (right panel), and the difference between the two time periods (left panel). Datasets generated by the Community Climate System Model (CCSM) model for the IPCC 4th Assessment Report, and were downloaded from http://www.gisclimatechange.org/. The 1979-1999 data are from the 20th Century Experiment and the 2030-2050 data are from emissions scenario A2. Boundaries of the coho salmon populations in the SONCC coho salmon ESU are also shown.

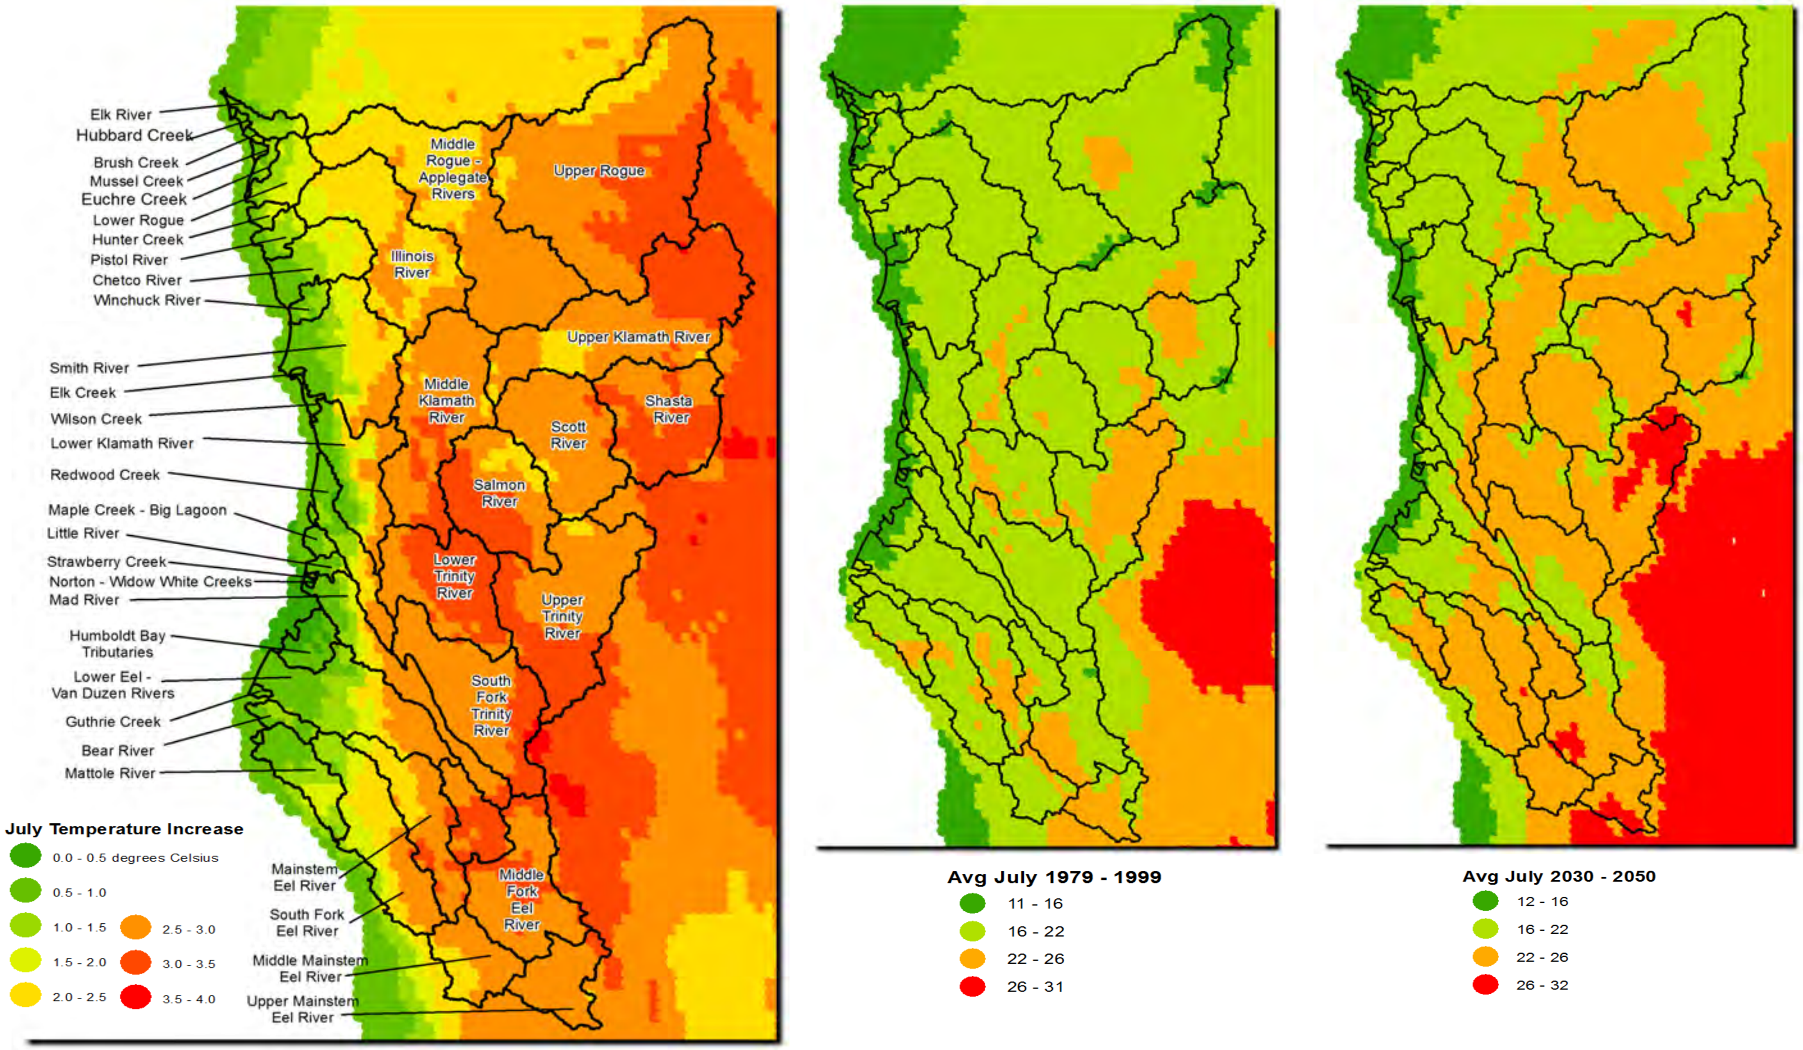

Figure B-5. Modeled average July temperatures for the years 1979 to 1999 (middle panel) and 2030 to 2050 (right panel), and the difference between the two time periods (left panel). Datasets generated by the Community Climate System Model (CCSM) model for the IPCC 4th Assessment Report, and were downloaded from http://www.gisclimatechange.org/. The 1979-1999 data are from the 20th Century Experiment and the 2030-2050 data are from emissions scenario A2. Boundaries of the coho salmon populations in the SONCC coho salmon ESU are also shown.

Modeled Future Precipitation Change

Regional forecasts of precipitation changes related to climate change are derived from projections of precipitation produced using a statistical downscaling method (Vertenstein et al. 2004). These projections are derived from the same A2 emission pathway and the Community Climate System Model (CCSM-3) (Vertenstein et al. 2004). The same time period is used to create model output. We used the general trends of the predicted changes in precipitation (i.e., increasing, decreasing, or stable) instead of the exact predicted values. High risk is assigned to populations where precipitation was already low and the expected trend was for decreasing precipitation over the next 20 years.

Modeled Sea Level Rise

Sea level rise has the potential to have a dramatic impact on salmon habitat in some SONCC coho salmon populations. To assess this aspect of climate change we use a coastal vulnerability index (CVI) provided by the U.S. Geological Survey (Thieler and Hammar-Klose 2000). This classification is based upon the variables geomorphology, regional coastal slope, tide range, wave height, relative sea-level rise, and shoreline erosion and accretion rates. The combination of these variables and the association of these variables to each other furnish a broad overview of regions where physical changes are likely to occur due to sea-level rise (Figure B-6).

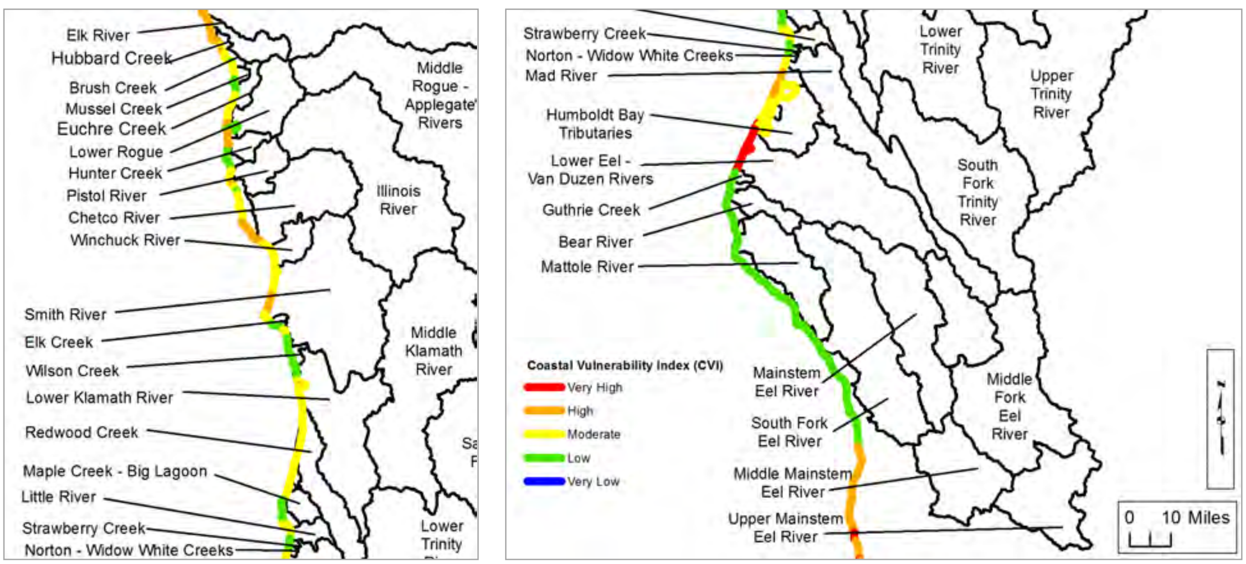

Figure B-6. Coastal Vulnerability Index (CVI) and boundaries of coho salmon populations in the northern (left panel) and southern (right panel) portions of the SONCC coho salmon ESU . CVI data from Thieler and Hammer-Klose (2000).

Impaired Estuary and Mainstem Function

Due to the lack of numeric data that covered the entire ESU, no numeric values or categories were used to develop rankings for this stress. Instead, professional judgment was used based on a series of information about the current state of estuarine or mainstem habitat and environmental conditions. Important considerations included the extent of development in the estuarine floodplain; known or presumed former extent of estuary habitat, availability of diverse and well-connected off-channel, pond, and wetland estuary and mainstem habitat; water quality; presence of dams and other obstacles to migration; and the extent of diking and ditching in the estuary. Life stage specific factors were also considered to contribute to this stress level. For fry, the stress level was elevated if there was a known fry migrant life history or the occurrence of fry migrants in the populations. For juveniles, the occurrence of estuarine life history types, accessibility issues (such as barriers that block access to tributary rearing habitat), the extent and quality of rearing habitat, and water quality issues were all used in developing stress rankings. Smolts were considered to be impacted by this stress if there were predation issues in the mainstem or estuary, poor migratory conditions (such as exposure to stressful water quality conditions, parasites, or diseases) that could reduce survival and growth, a lack of refugia or holding habitat in the mainstem and/or estuary, or ocean accessibility issues (such as a seasonal berm). The adult life stage was ranked based on the accessibility of the watershed, poor migratory conditions in the estuary and/or mainstem which could reduce survival, and the availability of holding habitat in the estuary.

Adverse Fishery and Collection-Related Effects (stress) and Fishing and Collecting (threat)

<u>Fishing Scoring System</u>

NMFS developed a scoring framework that estimates the combined annual ocean and freshwater fishing exploitation for the adult life stage of each population. The framework incorporates an extinction risk status adjustment that increases the score if the population is at moderate or high extinction risk in relation to depensation.

The adult life-stage fishing ratings were determined using the bins in Table B-13. For example, a population with 8% adult exploitation and a status adjustment value of 2 (below depensation and therefore high risk)(Table B-14) would score a 16 or “medium”, and a population with 6% adult exploitation and a status adjustment value of 1.5 (moderate risk) would score a 9 or “low.” After each life-stage was rated, an “overall” rating was determined using the Conservation Action Planning (CAP) methodology.

Table B-13. Bins used to rate the stress and threat for fishing.

Low	0-14.99
Medium	15-29.99
High	30-39.99
Very High	>=40

Table B-14. Extinction-risk status adjustment.

Status Adjustment Value	Population Status
1	Low risk of extinction
1.5	Moderate risk of extinction
2	High risk of extinction

Determination of Ocean Exploitation

The ocean exploitation rate used for all populations was the average ocean exploitation rate as reported by the Pacific Fisheries Management Council, from 1997 to 2013. The PFMC exploitation methodology uses Rogue River and Klamath River hatchery stocks as indicators for the SONCC coho salmon ESU. This rating system assumes SONCC coho salmon populations are exploited at the same rate as the hatchery indicator stocks.

Determination of Estuarine/Freshwater Exploitation

Due to a lack of data documenting population-level estuary/freshwater fishing impacts, NMFS estimated the percent exploitation for each population using the best available information (e.g., "catch-card" data in Oregon; tribal harvest data in the Klamath River) and professional judgment. Exploitation estimates for most California populations relied on rough estimates of coho salmon bycatch due to overlap of run timing with known inland fisheries for other salmonids (e.g., South Fork Eel River steelhead fishery).

Determination of Rating for Collecting Stress and Threat

NMFS authorizes scientific collection activities through ESA section 10(a)(1)(A) research permits and ESA section 4(d) programs. The authorized activities must not operate to the disadvantage of the listed species and must provide a bona fide and necessary or desirable scientific purpose or enhance the propagation or survival of the listed species. In addition, NMFS must determine whether the scientific collection is likely to jeopardize the continued existence of any listed species or result in the destruction or adverse modification of critical habitat. These provisions, along with the assumption all existing collection activities have been authorized, resulted in the determination that the stress and threat from collection activities is low for all populations.

Adverse Hatchery-Related Effects (stress) and Hatcheries (threat)

The percent of observed adults of hatchery origin is used as an indicator of relative genetic risk to a coho salmon population. Use of less than 5 percent as the threshold for low risk is consistent with the approach described in Williams et al. (2008). Williams et al. (2008) does not provide guidance regarding degree of risk above 5 percent. The status review for Oregon salmon and steelhead populations in the Willamette and Lower Columbia basins (McElhany et al. 2007) describes categories of genetic risk from hatcheries with break points at 10 percent and 30 percent, and this convention was adopted. Ecological effects of hatcheries are accounted for in the Medium stress and threat rank, which is assigned if there is a salmonid hatchery in the basin.

Table B - 1. Criteria for ranking hatchery-related stress (Adverse Hatchery-Related Effects) and threat (Hatcheries).

Rank	Definition
Low	Less than 5 percent of observed adults are of hatchery origin.
Medium	Greater than or equal to 5 percent and less than or equal to 10 percent of observed adults are of hatchery origin OR there is a salmonid hatchery in the basin.
High	Greater than 10 percent and less than 30 percent of observed adults are of hatchery origin.
Very High	Greater than or equal to 30 percent of observed adults are of hatchery origin.

B.6 Stress Analysis

Stresses are the physical, biological, or chemical conditions and associated ecological processes that may impede SONCC ESU coho salmon recovery. When particular conditions are not present, individuals can suffer reduced growth, mortality, or inhibited fertility. Some common examples of stresses are insufficient food, impaired water quality, predation, and insufficient shelter. When habitat required by a species is in short supply, a bottleneck results and this habitat becomes limiting (Reeves et al. 1989).

NMFS utilized the CAP workbooks and summary tables, and professional judgment to determine stress ratings, and developed a narrative to document the results. The results of these exercises were then considered when developing recovery actions. Key limiting stresses and threats were identified as the stresses and threats most affecting current population viability. NMFS identified two key limiting stresses and two key limiting stresses in the stress and threat summary tables, and developed a population-specific narrative to explain them. One factor in the assignment of priorities to recovery actions was whether the recovery action would address a key limiting stress or key limiting threat for the particular population. If it would, the recovery action could be eligible for a higher priority compared to if it would not address a key limiting stress or key limiting threat.

Appendix D. Methods Used to Select Core Populations

NOAA's National Marine Fisheries Service (NMFS) considers the role each population is expected to play in a recovered Evolutionarily Significant Unit (ESU) to determine population abundance and juvenile occupancy targets for all the populations in the SONCC coho salmon ESU. Independent populations are evaluated using a modified Bradbury et al. (1995) framework. This evaluation produces a set of biological and habitat scores for each independent population which informs development of demographic targets for each independent population. NMFS' objective is to develop scientifically sound demographic targets that reflect each population's capacity for coho salmon production and potential for meeting demographic and threat abatement recovery criteria. Professional judgment is relied upon to rate biological integrity parameters.

D.1 Demographic Population Targets

NMFS identified five population categories and the method to establish demographic targets for each category (Table D-1). The rationale for NMFS' choice of each population's recovery role, and associated demographic targets, is described in Exhibits 1 to 7.

Table D-1. Population type (as determined by Williams et al. 2006), category, demographic target, and life stage used to measure progress toward target.

Type	Recovery Role	Demographic Target	Life Stage
Dependent	Dependent	Juvenile occupancy (80 percent of habitat occupied in years following spawning of brood years with high marine survival)	Juvenile
Independent	Non-Core 2		
	Non-Core 1	Moderate risk threshold (depensation threshold multiplied by four)	Spawner
	Core	≥ Low risk threshold	

Extirpated Populations

Some populations in the SONCC coho salmon ESU may be extirpated. To determine whether each extirpated population should have a recovery target, NMFS considers several questions related to coho salmon absence and potential for recovery.

Evidence of coho salmon absence

Have there been surveys that document the absence of coho salmon? How extensive have they been? How recently were they completed? Is there documented past presence or absence of coho salmon? How much uncertainty surrounds the information?

Prospects of coho salmon use

Are there characteristics of the watershed which suggest it will likely not support coho salmon in the future? What is the current condition of accessible habitat? What are the prospects for improvement of accessible habitat? What are the prospects for threat abatement?

Connectivity

Would designation as an extirpated population create a gap of more than 30 km (Williams et al. 2008) between population river mouths along the coastline? If so, a target of juvenile occupancy is required.

Dependent populations

All populations identified as dependent by Williams et al. (2006) are assigned the juvenile occupancy demographic target. If NMFS determines a dependent population is extirpated, it has no juvenile occupancy requirement.

Independent populations

To determine the appropriate target for each independent population, NMFS considers the current condition of the population and its habitat, as well as the role that population is expected to play in a recovered ESU (i.e., core, non-core).

Method used to score characteristics of independent populations

NMFS developed a framework to describe characteristics of each independent population, starting with a model provided by Bradbury et al. (1995). This model uses three groupings of criteria for ranking watersheds for Pacific salmon restoration prioritization: 1) biological and ecological resources (Biological Importance); 2) watershed integrity and salmonid extinction risk (Integrity and Risk); and 3) potential for restoration (Optimism and Potential). Some of the ranking criteria proposed under these categories are also used in the NMFS method, and NMFS developed additional criteria. Scores given to each criterion are based on information in the population profiles and professional judgment. Other factors that pertain to the potential success of restoration (e.g., economic, social, or political) are considered, and although they are not scored, they may influence the final choice of population category and demographic targets for independent populations. These other factors are described in Exhibits 1 through 7.

Biological Importance

Scores for Biological Importance are based on the concept of viable salmonid populations (VSP) (McElhany et al. 2000), and are used to describe the current status of the population – population size, productivity, spatial structure, and diversity. Almost all populations are information limited, so perceived differences between populations in population size, productivity, spatial structure, and diversity could be due to a lack of data rather than true differences. These limitations are described in Exhibits 1 to 7.

Population Size and Productivity

Coho salmon typically follow a three year life cycle, producing three cohorts. NMFS' rating of the current population size and productivity of populations is based on the number of cohorts present, the consistency of runs, and trends over time. The number of individuals (population size) and growth rate (productivity) of a population are interrelated risk factors that affect population viability over time. Small populations are subject to numerous risks due to low abundance, whereas large populations are more resilient to the same risks. Productivity refers to production over the entire life cycle. The trends in abundance reflect the long-term population growth rate (McElhany et al. 2000).

The following metrics, described in Table D-2 through Table D-7, are especially important because a coho salmon population that drops to extremely low levels of abundance and productivity represent greater challenges for restoration and recovery. Scores are determined based on the following guidance.

Population Size

Table D-2. Metric used to assess population size parameter.

Score	Description
0	No coho salmon are produced by any cohort, AND any adults are likely strays.
1	Number of spawners is consistently (multiple generations) < 50 percent of the depensation threshold.
2	Number of spawners is consistently (multiple generations) ≥ 50 percent of the depensation threshold.
3	Number of spawners is consistently (multiple generations) > the depensation threshold.

Population Productivity

Table D-3. Metric used to assess population productivity parameter.

Score	Description
0	No coho salmon are produced in any cohort, AND any adults are likely strays.
1	At least one naturally-spawned cohort is absent, or close to absent, AND the other cohorts are not consistently present (at least six consecutive years) or show decreasing trends in abundance.
2	Three cohorts are consistently present (at least six consecutive years) AND all cohorts show decreasing trends in abundance.
3	Three cohorts are consistently present (at least six consecutive years) AND at least one cohort shows no change in trend in abundance or an increasing trend in abundance.

Spatial Structure and Diversity

NMFS expects that populations that are well distributed have a diverse array of life history traits and maintain greater genetic diversity. NMFS expects such populations will be more resilient and have higher potential for recovery than populations with diminished spatial structure and diversity.

Spatial Structure

The spatial structure of a population depends on habitat quality and spatial configuration, and the dynamics and dispersal characteristics of individuals in the population (McElhany et al. 2000).

The spatial structure rating is based on the current spatial extent of the population compared with the potential juvenile habitat, as described by a model of intrinsic habitat potential (IP).

Table D-4. Metric used to assess spatial structure parameter.

Score	Description
0	No coho salmon are present from any cohort, and any adults are likely strays.
1	Coho salmon occur in 0-25 percent of the IP habitat outside the temperature mask*.
2	Coho salmon occur in ≥25 but ≤50 percent of the IP habitat outside the temperature mask*.
3	Coho salmon occur in >50 percent of IP habitat outside the temperature mask*.
*The temperature mask (Williams et al. 2006) was applied to the IP model results to exclude areas with high air temperatures from calculation of spawner targets.	

Diversity

This parameter was made up of 50 percent Life History Diversity and 50 percent Genetic Diversity. Genetic Diversity included two equally-weighted elements: Hatchery Influence and Small Population Dynamics (depensation).

Life History Diversity

Within and among populations, coho salmon exhibit diverse life history traits which have the potential to enhance growth and survival of individuals in a spatially and temporally variable environment. Because populations are made up of individuals, maintaining diverse life history traits (1) allows for individuals to utilize a wide range of habitats; (2) protects species against short term spatial and temporal changes in habitat; and (3) increases the likelihood that some individuals will survive and reproduce. The diversity of life history traits expressed by individuals, and the availability of a diversity of habitats, spreads any risk to population viability over space and time (Weitkamp et al. 1995, Spence et al. 1996, McElhany et al. 2000).

Life history traits are phenotypic and genotypic characteristics which provide the potential for individuals to utilize multiple habitats in order to enhance growth and survival. These traits include: adult age, size, fecundity, run and spawning timing, and spawning behavior; egg size and developmental rate; juvenile physiology and behavior; smolt size, age, and outmigration timing; disease resistance; and ocean distribution patterns (Weitkamp et al. 1995, Spence et al. 1996, McElhany et al. 2000).

Table D-5. Metrics used to assess life history diversity parameter.

Score	Description
0.5	Diverse habitat types are not present, so potential for expression of atypical life history traits is not apparent, AND there is no evidence of expression of atypical life history traits.
1	Diverse habitat types are present, suggesting potential for expression of atypical life history traits, AND there is no evidence of expression of atypical life history traits.
1.5	Diverse habitat types are present, suggesting potential for expression of atypical life history traits, AND there is evidence of expression of atypical life history traits.

Hatchery Influence

Table D-6. Metrics used to assess hatchery influence parameter.

Score	Description
0.25	The proportion of hatchery strays in the spawning population is high (Proportion of Natural Influence [PNI] <0.3) in >50 percent of years, and these strays support the population.
0.5	The proportion of hatchery strays in the spawning population is moderate (PNI >0.5) in >50 percent of years, and these strays do not support the population.
0.75	The proportion of hatchery strays in the spawning population is low or zero (PNI >0.7) in >50 percent of years, and these strays do not support the population.

Small Population Dynamics (Depensation)

Small populations tend to have less genetic diversity than large ones. The depensation threshold is used to define a small population. The score for small population dynamics as it relates to genetic diversity can be calculated by multiplying the population's score for population size (Table D-2) by 0.25.

Table D-7. Metrics used to assess small population dynamics parameter.

Score	Description
0	No coho salmon are produced by any cohort AND any adults are likely strays.
0.25	Number of spawners is consistently (multiple generations) < 50 percent of depensation threshold.
0.5	Number of spawners is consistently (multiple generations) 51 percent to 100 percent of depensation threshold.
0.75	Number of spawners is consistently (multiple generations) greater than depensation threshold.

Habitat Integrity and Risks

The Habitat Integrity and Risks parameter describes the relative habitat integrity (lack of human-caused disturbance; Bradbury et al. 1995) and relative risk to current biological and ecological resources (Bradbury et al. 1995) in each population. The following metrics were chosen to assess Habitat Integrity and Risks because they were related to the parameter, and because numeric data describing them were readily available.

Road Density

This metric is the average density (miles per square mile) of roads in the population area. It is based on the rationale that areas with high road densities are more prone to unnatural levels of disturbance and relatively high rates of chronic sedimentation, while areas with lower road densities have a higher integrity and less risk. Scores were based on a frequency distribution of road density data from the populations in the ESU divided into roughly equal thirds and scored as 3 for the lowest third (road density 1.6-2.5), 2 for the middle third (2.6-3.0), and 1 for the highest third (3.24-12.59).

Number of Stresses Ranked High or Very High

This metric is the total number of high or very high stresses indicated in the stress summary tables from population profiles. It is based on the rationale that numerous high-level stresses are an indication of a lower ecological integrity and higher degree of risks. Scores were based on a frequency distribution of the number stresses for each population in the ESU divided into roughly equal thirds and scored as 3 for the lowest third (0-3), 2 for the middle third (4-6), and 1 for the highest third (7-9).

Slope

This metric is the proportion of the watershed with a percentage of slope ≥ 55 percent based on GIS analysis of 30-meter digital elevation model. It is based on the rationale that populations within a stratum with more high-gradient area are more likely to experience large-scale disturbance (e.g., mass-wasting), whereas areas with a less high-gradient habitat are likely to experience these disturbances on a smaller scale within the landscape. Scores were based on a frequency distribution of proportion watershed with slope ≥ 55 percent for each population divided into roughly equal thirds and scored as 3 for the lowest third (proportion 0.04-0.09), 2 for the middle third (0.11-0.24), and 1 for the highest third (0.26-0.51).

Forest Integrity

This metric is based on the percentage of large trees (>30" or >20" depending on location) and change scene detection (percent harvested, percent change due to other impacts). Both are GIS-based and determined from LandSat imagery. This metric was chosen based on the rationale that areas that have a higher degree of mature forest and/or have been less impacted by timber harvest have a higher resiliency and more ecological integrity. Large tree scores were based on a frequency distribution of data from the ESU divided into roughly equal thirds and scored as 0.5 for the lowest third, 1 for the middle third, and 1.5 for the highest third. Harvest scores were based on a frequency distribution of data from the ESU divided into roughly equal thirds and scored as 1.5 for the lowest third, 1 for the middle third, and 0.5 for the highest third. These two scores were then combined for the overall score.

Optimism and Potential

The Optimism and Potential parameter describes the relative degree of optimism that freshwater or estuarine ecosystems can be protected or restored and the potential benefits to populations if protection and restoration are effective (Bradbury et al. 1995). The following metrics were chosen to assess Optimism and Potential because they are related to the parameter, and numeric data is readily available.

Public Land

This metric is the percent of land within the population that is in public ownership. Populations within a stratum with more public land are assumed to benefit from higher standards of management and greater ease of implementation of recovery measures. Individual scores were based on a frequency distribution of data from the ESU divided into roughly equal thirds and scored as 1 for the lowest third, 2 for the middle third, and 3 for the highest third.

California State Recovery Priority

The California Department of Fish and Game (CDFG) Coho Recovery Strategy (CDFG 2004) used a prioritization model to predict restoration and management potential based on the existing population status, risks, and watershed condition. This metric, which is based on the CDFG scores of restoration and management potential, indicates which areas the state of California believes have the greatest likelihood for successful coho recovery. A similar metric is not available for Oregon populations. Scores were based on a frequency distribution of scores for each population in the ESU divided into roughly equal thirds and scored as 1 for the lowest third (score 1.0-1.5), 2 for the middle third (2.0-3.2), and 3 for the highest third (3.3-5.0).

Number of Threats Ranked High or Very High

This metric is the total number of high or very high threats as shown in the threat summary tables from population profiles. It is based on the rationale that numerous high-level threats means there likely is a lower ecological integrity, higher degree of risk, and a reduced potential for success. Scores were based on a frequency distribution of the number of high/very high threats for each population in the ESU and were divided into roughly equal thirds and scored as 3 for the lowest third (0-3), 2 for the middle third (4-6), and 1 for the highest third (7-9).

Number of Other Listed Anadromous Salmonid Species

This metric is the number of other NMFS-listed anadromous species (e.g., Chinook salmon, steelhead) that occur within the population area. It is based on the rationale that a population with more listed species is more likely to be high priority for restoration and will likely attract more restoration effort. Scores were based on a frequency distribution of number species for each population in the ESU divided into roughly equal thirds and scored as 1 for the lowest third, 2 for the middle third, and 3 for the highest third.

Number of Other Non-Listed Anadromous Salmonid Species

This metric is the number of non-listed anadromous salmonid species that occupy the population area. It is based on the rationale that populations with other anadromous salmonid species maintain some of the habitat features that are critical for supporting coho salmon populations. Scores were based on a frequency distribution of number salmonid species for each population in the ESU divided into roughly equal thirds and scored as 1 for the lowest third (0-2 species), 2 for the middle third (3-4), and 3 for the highest third (5-6).

Using Ratings to Choose Core Populations

NMFS considers the population ratings to inform the choice of core populations. Consistent with Bradbury et al. (1995), NMFS places most importance on the Biological Importance (BI) score. The BI scores, and other BI-related considerations, play a strong role in the decision because they are relevant to how quickly a population can improve from its current state. Populations with the highest BI scores are likely in the best condition and are expected to recover more quickly than populations with lower BI scores. The scores for the other two categories are considered if the BI scores do not support a clear choice.

Using Ratings to Determine Targets for Non-Core Populations

There are a range of possible targets for non-core populations, and reasons why a particular target may be chosen. NMFS considers two factors when setting these targets: 1) What are the prospects for recovery in a particular population? NMFS uses the scores described in the appropriate sections (i.e., D.1 through D.7) to answer this question; and 2) Given what was learned for factor 1, what role does each population need to play in a recovered ESU? Is the population more or less important as a source to recolonize areas? The rationale for selection of particular targets for each population is explained in the appropriate section below (i.e., D.1 through D.7).

Non-Core 2

The target for populations in this category is 80 percent of habitat occupied in years following spawning of brood years with high marine survival (Table 4-1). NMFS chooses this target if the chance of recovery of a coho salmon population in a basin is very low, but it is feasible that some habitat could be restored to support all life stages of coho salmon. If strays were to arrive, the basin would be able to support all life stages, and juveniles may be observed in some years. A population with this target would not be relied upon to provide a source of colonists for other populations.

Non-Core 1

The target for populations in this category is the four spawners per IP-km (see Section 2.3.2). NMFS chooses this target if the population is likely to ultimately produce considerably more than the depensation threshold, but less than the low risk threshold.

Core

The target for populations in this category is the low risk threshold. NMFS chooses this target for a population after considering its current condition, its geographic location in the ESU, its low risk threshold compared to the number of spawners needed for the entire stratum, and other factors. The rationale for selection of particular core populations is explained in the appropriate section below (i.e., D.1 through D.7).

D.2 Northern Coastal Stratum Population Targets

Application of the method used to select each population's recovery role (i.e., core, non-core 1, non-core 2, extirpated) and identification of appropriate population adult spawner abundance or juvenile occupancy targets resulted in the following Biological Importance (BI), Integrity and Risks (IR), and Optimism and Potential (OP) scores; discussion of other related considerations such as cost; and conclusion. Unless otherwise noted, results are based on information presented in Northern Coastal Stratum population profiles.

Table D-8. Biological Importance (BI) Score for Northern Coastal Populations.

Biological Importance Score							
				Diversity			
Population	Abundance	Productivity	Spatial	Life History	Hatchery	Depensation	Total
Chetco River	2	2	2	1	0.75	0.25	8
Elk River	2	2	2	1	0.75	0.25	8
Lower Rogue River	2	2	1	1	0.5	0.5	7
Winchuck River	1	1	1	1	0.75	0.25	5

Available data indicate the Winchuck River population abundance is currently well below the depensation threshold, while the Elk River, Chetco River, and Lower Rogue River populations have at least one year class that is likely above the depensation threshold. Coho salmon in the Chetco River and Elk River populations are believed to occupy a higher percentage of the IP habitat in their basins, while the Lower Rogue River population is believed to be constrained to a few tributaries.

The extent of life history diversity is rated the same for all populations due to similar coastal and estuary condition. Hatchery influence is of low concern in the Chetco River, Elk River, and Winchuck populations. However, stray coho salmon from the Cole Rivers hatchery are known to occasionally spawn in the Lower Rogue River. The Lower Rogue River population supports more coho salmon than the others, so it is less affected by depensatory effects.

Table D-9. Integrity and Risks (IR) Scores for Northern Coastal Populations.

Integrity and Risks Score					
Population	Road	Stress	Slope	Forest	Total
Chetco River	3	2	1	3	9
Elk River	3	3	1	3	10
Lower Rogue River	1	2	2	2	7
Winchuck River	3	2	1	2	8

Road density is higher in the Lower Rogue River than in the other populations. There were no scored differences in the number of high or very high stresses across populations. The Lower Rogue River has a lower incidence of steep slopes compared to the other populations.

Populations with more high-gradient areas may be more vulnerable to large-scale disturbance than areas with less high-gradient areas. The forest integrity of the Chetco and Elk rivers was rated higher than that of the other population area, suggesting more mature forest and more resiliency and ecological integrity in the Chetco River and Elk River populations.

Table D-10. Optimism and Potential (OP) Scores for Northern Coastal Populations.

Optimism and Potential						
Population	Federal Land	CDFG	Listed Species	Species	Threat	Total
Chetco River	3	NA	0	2	2	7
Elk River	3	NA	0	2	2	7
Lower Rogue River	2	NA	0	3	2	7
Winchuck River	3	NA	0	2	2	7

The proportion of publicly–owned land is greater in the Chetco River, Elk River, and Winchuck River populations than in the Lower Rogue River population. Populations with more public land are assumed to benefit from higher standards of management and greater ease of implementation of recovery measures. There are more salmonid species in the Lower Rogue River than in the other populations. A population with more salmonid species may maintain more of the habitat features critical for supporting coho salmon populations than a population with less salmonid species. There are less highly-ranked threats in the Elk River and Winchuck River than the other populations, possibly indicating greater ecological integrity and a greater potential for success in restoring coho salmon.

The Elk River has great potential for recovery due to an ongoing public effort to protect and restore salmon habitat, as well as the management of a large portion of the watershed as Wilderness or a Late Successional Reserve. All population areas possess suitable private land which could contribute toward restoration if state, federal, or private funding was available.

Other Considerations

Cost

Preliminary results indicate the total cost of recovery actions needed in each potential core population is as follows:

Elk River – $20 million
Lower Rogue River - $30 million
Chetco River - $27 million
Winchuck River - $14 million

The cost estimates reflect the recovery role for each population. Therefore, the cost estimates for recovery actions identified for non-core populations do not include recovery actions that may be necessary were they made core populations. Cost estimates are often based on the size of a watershed, or length of IP, making costs to produce nearly equal number of spawners disproportionately large for small population areas, and vice versa.

Preliminary cost estimates reveal the cost of recovery actions identified for the Lower Rogue River population is higher than the cost for the other populations. This result is due to extensive road treatment and decommissioning actions, as well as estuarine restoration, in the Lower Rogue River. Although the Lower Rogue River is not proposed as a core population, the estuarine restoration actions there are needed by other populations in the Rogue basin. If the Chetco River was not selected as a core population, then the remaining three populations would have to be selected in order to meet the stratum 50% abundance threshold. This scenario would result in a more costly scenario.

Table D-11. Score Summary for Northern Coastal Populations.

Population	BI	IR	OP	Total	Low Risk Spawner Threshold
Chetco River	8	9	7	24	4,500
Elk River	8	10	7	25	2,400
Lower Rogue River	7	7	7	21	3,000
Winchuck River	5	8	7	20	2,200
Number spawners needed to meet stratum requirement (50% of total)					6,050

Table D-12. Spawner Targets for Northern Coastal Populations.

Population	Recovery Role	Target
Chetco River	Core	4,500
Elk River	Core	2,400
Lower Rogue River	Non-Core 1	320
Winchuck River	Non-Core 1	230
		Total Core : 6,900 Spawners

The Chetco River and Elk River populations are the best choices for core populations in this stratum primarily because the coho salmon populations found there are in the best condition. In addition, their IR scores are the highest, indicating greater watershed integrity. The core population targets would result in a low risk of extinction. The Lower Rogue River and Winchuck River targets would result in a moderate risk of extinction.

D.3 Interior Rogue Stratum Population Targets

Application of the method used to select each population's recovery role (i.e., core, non-core 1, non-core 2, extirpated) and identification of appropriate population adult spawner abundance or juvenile occupancy targets resulted in the following Biological Importance (BI), Integrity and Risks (IR), and Optimism and Potential (OP) Scores; discussion of other related considerations such as cost; and conclusion. Unless otherwise noted, results are based on information presented in Interior Rogue River Stratum population profiles.

Table D-13. Biological Importance (BI) Score for Interior Rogue Populations.

Biological Importance Score							
				Diversity			
Population	Abundance	Productivity	Spatial	Life History	Hatchery	Depensation	Total
Upper Rogue River	3	2	2	1	0.5	0.75	9.25
Middle Rogue/Applegate	3	2	1	1	0.75	0.75	8.5
Illinois River	3	2	2	1	0.75	0.75	9.5

The number of adults in each population is consistently greater than the depensation threshold, and all populations have three cohorts consistently present. The Illinois and Upper Rogue have more adult coho salmon than the Middle Rogue/Applegate River.

Juvenile coho salmon are better distributed in the Upper Rogue River and Illinois River population areas than in the Middle Rogue/Applegate population areas (between 25 and 50 percent of IP occupied, compared to 0 to 25 percent occupied). Juvenile density is higher in the Upper Rogue River and Illinois River populations than in the Middle Rogue/Applegate River.

Diversity measures are the same across all populations, except hatchery influence is greater in the Upper Rogue River than in the other two populations.

Table D-14. Integrity and Risks (IR) Scores for Interior Rogue Populations.

Integrity and Risks Score					
Population	Road	Stress	Slope	Forest	Total
Upper Rogue River	1	1	3	3	8
Middle Rogue/Applegate	1	1	1	2	5
Illinois River	2	1	1	2	6

The road density is lower in the Illinois River than in the other two populations. There were no scored differences in the number of high or very high stresses in the three populations. The Upper Rogue River has a lower incidence of steep slopes than seen in the other two populations. Populations with more high-gradient areas may be more vulnerable to large-scale disturbance than areas with less high-gradient areas. The forest integrity of the Upper Rogue River was rated higher than that of the Middle Rogue/Applegate and Illinois Rivers, indicating there is more mature forest and so more resiliency and ecological integrity in the Upper Rogue River.

The natural hydrograph of the Illinois River is still in place and not affected by dams as are the Upper Rogue (William L. Jess Dam) and Middle Rogue/Applegate Rivers (William L. Jess and Applegate dams).

Table D-15. Optimism and Potential (OP) Scores for Interior Rogue Populations.

Optimism and Potential Score						
Population	Public Land	CDFG	Listed Species	Species	Threat	Total
Upper Rogue River	2	NA	0	3	1	6
Middle Rogue/Applegate	3	NA	0	3	1	7
Illinois River	3	NA	0	3	1	7

The proportion of publicly–owned land is greater in the Middle Rogue/Applegate River and Illinois Rivers than in the Upper Rogue River. Populations with more public land may benefit from higher standards of management and greater ease of implementation of recovery measures. More public land is owned by the U.S. Forest Service than BLM in the Illinois River basin. The U.S. Forest Service and BLM currently manage land under the Northwest Forest Plan. All three populations host at least five salmonid species A population with more salmonid species may maintain more of the habitat features critical for supporting coho salmon populations than a population with less salmonid species. The threat rating for the Upper Rogue River was less than for the other two populations, possibly indicating greater ecological integrity and a greater potential for success in restoring coho salmon.

Recent removal of mainstem dams on the Upper Rogue River has restored passage to much of the basin. Much of the Middle Rogue River is too steep for coho salmon, and many of the lower gradient areas are highly impacted and do not present a great opportunity for restoration. The Applegate is less impacted, but has less recovery potential than the Illinois River. All population areas possess suitable private land which could contribute toward restoration if state, federal, or private funding was available.

Other Considerations

Cost

Preliminary results indicate the total cost of recovery actions needed in each potential core population is as follows:

Illinois River – $251 million
Upper Rogue River - $509 million
Middle Rogue/Applegate River - $455 million

The cost estimates reflect the recovery role for each population. Therefore, the cost estimates for recovery actions identified for non-core populations do not include recovery actions that may be necessary were they made core populations. Cost estimates are often based on the size of a watershed, or length of IP, making costs to produce nearly equal number of spawners disproportionately large for small population areas, and vice versa.

Table D-16. Score Summary for Interior Rogue Populations.

Population	BI	IR	OP	Total	Low Risk Spawner Threshold
Upper Rogue River	9.25	8	6	23.25	18,000
Middle Rogue/Applegate	8.5	5	7	20.5	14,700
Illinois River	9.5	6	7	22.5	11,800
Number spawners needed to meet stratum requirement (50% of total)					22,250

Table D-17. Spawner Targets for Interior Rogue Populations.

Population	Recovery Role	Target
Upper Rogue River	Core	13,800
Middle Rogue/Applegate	Non-Core 1	2,400
Illinois River	Core	11,800
		Total Core : 25,600 Spawners

The Upper Rogue River and Illinois River populations are the best choices for core populations in this stratum, primarily because the coho salmon populations found there are in the best condition. In addition, the Upper Rogue has more mature forest and the lowest number of threats compared to the other population areas, and the Illinois has greater recovery potential than the Middle Rogue because it is less urbanized. The core population targets would result in a low risk of extinction. The Middle Rogue/Applegate River target would result in a moderate risk of extinction.

D.4 Central Coastal Stratum Population Targets

NMFS applied the modified Bradbury et al. (1995) framework to the Central Coastal Stratum to select each population's recovery role (i.e., core, non-core 1 or 2, extirpated) and to identify the population spawner abundance or juvenile occupancy targets. Application of the framework resulted in the following Biological Importance (BI), Integrity and Risk (IR), and Optimism and Potential (OP) scores for each independent population in the stratum. The BI score for this stratum represents the mean of four staff scores, which are largely based upon best professional judgment given the paucity of data within the stratum. Otherwise, results are based on information presented in the Central Coastal Stratum population profiles.

Table D-18. Biological Importance (BI) Scores for Central Coastal Populations.

	Biological Importance						
Population	Abundance Score	Productivity Score	Spatial Score	Life History	Hatchery	Depensation	BI Score
Little River	3	3	3	1	0.75	0.75	11.5
Lower Klamath R.	2	2	3	1.5	0.5	0.5	9.5
Mad River	2	2	2	1.5	0.75	0.5	8.75
Redwood Creek	3	2	2	1.5	0.75	0.75	10
Smith River	2	2	2	1.5	0.75	0.5	8.75

Population abundance is uncertain as surveys are few and results are variable. Data from Redwood Creek are some of the most robust within the stratum, with data sets spanning 12 years. However, the most robust data on spawner abundance is from Prairie Creek, a tributary to Redwood Creek. Data indicate that spawner escapement in Prairie Creek is highly variable between years, ranging from 680 spawners in 2002 to a low of 28 adults in 2010. Within the five-year period from 2007 to 2011, three of five years the spawner estimates for Prairie Creek exceeded the depensation threshold of 151 spawners calculated for Redwood Creek watershed, although during one of those years the estimate was very close to depensation. Prairie Creek is a stronghold for coho salmon in Redwood Creek, whereas very little production is documented elsewhere in the watershed. In contrast, data are limited for the Little River, Mad River, and Smith River. Based upon NMFS' professional judgment, Little River likely produces equal to or greater than the depensation threshold (34), whereas population abundance in the Mad and Smith rivers are likely below depensation (153 and 325, respectively). Finally, NMFS debated whether the data from the Lower Klamath was reliable. While the data suggest that the Lower Klamath is likely above the depensation threshold, staff members were concerned that the use of juvenile data may poorly reflect abundance and distribution of the population due to the presences of juveniles from upper basin populations (non-natal rearing).

Table D-19. Integrity and Risks (IR) Scores for Central Coastal Populations.

	Integrity and Risks				
Population	Roads Score	Stress Score	Slope Score	Forest Score	IR Score
Little River	1	3	3	2	9
Lower Klamath River	1	2	2	2	7
Mad River	1	2	2	2	7
Redwood Creek	1	2	3	3	9
Smith River	1	2	1	2	6

Road density is of concern throughout the stratum, and as such, each basin scored a one for road density. Populations differ, however, according to the remainder of the metrics that make up the Integrity and Risk score. The larger of the basins in this stratum, the Lower Klamath, Smith, and Mad rivers, and Redwood Creek scored as a two for high-level stresses. The Smith River scored low in the slope metric due to the proportion of the basin contained in high gradient reaches; however, the metric oversimplifies the relationship between slope and the risk of mass wasting. While the Smith River may have a higher proportion of steep slopes than other watersheds within the stratum, the underlying geology is inherently different between the Smith River and the other basins within the stratum. The Smith River basin contains more competent rocks (primarily Josephine Ophiolite sequence) and produces coarser grain landslides that tend to be less detrimental to fish and their habitat, and can contribute to the formation and maintenance of spawning habitat. In contrast, other basins within the stratum consist primarily of sedimentary rocks, which produce finer grain landslides that can severely damage salmonid habitat. Consequently, NMFS considered the final IR scores for each population in concert with relative strength of each metric in arriving at the final recommendation for the core populations for the stratum.

Table D-20. Optimism and Potential (OP) Scores for Central Coastal Populations.

	Optimism and Potential					
Population	Land Score	CDFG Score	Listed Species Score	Species Score	Threat Score	OP Score
Little River	1	3	2	2	3	11
Lower Klamath River	2	3	1	3	2	11
Mad River	2	3	3	3	2	13
Redwood Creek	2	3	3	3	3	14
Smith River	3	3	1	3	2	12

The three highest scoring populations for Optimism and Potential (OP) are the Mad River, Smith River, and Redwood Creek. The number of listed anadromous fish species influences this score with the Mad River and Redwood Creek occurring within the range of all listed anadromous fish within the stratum. That is, although Pacific eulachon are listed within the Central Coastal stratum, they are generally relegated to larger watersheds such as the Lower Klamath, Smith, and Mad rivers. In contrast, the Northern California steelhead DPS and the California Coastal

Chinook salmon ESU are limited to watersheds south of the Klamath River. Thus, the Mad River and Redwood Creek contain the highest number of listed anadromous fish species. The final OP score for the Smith River also reflects the fact that this basin has the highest proportion of lands within public ownership.

Other Considerations

Climate change

The anticipated effect of future climate change influenced the final core populations selected for this stratum. NMFS expects that projected temperature increases and changes in precipitation patterns from climate change models would have a relatively smaller effect on coho salmon and their habitat in the Smith River basin than other watersheds within the stratum. Because the headwaters of the Smith River originate on US Forest Service land, which is managed to protect water quality and quantity, and water quantity and water temperatures are not currently limiting coho salmon in the Smith River, the Smith River population may be more buffered from the effects of climate change. NMFS expects that climate change would not decrease the availability of suitable habitat for coho salmon in the Smith River, or if suitable habitat were to decline due to climate changes, then we would expect such declines to be less severe than the declines that would occur in neighboring basins.

Cost

Preliminary results indicate the total cost of recovery actions needed in each potential core population of this stratum is as follows:

Smith River - $136 million
Lower Klamath River - $158 million
Redwood Creek - $139 million
Mad River - $116 million
Little River – $23 million

The cost estimates reflect the recovery role for each population. Therefore, the cost estimates for recovery actions identified for non-core populations do not include recovery actions that may be necessary were they made core populations. Cost estimates are often based on the size of a watershed, or length of IP, making costs to produce nearly equal number of spawners disproportionately large for small population areas, and vice versa.

Table D-21. Score summary for Central Coastal Populations.

Population	BI Score	IR Score	OP Score	Total Score	Low Risk Spawner Threshold
Little River	11.5	9	11	31.5	1,400
Lower Klamath River	9.5	7	11	27.5	5,900
Mad River	8.75	7	13	28.75	4,500
Redwood Creek	10	9	14	33	4,900
Smith River	8.75	6	12	26.75	6,800
Number spawners needed to meet stratum requirement (50% of total)					12,550

Given the paucity of data to inform the scoring methodology, NMFS spent considerable time deliberating the merits of choosing the populations with the highest overall scores. According to above BI scores the Smith River and Mad River tied for the third highest scoring population. After much deliberation, NMFS decided the Lower Klamath River, Redwood Creek, and Smith River should be designated as core populations. Rationale for recommendation:

Lower Klamath River – CORE

- Abundance likely above depensation threshold
- Estuarine habitat is considered some of the highest quality in the stratum
- Supports upstream populations in the Interior Klamath Stratum and the Interior Trinity Stratum, five of which are core populations
- Currently coho salmon are widely distributed

Smith River – CORE

- Northern expression within stratum, key basin for seeding dependent populations nearby and maintaining metapopulation structure with populations in most northern extent of SONCC ESU coho salmon range (northern coastal stratum)
- Unique geology (Siskiyou bioregion)
- Cold water tributaries originate in Siskiyou Mountains; within stratum considered basin most resilient to climate change; water temperatures likely least impacted within stratum
- Hydrology considered less impacted than other basins within stratum; no large hydroelectric dams, headwaters contained within wilderness or other public land
- Steep geology, possibly more springs than other basin
- Currently coho salmon are widely distributed

Redwood Creek – CORE

- Abundance likely below depensation threshold
- Only basin in stratum with documented 2 year freshwater rearing of juveniles
- Lower watershed managed by Redwood National and State Parks, which has goals that include recovering listed species
- Currently coho salmon are suspected to have a limited distribution

Mad River – Non-Core 1

- Neighboring basin to south coastal stratum; would assist in seeding and maintaining metapopulation dynamics
- Optimism increasing; increasing interest in disperse parties for restoring/making improvements; most urban development within stratum
- Currently coho salmon are moderately distributed

Little River – Non-Core 1

- Abundance likely above depensation threshold; however, population considered too small to contribute substantially to the 50% target for stratum viability
- Presently considered "potentially independent" population; genetic studies needed to determine if supports a unique population or clusters with neighboring basin
- Majority of watershed in Green Diamond ownership and covered by AHCP; fate of population highly dependent upon Green Diamond management practices.
- Estuarine habitat degraded by grazing practices
- High spawner requirement likely difficult to meet

Table D-22. Spawner Targets for Central Coastal Populations.

Population	Category	Target
Little River	Non-Core 1	140
Lower Klamath River	**Core**	**5,900**
Mad River	Non-Core 1	550
Redwood Creek	**Core**	**4,900**
Smith River	**Core**	**6,800**
		Total Core : **17,600 spawners**

The Lower Klamath River, Redwood Creek, and Smith River are considered the best candidates to serve as the core populations in this stratum because these populations represent the populations that NMFS believes have the highest likelihood of persisting as strongholds in the face of climate change. With the exception of Redwood Creek, these basins also currently contain the widest in-basin distribution of coho salmon, which suggests that these basins are more resilient to stochastic events and within basin re-seeding can occur. Although the distribution of coho salmon within Redwood Creek is limited, Redwood Creek, in particular Prairie Creek, is an important stronghold within the stratum at present and is expected to persist due to the protections afforded the watershed by Redwood National and State Parks. Similarly, the Smith River contains a considerable amount of protected habitat because much of the watershed is contained within US Forest Service lands and the Redwood National and State Parks.

D.5 Interior Klamath Population Targets

Application of the method used to select each population's recovery role (i.e., core, non-core 1, non-core 2, extirpated) and identification of appropriate population adult spawner abundance or juvenile occupancy targets resulted in the following Biological Importance (BI), Integrity and Risks (IR), and Optimism and Potential (OP) Scores; summary of findings; discussion of other related considerations such as cost; and conclusion. Unless otherwise noted, results are based on information presented in Interior Klamath Stratum population profiles.

Table D-23. Biological Importance (BI) Score for Interior Klamath populations.

Population	Abundance Score	Productivity Score	Spatial Score	Life History Score	Hatchery Score	Depensation Score	BI Score
Mid-Klamath	3	2	3	1	0.75	0.75	10.5
Salmon	1	2	1	0.5	0.75	0.25	5.5
Scott	3	2	3	1	0.5	0.75	10.25
Shasta	1	1	1	1.5	0.25	0.25	5
Upper Klamath	2	2	1	1	0.25	0.5	6.75

Table D-24. Integrity and Risks (IR) Scores for Interior Klamath populations.

Population	Roads Score	Stress Score	Slope Score	Forest Score	IR Score
Mid-Klamath	3	1	1	3	8
Salmon	3	3	1	3	10
Scott	2	2	2	3	9
Shasta	3	1	3	3	10
Upper Klamath	2	1	2	3	8

Table D-25. Optimism and Potential (OP) Scores for Interior Klamath populations.

Population	Land Score	CDFG Score	Listed Species Score	Species Score	Threat Score	OP Score
Mid-Klamath	3	2	0	3	3	11
Salmon	3	2	0	3	3	11
Scott	2	3	0	2	1	8
Shasta	2	3	0	2	2	9
Upper Klamath	2	3	0	2	1	8

Summary of Population Profile Findings

Scott River Population

- High natural production in recent history.
- Current distribution of coho salmon in the Scott River is widespread.
- Exhibits a wide variety of habitats and life histories.
- Limiting factors that currently limit production are well understood.
- Potential for high production given the high IP, and large runs of Chinook.
- One strong brood year.
- Strong monitoring program exists.

Shasta River Population

- Low numbers of abundance contrast with high value of Integrity and Optimism.
- High production of Chinook salmon currently exists, indicating production value for coho could exist if limiting factors are addressed.
- Diversify of habitat features (e.g., spring flow dominated hydrology) and life history traits contribute to the overall adaptability and resiliency of the stratum to combat future climate effects and catastrophic events.
- Stressors are well understood, as are the identification of effective restoration priorities.
- Location allows for strays to support other populations.
- Recent success in acquiring more than 6,000 acres within the Big Springs Complex increases optimism for long term recovery.
- Large quantity of high IP habitat.
- Strong monitoring program exists.

Upper Klamath Population

- Optimism high given the KHSA/KBRA.
- Population comprised of a series of small streams, some intermittent.

- High quality habitat above Iron Gate Dam will be made available upon fish passage. Cold water tributaries will provide refugia from climate effects.
- Selection as core allows for full extent and range of occupied habitat to be restored, enhancing the spatial structure of the ESU.
- Location allows for strays to support other populations.
- Moderate monitoring program exists (Bogus Creek, Iron Gate Hatchery).

Middle Klamath Population

- Population may be above depensation threshold.
- Provides non-natal rearing habitat and migratory habitat.
- Comprised of a series of low production tributaries with generally monotypic habitat features.
- Formation of low gradient coho habitat systems is constrained by the geology of the Klamath Mountain geomorphic province (particularly the northern range). Deep soils, steep slopes, high precipitation and sediment yields are natural factors controlling the geomorphology within the Middle Klamath population unit. This geomorphology naturally confines coho distribution and abundance.
- Habitat condition is currently good relative to Shasta and Scott.
- High amount of public land ownership
- Concern that recovery actions will not result in population response to the degree necessary to meet the low risk threshold.
- Poor monitoring program exists.

Salmon River Population

- Geology is rocky and does not provide a lot of high IP habitat
- Carrying capacity of the sub-basin is likely lower than other populations in stratum

Other Considerations

Co-manager comments

Co-manager comments included recommendations to (1) re-consider the Shasta population as a core population and replace the selection with the Middle Klamath population; and (2) re-evaluate depensation threshold targets for non-core populations.

We did not find compelling evidence to re-configure the original recommendation to select Upper Klamath, Shasta River, and Scott River as core populations for the Klamath Interior stratum. The decision to select the Shasta River population is based on the factors described above including: a clear understanding of limiting factors and restoration priorities, a high potential for production value, a diversity of life history strategies and habitat features, and a long term data and strong monitoring program. No new information was discovered that warranted changing the selections of the Scott and Upper Klamath populations as core.

Revised IP

The amount of IP above Dwinnell Dam in the Shasta River was calculated and removed from the IP value used to calculate the population's spawner target, but was included in the calculation for the population's low-risk spawner threshold which contributes to the 50% stratum viability target.

IP was revised due to previously unaccounted for natural barriers in the Salmon, Scott, and Shasta river population areas. These revisions are described in Appendix A.

Cost

Preliminary results indicate the total cost of recovery actions needed in each potential core population is as follows:

Upper Klamath - $668 million
Shasta River - $203 million
Scott River - $296 million
Mid-Klamath - $50 million
Salmon River - $25 million

The cost estimates reflect the recovery role for each population. Therefore, the cost estimates for recovery actions identified for non-core populations do not include recovery actions that may be necessary were they made core populations. Cost estimates are often based on the size of a watershed, or length of IP, making costs to produce nearly equal number of spawners disproportionately large for small population areas, and vice versa.

Table D-26. Score Summary for Interior Klamath populations.

Population	BI Score	IR Score	OP Score	Total Score	Low Risk Spawner Threshold
Mid-Klamath	10.5	8	11	29.5	3,900
Salmon	5.5	10	11	26.5	3,900
Scott	10.25	9	8	27.25	6,500
Shasta	5	10	9	24	5,900
Upper Klamath	6.75	8	8	22.75	8,500
Number spawners needed to meet stratum requirement (50% of total)					14,350

Table D-27. Spawner Targets for Interior Klamath populations.

Population	Recovery Role	Target
Scott	**Core**	**6,500**
Shasta	**Core**	**4,700** [1]
Upper Klamath	**Core**	**8,500**
Middle Klamath	Non-Core 1	450
Salmon	Non-Core 1	450
		Total Core: **19,700 Spawners**

[1]IP-km above Dwinnell Dam not included in calculation of population spawner target. See Chapter 4 for explanation of spawner target methodology.

Three core populations, the Upper Klamath, Shasta River, and Scott River populations were chosen for this diversity stratum. This combination allows for the largest amount of IP habitat, spatial diversity, greatest production potential, most appropriate habitat, and unique life history traits to be restored and will achieve the goal of 50% stratum abundance. Non-core population targets represent a four-fold increase in abundance over depensation thresholds.

D.6 Interior Trinity River Population Targets

Application of the method used to select each population's recovery role (i.e., core, non-core 1, non-core 2, extirpated) and identification of appropriate population adult spawner abundance or juvenile occupancy targets resulted in the following Biological Importance (BI), Integrity and Risks (IR), and Optimism and Potential (OP) scores; discussion of other related considerations such as cost; and conclusion. Unless otherwise noted, results are based on information presented in the Interior Trinity River Stratum population profiles.

Table D-28. Biological Importance (BI) Scores for Interior Trinity Populations.

Biological Importance							
Population	Abundance Score	Productivity Score	Spatial Score	Life History Score	Hatchery Score	Depensation Score	BI Score
Lower Trinity River	2	3	3	1	0.25	0.5	9.75
South Fork Trinity River	2	2	1	0.5	0.25	0.5	6.25
Upper Trinity River	3	3	3	1.5	0.25	0.75	9.5

The two highest scoring populations for Biological Importance (BI) are the Lower Trinity and the Upper Trinity. Of great concern across the stratum is the high proportion of hatchery fish within the Trinity watershed. This concern is greatest for the Upper Trinity population where hatchery fish dominate the run (typically, greater than 85% with some years as high as 97% hatchery fish comprising the run [see the year 2000, in Table 2 of the Upper Trinity River population profile]). Population abundance is uncertain for all three populations because surveys are few throughout the basin, although estimates are most robust for Upper Trinity population due to the survey efforts at the Willow Creek weir. Based on this effort, it appears that in some years naturally spawning coho salmon to the Upper Trinity River may exceed the low risk spawner threshold. In contrast, best available information suggests that the South Fork Trinity River and the Lower Trinity River are not likely meeting the population's depensation thresholds.

Table D-29. Integrity and Risks (IR) Scores for Interior Trinity Populations.

Integrity and Risks					
Population	Roads Score	Stress Score	Slope Score	Forest Score	IR Score
Lower Trinity River	3	2	1	2	8
South Fork Trinity River	1	2	2	2	7
Upper Trinity River	3	2	1	3	9

Table D-30. Optimism and Potential (OP) Scores for Interior Trinity Populations.

Optimism and Potential						
Population	Land Score	CDFG Score	Listed Species Score	Species Score	Threat Score	OP Score
Lower Trinity River	3	2	0	3	2	10
South Fork Trinity River	3	2	0	3	2	10
Upper Trinity River	3	2	0	2	2	9

Other Considerations

Cost

Preliminary results indicate the total cost of recovery actions needed in each potential core population of this stratum is as follows:

Lower Trinity River—$68 million
South Fork Trinity River—$123 million
Upper Trinity River—$33 million

The cost estimates reflect the recovery role for each population. Therefore, the cost estimates for recovery actions identified for non-core populations do not include recovery actions that may be necessary were they made core populations. Cost estimates are often based on the size of a watershed, or length of IP, making costs to produce nearly equal number of spawners disproportionately large for small population areas, and vice versa.

Table D-31. Score Summary for Interior Trinity Populations.

Population	BI Score	IR Score	OP Score	Total Score	Low Risk Spawner Threshold
Lower Trinity River	9.75	8	10	27.75	3,600
South Fork Trinity River	6.25	7	10	23.25	6,400
Upper Trinity River	9.5	9	9	27.5	7,300
Number spawners needed to meet stratum requirement (50% of total)					8,800

Table D-32. Spawner Targets for Interior Trinity Populations.

Population	Category	Target
Lower Trinity River	**Core**	**3,600**
South Fork Trinity River	Non-core 1	970
Upper Trinity River	**Core**	**5,800**
		Total Core : **9,700 Spawners**

The Lower Trinity and Upper Trinity River populations are considered the best candidates to serve as the core populations in this stratum for several reasons. Chief among these is a concern that the IP model likely overestimates the current production potential of the South Fork, given the severe degradation that has occurred within the basin as a result of historic flooding. In addition, only a small portion of the tributaries in the South Fork is likely to support coho salmon or their reintroduction in the near future. In comparison, the Lower Trinity and Upper Trinity have nearly three times the number of tributaries that could support coho salmon (See also CDFG 2004). Moreover, according to the Trinity River Flow Evaluation document (USFWS and HVT 1999) about 80 percent of the best coho salmon habitat within the basin historically occurred upstream of the dams.

D.7 Southern Coastal Stratum Population Targets

Application of the method used to select each population's recovery role (i.e., core, non-core 1, non-core 2, extirpated) and identification of appropriate population adult spawner abundance or juvenile occupancy targets resulted in the following Biological Importance (BI), Integrity and Risks (IR), and Optimism and Potential (OP) Scores; discussion of other related considerations such as cost; and conclusion. Unless otherwise noted, results are based on information presented in Southern Coastal Stratum population profiles.

Table D-33. Biological Importance (BI) Score for Southern Coastal Populations.

Biological Importance Score							
				Diversity			
Population	Abundance	Productivity	Spatial	Life History	Hatchery	Depensation	Total
Bear River	0	0	0	0.5	0.75	0	1.25
Humboldt Bay Tribs	3	2	3	1.5	0.75	0.75	11
Lower Eel / Van Duzen	2	2	1	1.5	0.75	0.50	7.75
Mattole River	1	2	1	1	0.75	0.25	6

Population abundance is uncertain as surveys are few and the results are variable. The Bear River population has a conspicuous absence of coho salmon. Surveyed streams in the Humboldt Bay Tributaries population indicate regular adult abundance greater than depensation (191), while the adult abundance is likely below depensation in the Lower Eel/Van Duzen and Mattole Rivers populations. All populations show evidence of decline in all three cohorts, except for Bear River which has no evidence of coho salmon being present.

Coho salmon are found well-distributed throughout the Humboldt Bay tributaries and estuary. However, they are found in less than a quarter of IP habitat in the Mattole River and Lower Eel / Van Duzen River populations – likely as a result of degraded or inaccessible habitat or lack of survey effort. In 2008, coho salmon adult spawners were found in just one Mattole River tributary.

Diversity across the stratum can be influenced by many factors, including life history strategies, hatcheries, and abundance proximity to depensation. The amount of environmental diversity in an area can indicate the degree of potential diversity that same area can support. Life history strategies are greater in Humboldt Bay Tributaries and Lower Eel/Van Duzen Rivers populations where greater environmental and habitat variability exists. The Humboldt Bay Tributaries population includes life history strategies that take advantage of relatively stable temperature and estuarine and bay habitat. The Lower Eel/Van Duzen Rivers population likely possesses many of the same life history strategies as found in the Humboldt Bay Tributaries population, plus strategies that succeed in warmer and dryer conditions farther inland.

Table D-34. Integrity and Risks (IR) Scores for Southern Coastal Populations.

Integrity and Risks Score					
Population	Road	Stress	Slope	Forest	Total
Bear River	1	2	2	2	7
Humboldt Bay Tributaries	1	2	3	1	7
Lower Eel / Van Duzen	1	2	2	2	7
Mattole River	2	2	1	2	7

Water in the mainstem Eel River is closely regulated in accordance with provisions identified in NMFS' biological opinion addressing the Potter Valley Project diversion, including opportunity to annually augment flow by 2,500 acre-feet. Water diversion in all other streams is largely unregulated or uncontrolled.

Humboldt Bay Tributaries and Lower Eel/Van Duzen Rivers populations are comprised of much low-grade slope areas, often associated with a delta or valley. Road densities on low-grade slopes likely produce less erosion and sedimentation than those on steep slopes or inherently unstable geologic material.

Principle stresses in the Lower Eel/Van Duzen Rivers population are altered sediment supply and impaired estuary function, compared to the Mattole River population where they are impaired water quality and altered hydrologic function. Cooling and increasing the volume of water in the Mattole River population is challenging, and severely influences survival. Decreasing sediment and improving estuary function in the Lower Eel/Van Duzen Rivers population appears feasible.

Much of the forest in the Humboldt Bay Tributaries population area has been harvested. However, several decades have passed since most harvest activity, resulting in mid-mature forests which provide more suitable habitat elements than less mature forest. A large portion of the Humboldt Bay Tributaries population area is managed under a federal aquatic habitat conservation plan or by federal agencies with salmonid conservation goals. Other forested areas in the Humboldt Bay Tributaries population area, and other population areas, are primarily regulated by the California Forest Practice Rules.

Table D-35. Optimism and Potential (OP) Scores for Southern Coastal Populations.

Optimism and Potential Score						
Population	Federal Land	CDFG	Listed Species	Species	Threat	Total
Bear River	1	2	1	1	3	8
Humboldt Bay Tributaries	1	3	3	2	2	11
Lower Eel / Van Duzen	2	3	3	2	1	11
Mattole River	2	3	3	2	2	12

There is high non-government organization (NGO) interest in salmon recovery in all populations, except Bear River. The Humboldt Bay Tributaries population is located in the heart of Humboldt County's hub, near Arcata and Eureka, California. Generating interest and support for restoring habitats in highly visible watersheds such as the Humboldt Bay Tributaries and Lower Eel/Van Duzen Rivers population areas is generally much easier than rural sites. However, some rural locations, such as in the Mattole River population, have created a culture centered on salmon restoration and conservation.

Moderate amounts of federal land managed with salmon conservation goals in the Lower Eel/Van Duzen Rivers and Mattole River populations provide enhanced opportunity for restoration opportunities. All population areas possess suitable private land which can contribute toward restoration through development, or implementation, of a federal habitat conservation plan, or are eligible for receipt of federal or state grant funding.

The number of threat categories that rank high or very high is a function of threat opportunity. The Lower Eel/Van Duzen Rivers scores low due to a larger array of different environs and thus human activity. For instance, the Lower Eel/Van Duzen Rivers population area may have more opportunity for agricultural threat because a large portion of the area is conducive to farming, in contrast to the Mattole River population area where little traditional farming opportunities exist. Threat opportunity may be linked to the size of the population area – potentially explaining why the large Lower Eel/Van Duzen Rivers population area received a low threat score.

In addition, the larger population areas with the greatest amount of IP habitat may equate to more opportunity for active and passive restoration.

Other Considerations

Cost

Preliminary results indicate the total cost of recovery actions needed in each potential core population is as follows:

Bear River - $21 million
Humboldt Bay Tributaries - $99 million
Lower Eel / Van Duzen - $567 million
Mattole River - $81 million

The cost estimates reflect the recovery role for each population. Therefore, the cost estimates for recovery actions identified for non-core populations do not include recovery actions that may be necessary were they made core populations. Refer to chapter 6 for additional information about cost.

Cost estimates are often based on the size of a watershed, or length of IP, making costs to produce nearly equal number of spawners disproportionately large for small population areas, and vice versa.

Table D-36. Score Summary for Southern Coastal Populations.

Population	BI	IR	OP	Total	Low Risk Spawner Threshold
Bear River	1.25	7	8	16.25	1,900
Humboldt Bay Tributaries	11	7	11	29	5,700
Lower Eel / Van Duzen	7.75	7	11	25.75	7,900
Mattole River	6	7	12	25	6,500
Number spawners needed to meet stratum requirement (50% of total)					11,000

Table D-37. Spawner Targets for Southern Coastal Populations.

Population	Recovery Role	Target
Bear River	Non-Core 2	Juvenile occupancy
Humboldt Bay Tributaries	**Core**	**5,700**
Lower Eel / Van Duzen	**Core**	**7,900**
Mattole River	Non-Core 1	1,000
		Total Core : **13,600 Spawners**

The Humboldt Bay Tributaries and Lower Eel/Van Duzen Rivers populations are the best candidates to efficiently serve as core populations in this stratum because they have the total highest BI scores, and their collective adult spawner abundance target exceeds the minimum stratum requirement. IR scores are nearly equal for all populations.

Targets for the Humboldt Bay Tributaries and Lower Eel/Van Duzen Rivers populations reflect the adult spawner abundance required for a low risk of extinction. The Mattole River population spawner abundance target is a product of the depensation threshold multiplied by four, because it is serving a non-core 1 role. The Bear River population target is juvenile occupancy, because it is serving as a non-core 2 population.

D.8 Interior Eel River Stratum Population Targets

Application of the method used to select each population's recovery role (i.e., core, non-core 1, non-core 2, extirpated) and identification of appropriate population adult spawner abundance or juvenile occupancy targets resulted in the following Biological Importance (BI), Integrity and Risks (IR), and Optimism and Potential (OP) Scores; discussion of other related considerations such as cost; and conclusion. Unless otherwise noted, results are based on information presented in Interior Eel River Stratum population profiles.

Table D-38. Biological Importance (BI) Score for Interior Eel River Populations.

Biological Importance Score							
				Diversity			
Population	Abundance	Productivity	Spatial	Life History	Hatchery	Depensation	Total
Mainstem Eel River	1	1	1	1	0.75	0.25	5
Middle Mainstem Eel River	1	1	1	1	0.75	0.25	5
Upper Mainstem Eel River	0	0	0	0.5	0.75	0	1.25
North Fork Eel River	0	0	0	0.5	0.75	0	1.25
Middle Fork Eel River	0	0	0	0.5	0.75	0	1.25
South Fork Eel River	3	3	2	1	0.75	0.75	10.5

Population abundance is uncertain as surveys are few and the results are variable. Limited surveys of the Upper Mainstem Eel River, Middle Fork Eel River, and North Fork Eel River sub-basins suggest that they do not support coho salmon consistently. The South Fork Eel River population abundance is likely above depensation (i.e., 460) in some years. All populations show evidence of decline in all three cohorts, particularly for the Upper Mainstem Eel, Middle Fork Eel, and North Fork Eel populations, which may have lost all three year classes.

Coho salmon distribution is largely un-documented in the populations within this stratum and is rated as very limited in all areas except the South Fork Eel River population. In the South Fork Eel River, coho salmon occur in 25 to 50 percent of Intrinsic Potential (IP) habitat, primarily in the western tributaries such as Hollow Tree Creek. In the western tributaries of the South Fork Eel River population, coho salmon are well distributed and occupy the majority (>90%) of IP habitat.

Diversity across the stratum is influenced by many factors, including life history strategies and abundance which is often below the depensation threshold. The rating for life history diversity assigned to all populations indicates they contain diverse habitat types which could support atypical life history strategies. Most populations in this stratum could be considered "long run" given the distance adult fish must migrate to their natal spawning grounds from the ocean, which constitutes a unique life history strategy. All populations rated the same for hatchery influence, with a presumed low proportion of hatchery strays in the spawning populations. All populations except the South Fork Eel River received a low score for depensation, because the number of spawners is likely significantly less than the depensation threshold.

Table D-39. Integrity and Risks (IR) Scores for Interior Eel River Populations.

Integrity and Risks Score					
Population	Road	Stress	Slope	Forest	Total
Mainstem Eel River	1	1	2	2	6
Middle Mainstem Eel River	1	1	2	3	7
Upper Mainstem Eel River	2	2	2	3	9
Middle Fork Eel River	2	2	2	2	8
North Fork Eel River	2	1	2	2	7
South Fork Eel River	1	1	2	2	6

Water in the mainstem Eel River is closely regulated in accordance with provisions identified in NMFS' biological opinion addressing the Potter Valley Project diversion, including opportunity to augment flow which may assist in reducing issues with water quality during periods of extremely low flows or muted spring flow. Water diversion in all other streams is largely unregulated or uncontrolled.

In the Upper Mainstem Eel River, Middle Fork Eel River, and North Fork Eel River, much of the high IP habitat is located under the temperature mask, indicating water temperature within these populations is likely intrinsically inhospitably warm.

The highest road densities occur in the Mainstem, Middle Mainstem, and Middle Fork Eel River populations. Principle stresses in most populations are sediment, degraded riparian condition, and floodplain and channel structure. The Upper Mainstem Eel River principal stresses, in contrast, are barriers obstructing passage and impaired water quality. These stresses in these populations may be more difficult to resolve than those in the other populations. All populations are comprised of primarily mid to low gradient stream reaches, often associated with a delta or valley. Forest integrity in the Middle Mainstem Eel River and Upper Mainstem Eel River populations was rated higher than other populations primarily due to lower harvest rates.

Table D-40. Optimism and Potential (OP) Scores for Interior Eel River Populations.

Optimism and Potential Score						
Population	Federal Land	CDFG	Listed Species	Species	Threat	Total
Mainstem Eel River	1	2	2	2	2	9
Middle Mainstem Eel River	2	3	1	2	1	9
Upper Mainstem Eel River	3	1	2	1	2	9
Middle Fork Eel River	2	1	3	2	2	10
North Fork Eel River	2	1	3	2	2	10
South Fork Eel River	1	3	3	2	1	10

There is a high level of interest in the South Fork Eel River population area, and it hosts the most abundant and stable spawning cohorts in the stratum. One of the most significant tributaries, Hollow Tree Creek, has consistent presence of all three cohorts of coho salmon. Out-migrant trapping efforts indicate that Hollow Tree Creek can produce more than 35,000 smolts per season. There is a draft federal aquatic Habitat Conservation Plan (HCP) throughout most of the Hollow Tree Creek watershed. The HCP, when finalized, would reduce sediment and improve habitat complexity in the near future. Several long-standing and well-supported non-government organizations, as well as state, federal and tribal entities regularly express interest in conserving salmon and aquatic habitat within the Eel River basin.

The Eel River estuary is located within the Lower Eel/Van Duzen Rivers population area (downstream of the Interior Eel River stratum) and has great potential for restoration because the estuary remains functional and there is high opportunity for increasing the size and availability of the floodplain and off channel habitats. The Eel River estuary likely serves as essential non-natal juvenile rearing habitat,. Impaired estuarine function is a stress to all populations in this stratum. All population areas possess suitable private land which can contribute toward restoration through development, or implementation, of a federal HCP. Much of the private land is eligible for receipt of federal or state grant funding.

Other Considerations

Cost

Preliminary results indicate the total cost of recovery actions needed in each potential core population is as follows:

Mainstem Eel River - $130 million
Middle Mainstem Eel River - $126 million
Upper Mainstem Eel River - $36 million
Middle Fork Eel River - $163 million
South Fork Eel River - $251 million

The cost estimates reflect the recovery role for each population. Therefore, the cost estimates for recovery actions identified for non-core populations do not include recovery actions that may be necessary were they made core populations. Cost estimates are often based on the size of a watershed, or length of IP, making costs to produce nearly equal number of spawners disproportionately large for small population areas, and vice versa.

Table D-41. Score Summary for Interior Eel River Populations.

Population	BI	IR	OP	Total	Low Risk Spawner Threshold
Mainstem Eel River	5	6	9	20	2,600
Middle Mainstem Eel River	5	7	9	21	6,300
Upper Mainstem Eel River	1.25	9	9	19.25	2,100
Middle Fork Eel River	1.25	8	10	19.25	2,900
North Fork Eel River	1.25	7	10	18.25	2,100
South Fork Eel River	10.5	6	10	26.5	9,300
Number spawners needed to meet stratum requirement (50% of total)					12,650

Table D-42. Spawner Targets for Interior Eel River Populations.

Population	Recovery Role	Target
Mainstem Eel River	**Core**	**2,600 spawners**
Middle Mainstem Eel River	**Core**	**6,300 spawners**
Upper Mainstem Eel River	Non-Core 2	Juvenile occupancy
Middle Fork Eel River	Non-Core 2	Juvenile occupancy
North Fork Eel River	Non-Core 2	Juvenile occupancy
South Fork Eel River	**Core**	**9,300 spawners**
		Total Core : **18,200 Spawners**

The Mainstem Eel River, Middle Mainstem Eel River, and South Fork Eel River populations are the best candidates to efficiently serve as core populations in this stratum because they have the total highest BI scores, and their collective adult spawner abundance target exceeds the minimum stratum requirement. Equally important, the other three populations – Upper Mainstem Eel River, Middle Fork Eel River, and North Fork Eel River – have inherently extremely low potential to produce coho salmon and several anthropogenic-derived challenges.

Targets for the Mainstem Eel River, Middle Mainstem Eel River, and South Fork Eel River populations reflect the adult spawner abundance required for core populations. Targets for core populations were set to achieve a low risk of extinction.

The target for the Middle Fork Eel River and North Fork Eel River populations is juvenile occupancy, which is the target for non-core 2 populations. This is based on the lack of coho salmon in these populations over the last several decades.

Over a period of several decades, the Upper Mainstem Eel River population has had very few observations of coho salmon at the fish counting station at Van Arsdale. Although recent observations in the last decade appear promising, the Upper Mainstem Eel River population remains unoccupied during almost all years on record. Furthermore, all of the IP habitat which is not covered by the temperature mask is located upstream of the Scott Dam. When IP habitats upstream of the dam or under the temperature mask are removed, it leaves this population with only 0.5 km of IP habitat (which is not enough lineal habitat to be considered as a population). Given the extremely episodic nature of coho salmon observations in the Upper Mainstem Eel River population, the non-core 2 population target for juvenile occupancy is the most reasonable target.

Appendix E. Recovery Action Cost Methodology

To determine recovery action costs for the SONCC coho salmon ESU, a systematic and consistent methodology is applied. In general, cost estimates are derived from previous, similar projects or tasks (Tables E-2 to E-51). Each recovery action cost estimate is limited to the monetary expenditure required to physically perform the task, and therefore does not include secondary costs (e.g., administrative, overhead) or economic costs or benefits (e.g., fishing, tourism, lost opportunity) that may result from action implementation. In order to facilitate the short-term and mid-term costs of the recovery actions, costs are presented in five year intervals out to 25 years (i.e., 0-5, 5-10, 15-20, 20-25), with one value estimated for costs beyond 25 years (i.e., 26+ years). Cost estimates are not calculated for those actions determined not essential for recovery ("NA" priority).

Factors such as project scale and location are accounted for when possible, and costs are calculated accordingly. For example, county and population-specific data is used to inform the cost of actions that occur in those particular areas. Additionally, the costs of past projects used to inform recovery action cost estimates are adjusted for inflation. The scale of a recovery action is often unknown. In these cases an assumption is made regarding the amount or extent of work needed to achieve the recovery objective. For example, if the amount of roads in need of decommissioning in a given population is unknown, the assumption is to reduce the amount of roads to a level equal to a "medium" threat. Table E-18 indicates the cost to decommission one mile of road in the Humboldt Bay watershed is $39,878. If 85 miles of road need to be decommissioned, the estimated cost is $3,389,630 ($39,878 multiplied by 85 miles).

Some recovery actions involve policy changes, coordination, or other activities that rely primarily on staff time. The cost of these actions may either be "0" or the cost of staff salary. When the cost is calculated as "0," the action was assumed to be cost of doing business. This would include an administrative action such as regulation change or a task that is part of an existing work load. When an action requires a staff person to go above and beyond their existing duties, the cost is calculated by multiplying the annual salary (Table E-2) of the occupation most likely to complete the task by the amount of time anticipated to complete the task. For example, an action to educate stakeholders regarding water conservation practices may require six months of a professional biologist's time. (Table E-2) indicates a professional biologist's time costs $68,030 a year. In this case, the estimated cost is $34,015 ($68,030 multiplied by 0.5 years).

Recovery action costs are calculated for each action-step level and calculated in spreadsheets containing population specific data (e.g., watershed acreage, amount of IP habitat, road density) and recovery action cost information. A sample spreadsheet outlining the process for calculating recovery action costs can be found in Table E-1.

Table E-1. Sample of the cost estimation spreadsheet.

Number of miles is unknown; use blanket assumption

Number of miles is unknown; use blanket assumption

Data from "Road Inventory" worksheet ($635/mi)

Data from "Population Statistics" worksheet (878 total road miles in the Mattole watershed)

Action Step	Explanation	Factor 1	Factor 2	Cost (years 1-5)
Assess and prioritize road-stream connection, and identify appropriate treatment to meet objective	Road inventory in Mattole * 878 miles total roads in watershed	635	878	$557,530
Decommission roads, guided by assessment	Road decom. in California * 286 miles (to obtain 2mi/mi² density)	39,878	286	$11,405,108
Upgrade roads, guided by assessment	Road upgrade in Mattole * 59.4 miles (10% of remaining roads after decom)	32,857	59.4	$1,951,706
Maintain roads, guided by assessment	Gravel road maintenance * 594 (# of road miles remaining after decom)	2,389	594	$1,419,066

Table E-38. Information used to estimate cost of water development away from streams.

Water Development Away from Streams		
Materials	**$/ft, $**	**Source**
Piping*	0.4	USEPA 1990
Tank**	407	

*If length of piping is unknown, assume 500 ft/project.
**If number of projects (tanks) is unknown, assume 1 per mile in 5% of high IP miles.

Table E-39. Information used to estimate cost of day-lighting a stream section.

Stream Day-lighting	
$/lineal foot*	**Source**
886	Leah Mahan: NOAA RC pers. comm. Dec. 2010; average from projects, Madrona Park Creek and Ravenna Creek

*If number of feet is unknown assume 5,280 (1 mi).

Table E-40. Information used to estimate cost of creating a conservation easement.

Conservation Easement		
Region	**$/acre**	**Source**
Wolverton Gulch, Van Duzen River, Humboldt County, Monterey County, Arroyo Seco River	1,992	NMFS 2008, pg. 55
South Coast, Santa Barbara	65,000	
San Joaquin River	6,867	
Battle Creek	395	
North Fork Cosumnes River	1,101	
Mill Creek/Deer Creek	223	
Tuolumne River	6,282	
San Joaquin Delta	3,205	
Mill Creek/Deer Creek - Sac River	5,385	
Sacramento River	1,646	
Lower Tuolumne/San Joaquin	1,646	
CA	534	

Table E-41. Information used to estimate cost of performing a road inventory.

Road Inventories		
Location	**$/mi**	**Source**
Humboldt County	829	NMFS 2008, pg. 61
Eel River	538	
Mattole River	635	
Russian River	936	
Salmon Creek	1068	
Gualala River	837	
Avg. all Inventories	807	

Table E-42. Information used to estimate cost of performing an erosion assessment.

Erosion Assessments		
Location	**$/acre***	**Source**
Humboldt County	9.5	NMFS 2008, pg 61
Del Norte County	11.9	
Average all assessments in CA**	10.7	

*When number of acres unknown, assume 25% of total watershed acres.

**Average does not include figure of $3,157/acre.

Table E-43. Information used to estimate cost of conducting a fuels management program.

Fuel Management Program		
Type of Program*	**$/acre***	**Source**
Prescribed burn: brush/grass	35	USDA Forest Service 2004
Prescribed burn: ponderosa pine	98	
Prescribed burn: mixed conifer	198	
Prescribed burn: Douglas fir	14	
Mechanical Treatment: Low intensity	426	FRFTP 2006
Mechanical Treatment: High Intensity	851	

*If type of program and number of acres is unknown, assume 25% of high IP habitat will treated w/ mechanical thinning and 25% will be treated with burning. Treat IP miles as square miles and convert to acres.

Table E-44. Information used to estimate cost of running a lifecycle monitoring station.

Life Cycle Monitoring Station	
$/Monitoring Station	**Source**
204,000	NMFS 2008

Table E-45. Information used to estimate cost of removing invasive plants.

Removal of Invasive Plant Species		
Species	**$/acre***	**Source**
Arundo	29,762	Neil 2002
Himalayan Blackberry	990	Bennet 2007 (avg)
Purple Loosestrife and Water Chestnut	361	USFWS 2001
Pepperweed and Giant Reed	1,000	Northern California Conservation Center 2010
Average (excluding outlier of Arundo)	784	

*If number of acres is unknown, assume 80 acres per mile will be treated in 5% of high IP miles.

Table E-46. Information used to estimate cost of eradicating pikeminnow.

Pikeminnow Eradication	
$/Fish	Source
6.65	NMFS 2008, pg. 67

*Cost averaged from rewards in a bounty program.

Table E-47. Information used to estimate cost of installing fish screens.

Fish Screens		
Size of Tributary	$/Screen*	Source
Large Trib	45,454	NMFS 2008, pg 16
Small Trib	11,364	

*If number and type of screens is unknown, assume 'small trib' and 1 screen per mile in 5% of the high IP miles.

Table E-48. Information used to estimate cost of maintaining fish screens.

Fish Screen Maintenance	
$/Screen/yr	Source
1,566	NMFS 2008, pg. 68

Table E-49. Information used to estimate cost of education and outreach programs.

Education and Outreach Programs		
Type	$/program	Source
General Education and Outreach	76,136	CDFG, 2004 pg I.42
Coho Specific Education	55,682	

Table E-50. Information used to estimate cost of all aspects of running a conservation hatchery.

Conservation Hatchery		
Type of Operation	$/year	Source
General Operation	120,000	pers. comm. Jeff Jahn 2010; estimate from Monterey County Conservation Hatchery
Robust Monitoring and Evaluation Program to Support Program	250,000	pers. comm. Jeff Jahn 2010; estimate from Russian River monitoring program
Genetic Component (samples, assessments)	50,000	pers. comm. Jeff Jahn 2010; estimate from Russian River genetic program

Table E-51. Information used to estimate cost of converting a production hatchery to a conservation hatchery.

Conversion to Conservation Hatchery		
Extent of Retrofit	**$/type**	**Source**
No retrofit needed, facilities in place	0	pers. comm. Jeff Jahn 2010; estimated based on heavy retrofitting in the Russian River Conservation Hatchery
Light retrofit (a few extra tanks, etc.)	50,000	
Medium retrofit	150,000	
Heavy retrofitting with extensive new infrastructure	500,000

Appendix G. Cost and Potential Lead for Recovery Actions

G.1 Cost of Recovery

This appendix contains an estimated cost for all recovery actions, as well as the potential lead for each recovery action. The methods used to calculate cost are described in Appendix D. No cost was estimated for actions rated priority BR, as these actions, although helpful, are not considered necessary to achieve ESA recovery of the SONCC coho salmon ESU. Cost is estimated in accordance with the year the action would occur relative to when implementation of this plan begins (year 1). Costs are broken into five-year increments (i.e., 1-5, 6-10, 11-15, 16-20, and 21-25) except for the last category, 26+, which includes all costs after year 25. The calculation of cost estimates does not imply funding availability.

The summarized cost of SONCC coho salmon recovery actions is presented by population and diversity stratum in Table G-1.

Table G-1. Summary of estimated cost of recovery actions for each population and diversity stratum.

Stratum	Population	Recovery Role	Cost for Recovery Actions
Southern Coast	Mattole River	Independent; Non-Core 1	$82,281,985
	Bear River	Potentially Independent, Non-Core 2	$20,752,335
	Lower Eel/Van Duzen rivers	Independent; Core	$565,862,528
	Humboldt Bay Tributaries	Independent; Core	$97,948,038
	Guthrie Creek	Dependent	$6,875,130
Stratum Total			*$773,720,015*
Interior Eel	Mainstem Eel River	Potentially Independent, Core	$128,010,151
	Middle Mainstem Eel River	Potentially Independent, Core	$162,780,123
	Upper Mainstem Eel River	Potentially Independent, Non-Core 2	$35,579,288
	South Fork Eel River	Independent, Core	$249,938,315
	Middle Fork Eel River	Independent, Non-Core 2	$162,780,123
	North Fork Eel River	Independent, Non-Core 2	$24,329,957
Stratum Total			*$763,417,956*

Stratum	Population	Recovery Role	Cost for Recovery Actions
Central Coast	Smith River	Independent, Core	$135,806,107
	Lower Klamath River	Independent, Core	$157,651,770
	Redwood Creek	Independent, Core	$139,011,838
	Maple Creek/Big Lagoon	Dependent	$25,991,878
	Little River	Potentially Independent, Non-Core 1	$23,482,027
	Mad River	Independent, Non-Core 1	$116,004,701
	Elk Creek	Dependent	$13,750,603

G.2 Explanation of fields

Recovery Action Step Number

The unique recovery action step identifier, composed of the recovery action number followed by an additional number which refers to the sequential order of the action step (e.g., 1, 2, 3, or 4). E.g., recovery action number SONCC-HBT.2.2, recovery action step number SONCC-HBT.2.2.1 refers to first recovery action step of that recovery action number). The recovery action step number is provided in Appendix F so the reader can cross reference information about a particular recovery action between the tables in the profiles and Appendix F.

Potential Lead

The "Potential Lead" is the entity most likely to carry out a recovery action based on its authority, expertise, or other factors. Identification of a candidate "Potential Lead" does not require the identified party to implement an action or to secure funding for such, nor does it preclude any other party from implementing the action or obtaining funds to do so.

5 Year Cost

The 5 year cost is the estimated cost to carry out the subject action in years 1 to 5. The method used to estimate cost is described in Section G.1 and Appendix D.

10 Year Cost

The 10 year cost is the estimated cost to carry out the subject action in years 6 to 10. The method used to estimate cost is described in Section G.1 and Appendix D.

15 Year Cost

The 15 years cost is the estimated cost to carry out the subject action in years 11 to 15. The method used to estimate cost is described in Section G.1 and Appendix D.

20 Year Cost

The 20 year cost is the estimated cost to carry out the subject action for years 16 to 20. The method used to estimate cost is described in Section G.1 and Appendix D.

25 Year Cost

The 25 year cost is the estimated cost to carry out the subject action for years 21 to 25. The method used to estimate cost is described in Section G.1 and Appendix D.

26+ Year Cost

The 26+ year cost is the estimated cost to carry out the subject action for years 26 and after. The method used to estimate cost is described in Section G.1 and Appendix D.

Total Cost

The total cost is the estimated cost to carry out the subject action over all years. The method used to estimate cost is described in Section G.1 and Appendix D.

Appendix H. Glossary and List of Abbreviations and Acronyms

H.1 Glossary

abundance: The number of individuals in a population or subpopulation.

adaptive management: In salmon recovery planning, a method of decision making in the face of uncertainty. A plan for monitoring, evaluation, and feedback is incorporated into an overall implementation plan so that the results of action can become feedback on design and implementation of future actions.

alevins: Larval life stage which lives in a redd and is dependent on food stored in a yolk sac.

anadromous: Species (e.g., salmon) that migrate as juveniles from freshwater to saltwater and then return as adults to spawn in freshwater.

anthropogenic: Of, relating to, or resulting from the influence of human beings on nature (Webster 2001).

artificial propagation: Any assistance provided by man in the reproduction of salmon. This assistance includes, but is not limited to, spawning and rearing in hatcheries, stock transfers, creation of spawning habitat, egg bank programs, captive breeding broodstock programs, and cryopreservation (Hard et al. 1992).

basin: Area of land where surface water converges to a single point, usually the exit of the basin, where the waters join another water body. Examples of basins are the Eel River basin, Rogue River basin, and Klamath-Trinity River basin. The basin is the largest classification unit in a hierarchical drainage system adopted by NMFS for the SONCC coho salmon ESU recovery plan. This hierarchical drainage system is made up of basins (largest scale), sub-basins (intermediate scale), and watersheds (smallest scale). See also *sub-basin* and *watershed*.

biological review team (BRT): The team of scientists from the National Marine Fisheries Service formed to conduct a status review.

broad-sense recovery: Goal of having populations of naturally produced salmon sufficiently abundant, productive, and diverse (in terms of life history and geographic distribution) that the ESU/DPS as a whole (a) will be self-sustaining, and (b) will provide significant ecological, cultural, and economic benefits (ODFW and NMFS 2011). This goal is consistent with ESA delisting, but is designed to achieve a level of performance for the ESUs and constituent population that is far more robust than that needed to remove the ESU from ESA protection (ODFW and NMFS 2011).

captive broodstock program: A form of artificial propagation involving the collection of individuals or gametes from a natural population and rearing of these individuals to maturity in captivity (Hard et al. 1992).

carrying capacity: The maximum population of a species that an area or specific ecosystem can support indefinitely without deterioration of the character and quality of the resource (NOAA 2006).

coefficient of variation (cv): the ratio of the standard deviation to the mean, which shows the extent of variability in relation to the mean.

confluence: A flowing together of two or more streams.

critical habitat: The specific areas within the geographical area occupied by the listed species at the time it is listed in accordance with the provisions of section 4 the ESA, on which are found those physical or biological features that are essential to the conservation of the species and which may require special management considerations or protection; and specific areas outside the geographical area occupied by the species at the time it is listed in accordance with the provisions of section 4 of the ESA, upon a determination by the Secretary that such areas are essential for the conservation of the species (ESA of 1973, as amended, 16 U.S.C. §1531 et seq.).

delist: When an ESA-listed species is removed from the list of species protected under the ESA.

delisting criteria: Criteria used to determine whether an ESA-listed species no longer needs the protections of the ESA and may be delisted.

dependent population: Populations that rely upon immigration from surrounding populations to persist. Without these inputs, Dependent Populations would have a lower likelihood of persisting over 100 years (Williams et al. 2006).

demographic: the statistics of a given population, such as abundance or growth rate.

depensation: The effect where a decrease in spawning stock leads to reduced survival or production of eggs through either (1) increased predation per egg given constant predator pressure, or (2) the "Allee effect" (the positive relationship between population density and the reproduction and survival of individuals) with reduced likelihood of finding a mate (Liermann and Hilborn 2001).

diversity: All the genetic and phenotypic (life history, behavioral, and morphological) variation within a population (NOAA 2006). Diversity includes diversity of (potential) selective environments, diversity of phenotypes, including life history types, and diversity of genetic variation, both neutral and selected (Williams et al. 2006).

diversity stratum: Groups of populations that span the diversity and distribution that currently exists or historically existed within the ESU (Williams et al. 2006). Diversity, broadly defined, was the basis for delineating these groups (Williams et al. 2006).

domestication selection: Natural selection operating on a population during artificial propagation that encourages adaptation to the hatchery environment at the expense of adaptation to the natural environment (Hard et al. 1992).

El Niño: A warming of the ocean surface off the western coast of South America that occurs every 4 to 12 years when upwelling of cold, nutrient-rich water does not occur. It causes die-offs of plankton and fish and affects Pacific jet stream winds, altering storm tracks and creating unusual weather patterns in various parts of the world (NOAA 2006).

ephemeral population: Populations which have a substantial likelihood of going extinct within a 100-year time period in isolation, and do not receive sufficient immigration to affect this likelihood. Habitats that support such populations are expected to be occupied only for relatively short periods of time, and rarely at high densities (Williams et al. 2006).

estuary: A coastal ecological ecosystem that is partially enclosed, receives freshwater input from land, and has a horizontal fresh-salt salinity gradient; the average salinity of estuarine waters is defined as being 30 practical salinity units (PSU) for at least 1 month per year (NOAA 2006).

extant: Not destroyed or lost (Webster 2001).

extinction: In evolutionary biology, the failure of groups of organisms of varying size and inclusiveness (e.g., local geographic or temporally-defined groups to species) to have surviving descendants.

extinction risk: The probability that a given population will become extinct within 100 years. Low probability of extinction is defined for this purpose as 5 percent over 100 years (Williams et al. 2006).

extirpation: Population-level extinction.

fry: A life stage of coho salmon defined by emergence from gravel in redds; the smallest fry are typically 30 to 45 mm, and at 50 to 60 mm they transition to the "juvenile" life stage. Both fry and juveniles are called "young of the year".

functionally independent population: Populations with a high likelihood of persisting in isolation over a 100-year time scale, which are not substantially altered by exchanges of individuals with other populations (Williams et al. 2006).

hatchery: Salmon hatcheries typically spawn adults in captivity and raise the resulting progeny in fresh water for release into the natural environment. In some cases, fertilized eggs are out-planted (usually in "hatch-boxes"), but it is more common to release fry (young juveniles) or smolts (juveniles that are physiologically prepared to undergo the migration into salt water). The fish are released either at the hatchery (on-station release) or away from the hatchery (off-station release). Releases may also be classified as within basin (occurring within the river basin in which the hatchery is located or the stock originated from) or out-of-basin (occurring in a river basin other than that in which the hatchery is located or the stock originated from). The broodstock of some hatcheries is based on adults that return to the hatchery each year; others rely on fish or eggs from other hatcheries, or capture adults in the wild each year (Hard et al. 1992).

hatchery fish: Fish that have spent some portion of their lives, usually their early lives, in a hatchery.

hatchery-origin fish: See *hatchery fish*.

independent population: Any collection of one or more local breeding units whose population dynamics or extinction risk over a 100-year time period is not substantially altered by exchanges of individuals with other populations (Williams et al. 2008). Also see “potentially independent population” and “functionally independent population”.

Intrinsic Potential: The potential of the landscape to support a population. The Intrinsic Potential of a watershed or stream reach, is used to evaluate the likelihood of the area to support fish, and is used when population characteristics are unknown (Williams et al. 2006).

jacks: Male salmon that return from the ocean to spawn one or more years before full-sized adults return. For coho salmon in California, Oregon, Washington, and southern British Columbia, jacks are 2 years old, having spent only 6 months in the ocean, in contrast to adults, which are 3 years old after spending 1½ years in the ocean (NOAA 2006).

juvenile: Life stage after the fry stage, beginning at about 50 to 60 mm. Juveniles typically rear in fresh water for up to 15 months, then migrate to the ocean as ‘‘smolts’’ in the spring.

key limiting stresses: Those stresses which have the greatest impact on current population viability.

key limiting threats: Those threats which have the greatest impact on current population viability.

large woody debris: Any large piece of woody material that intrudes into a stream channel, whose smallest diameter is greater than 10cm, and whose length is greater than 1 m.

limiting factor: An environmental factor that limits the growth or activities of an organism or that restricts the size of a population or its geographical range.

listed species: Any species of fish, wildlife or plant which has been determined to be endangered or threatened under the ESA.

natural fish: See *wild fish*.

natural-origin fish: See *wild fish*.

osmoregulation: The active regulation of an organism’s fluids to keep them from becoming too diluted or too concentrated.

pelagic: Of or pertaining to the open ocean.

phenotype: The observable physical or biochemical characteristics of an organism, as determined by both genetic makeup and environmental influences.

pinniped: Carnivorous aquatic mammals that include the seals, walrus, and similar animals having finlike flippers as organs of locomotion.

population: A group of individuals of the same species that live in the same place at the same time and exhibit some level of reproductive isolation from other such groups. In some contexts, a randomly mating group of individuals that is reproductively isolated from other groups is considered a population. A population may consist of a single isolated run or more than one connected run. Synonymous with *stock* (McElhany et al. 2000).

population size: The number of adults in a population.

potentially independent population: Populations with a high likelihood of persisting in isolation over a 100-year time scale, but which are too strongly influenced by immigration from other populations to exhibit independent dynamics (Williams et al. 2006).

power analysis: A statistical procedure to determine the probability of detecting a trend when a trend in fact exists.

productivity: The population growth rate, measured as the spawner-to-spawner ratio (returns per spawner or recruits per spawner).

recovery: The reestablishment or rehabilitation of a threatened or endangered species to a self-sustaining level in its natural ecosystem (NOAA 2006).

recovery domain: The geographic area for which a Technical Recovery Team is responsible.

recovery plan: Under the ESA, a document identifying actions needed to improve the status of a species or ESU to the point that it no longer requires protection (*Hard et al. 1992*) (see ESA Section 4(f), 16 U.S.C. §1533(f), for applicable requirements).

recovery supplementation: Short-term artificial propagation designed to reduce the risk of extinction of a small or chaotically fluctuating recovering population in its natural habitat by temporarily increasing population size using recovery hatchery fish, while maintaining available genetic diversity and avoiding genetic change in the natural and hatchery populations.

redd: Gravel nest excavated by spawning female coho salmon.

refugia: An area where special environment circumstances occur, enabling individuals to survive in specific life stages.

residualization: The process by which anadromous juvenile salmonids fail to emigrate seawards within the primary migration period.

riparian area: An area with distinctive soils and vegetation between a stream or other body of water and the adjacent upland. It includes wetlands and those portions of floodplains and valley bottoms that support riparian vegetation (Belsky et al. 1999).

riparian vegetation: Vegetation growing on or near the banks of a stream or other body of water in soils that exhibit some wetness characteristics during some portion of the growing season (Welsch 1991).

self-sustaining population: A population that perpetuates itself without human intervention, without chronic decline, and in its natural ecosystem, at sufficient levels that the protections of the ESA are no longer required.

smoltification: The process whereby a salmonid fry transforms into the smolt life stage.

spatial structure: The spatial distribution of individuals in a population.

spawner surveys: Spawner surveys utilize counts of live fish, redds (nests dug by females in which they deposit their eggs) and fish carcasses to estimate spawner abundance and identify habitat being used by spawning fish. Annual surveys can be used to compare the relative magnitude of spawning activity between years.

species: Generally, a fundamental category of taxonomic classification, ranking below a genus or subgenus and consisting of related organisms capable of interbreeding. Under the ESA, it includes any subspecies of fish or wildlife or plants, and any distinct population segment of any species of vertebrate fish or wildlife which interbreeds when mature (ESA of 1973, as amended, 16 U.S.C. §1531 et seq.)

stochastic: The term is used to describe natural events or processes that are random. Examples include environmental conditions such as rainfall, runoff, and storms, or life-cycle events, such as survival or fecundity rates.

stock: See *population.*

stress: The physical, biological, or chemical conditions and associated ecological processes that may impede SONCC coho salmon ESU recovery. Stresses are caused by threats.

sub-basin: Area of land draining into a stream or river within a large basin. Examples of sub-basins are the Middle Klamath River, the Upper Mainstem Eel River, the Lower Rogue River, and the South Fork Trinity River. The sub-basin is the intermediate classification in a hierarchical drainage system adopted by NMFS for the SONCC coho salmon ESU recovery plan. This hierarchical drainage system is made up of basins (largest scale), sub-basins (intermediate scale), and watersheds (smallest scale). See also *basin* and *watershed*.

take: To harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to engage in any such conduct to a Federally listed species (ESA of 1973, as amended, 16 U.S.C. §1531 et seq.).

technical recovery team (TRT): The team of scientists from NMFS and other entities formed to develop biological viability criteria for listed Evolutionarily Significant Units (ESUs) that will be considered in setting recovery goals (Williams et al. 2006).

threat: Activities or impacts that cause or contribute to the stresses that limit recovery of the SONCC coho salmon ESU.

threatened species: Any species which is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range (ESA, as amended, 16 U.S.C. §1531 et seq.).

viability: The likelihood that a population will sustain itself over a 100-year time frame (McElhany et al. 2000).

viable salmonid population: An independent population of any Pacific salmonid (genus *Oncorhynchus*) that has a negligible risk of extinction due to threats for demographic variation (random or directional), local environmental variation, and genetic diversity changes (random or directional) over a 100-year time frame (McElhany et al. 2000).

watershed: Area of land draining into a stream or river within a basin or sub-basin. The watershed is the smallest classification in a hierarchical drainage system adopted by NMFS for the SONCC coho salmon ESU recovery plan. This hierarchical drainage system is made up of basins (largest scale), sub-basins (intermediate scale), and watersheds (smallest scale). See also *basin* and *sub-basin*.

wild fish: Fish that are offspring of parents that spawned in the wild. Wild fish spend their entire lives in the natural environment.

young-of-the-year: Term used to collectively refer to fry and juvenile life stages.

H.2 Abbreviations and Acronyms

The following are is a list of selected acronyms and abbreviations used throughout the plan.

ACOE	-U.S. Army Corps of Engineers
ACS	-Aquatic Conservation Strategy
ARWC	-Applegate River Watershed Council
BCWC	-Bear Creek Watershed Council
BLM	-Bureau of Land Management
BMPs	-Best Management Practice
BOF	-California Board of Forestry
BRT	-Biological review teams
CAP	-Conservation Action Planning
CalFire	-California Department of Forestry and Fire Protection
CDFG	-California Department of Fish and Game (now California Department of Fish and Wildlife)
CDFW	-California Department of Fish and Wildlife (formerly California Department of Fish and Game)
CDWR	-California Department of Water Resources
CEQA	-California Environmental Quality Act
CFR	-Code of Federal Regulations
cfs	-Cubic feet per second
CPS	-Coastal Pelagic Species
CWA	-Federal Clean Water Act
dbh	-Diameter at breast height
DIDSON	-Dual-frequency IDentification SONar
DPS	-Distinct Population Segment
EPT	-Ephemeroptera Plecoptera Trichoptera
ESA	-Federal Endangered Species Act
ESU	-Evolutionarily Significant Unit
FEMAT	-Forest Ecosystem Management Assessment Team
FERC	-Federal Energy Regulatory Commission
FR	-Federal Register
ft	-Feet
GDRC	-Green Diamond Resource Company
GIS	-Geographic Information System
HBHRCD	-Humboldt Bay Harbor, Recreation, and Conservation District
HBMWD	-Humboldt Bay Municipal Water District
HBWAC	-Humboldt Bay Watershed Advisory Council
HCP	-Habitat Conservation Plan
HCRCD	-Humboldt County Resource Conservation District
HGMP	-Hatchery and Genetic Management Plan
HRC	-Humboldt Redwood Company
HSRG	-Hatchery Scientific Review Group
HSA	-Hydrologic Subarea
HVT	-Hoopa Valley Tribe

IBI	-Index of Biological Integrity
IMST	-Independent Multidisciplinary Science Team
IP	-Intrinsic Potential
KNF	-Klamath National Forest
KRIS	-Klamath River Information System
LCM	-Life Cycle Monitoring
LRMP	-Land and Resource Management Plan
LWD	-Large Woody Debris
MKWC	-Middle Klamath Watershed Council
MRC	-Mendocino Redwood Company OR Mattole Restoration Council
MRSD	-Minimum required spawner density
MSA	-Magnuson-Stevens Fishery Conservation and Management Act
MWAT	-Mean Weekly Average Temperature
MWMT	-Mean Weekly Mean Temperature
NA or N/A	-Not Applicable
NCCP	-Natural Community Conservation Plan
NCRWQCB	-North Coast Regional Quality Control Board
NCWAP	-North Coast Watershed Assessment Program
NMFS	-National Marine Fisheries Service
NOAA	-National Oceanic and Atmospheric Administration
NPDES	-National Pollutant Discharge Elimination System
NRC	-National Research Council
NRCS	-Natural Resources Conservation Service
NTU	-Nephelometric Turbidity Unit
NWFP	-Northwest Forest Plan
ODEQ	-Oregon Department of Environmental Quality
ODFW	-Oregon Department of Fish and Wildlife
ODOT	-Oregon Department of Transportation
OFPA	-Oregon Forest Practices Act
OWEB	-Oregon Watershed Enhancement Board
OWRD	-Oregon Water Rights Division
PALCO	-Pacific Lumber Company
PDO	-Pacific Decadal Oscillation
PFMC	-Pacific Fishery Management Council
PIT	-Passive Integrated Transponder
PWA	-Pacific Watershed Associates
RCD	-Resource Conservation District
RM	-River Mile
RNSP	-Redwood National and State Parks
RWQCB	-Regional Water Quality Control Board
SCWC	-South Coast Watershed Council
SOD	-Sudden oak death
SONCC	-Southern Oregon/Northern California Coast Coho
Sq mi	-Square mile
SRRC	-Salmon River Restoration Council
SWRCB	-California State Water Resources Control Board

SRWC	-Scott River Watershed Council
TMDL	-Total Maximum Daily Load
TNC	-The Nature Conservancy
TRH	-Trinity River Hatchery
USDA	-United States Department of Agriculture
USDOI	-United States Department of the Interior
USEPA	-United States Environmental Protection Agency
USFS	-United States Forest Service
USFWS	-United States Fish and Wildlife Service
USGS	-United States Geological Survey
VSP	-Viable Salmonid Population
WCF	- Watershed Condition Framework
YTFP	- Yurok Tribal Fisheries Program

Appendix I. Electronic Maps Used in Threats Assessment

I.1 Overview

NOAA's National Marine Fisheries Service (NMFS) created GIS (Geographic Information System) maps using the instream monitoring and landscape data compiled for each population. *These maps are available upon request from the SONCC recovery coordinator in Adobe Acrobat (PDF) format and are designed to be used as electronic documents, not printed*. The many layers in the maps can be toggled on/off and users can zoom in to see more detail. There are two PDF maps included for each population. The main set of maps contains the stress and threats data, in addition to base layers such as coho salmon IP and streams, and was completed in May 2010. The second set of maps was completed in December 2009 and includes canopy change over various time periods and tree size. Due to the large number of layers in the maps, full legends could not be included within the individual maps; therefore, a separate legend PDF is provided for each of the two map types. These maps were used to analyze and interpret habitat condition across the landscape.

I.2 Inventory of Electronic Files

There are 92 electronic map files in PDF format:

- One introductory guide that explains how to use the stresses and threats PDF maps, and provides a legend for the layers in the stresses and threats map. File name:
  - soncc_pop_maps_legend_and_instructions_2011_12_11.pdf
- 40 PDF maps (one for each population in the SONCC coho salmon ESU) with stress data and threats data. The file name of each map starts with the population name, then ends with "_soncc_cap_indicators_sources.pdf":
  - Bear River_soncc_cap_indicators_sources.pdf
  - Brush Creek_soncc_cap_indicators_sources.pdf
  - Chetco River_soncc_cap_indicators_sources.pdf
  - Elk Creek_soncc_cap_indicators_sources.pdf
  - Elk River_soncc_cap_indicators_sources.pdf
  - Guthrie Creek_soncc_cap_indicators_sources.pdf
  - Humboldt Bay Tributaries_soncc_cap_indicators_source.pdf
  - Hunter Creek_soncc_cap_indicators_sources.pdf
  - Illinois River_soncc_cap_indicators_sources.pdf
  - Little River_soncc_cap_indicators_sources.pdf
  - Lower Eel - Van Duzen Rivers_soncc_cap_indicators_source.pdf
  - Lower Klamath River_soncc_cap_indicators_sources.pdf
  - Lower Rogue_soncc_cap_indicators_sources.pdf
  - Lower Trinity River_soncc_cap_indicators_sources.pdf
  - Mad River_soncc_cap_indicators_sources.pdf
  - Mainstem Eel River_soncc_cap_indicators_sources.pdf

  - Maple Creek - Big Lagoon_soncc_cap_indicators_source.pdf
  - Mattole River_soncc_cap_indicators_sources.pdf
  - Middle Fork Eel River_soncc_cap_indicators_sources.pdf
  - Middle Klamath River_soncc_cap_indicators_sources.pdf
  - Middle Mainstem Eel River_soncc_cap_indicators_sourc.pdf
  - Middle Rogue - Applegate Rivers_soncc_cap_indicators.pdf
  - Mussel Creek_soncc_cap_indicators_sources.pdf
  - North Fork Eel River_soncc_cap_indicators_sources.pdf
  - Norton - Widow White Creek_soncc_cap_indicators_source.pdf
  - Pistol River_soncc_cap_indicators_sources.pdf
  - Redwood Creek_soncc_cap_indicators_sources.pdf
  - Salmon River_soncc_cap_indicators_sources.pdf
  - Scott River_soncc_cap_indicators_sources.pdf
  - Shasta River_soncc_cap_indicators_sources.pdf
  - Smith River_soncc_cap_indicators_sources.pdf
  - South Fork Eel River_soncc_cap_indicators_sources.pdf
  - South Fork Trinity River_soncc_cap_indicators_source.pdf
  - Strawberry Creek_soncc_cap_indicators_sources.pdf
  - Upper Klamath River_soncc_cap_indicators_sources.pdf
  - Upper Mainstem Eel River_soncc_cap_indicators_source.pdf
  - Upper Rogue_soncc_cap_indicators_sources.pdf
  - Upper Trinity River_soncc_cap_indicators_sources.pdf
  - Wilson Creek_soncc_cap_indicators_sources.pdf
  - Winchuck River_soncc_cap_indicators_sources.pdf

- One introductory guide that explains how to use the canopy change and tree size PDF maps, and provides a legend for the layers in the stresses and threats map. File name:

  - change_detect_legend_and_instructions_2011_12_11.pdf

- 40 PDF maps (one for each population in the SONCC coho salmon ESU) of the canopy change and tree size data. The file name of each map starts with the population name, then ends with "_change_detect.pdf":

  - Bear River_change_detect.pdf
  - Brush Creek_change_detect.pdf
  - Chetco River_change_detect.pdf
  - Elk Creek_change_detect.pdf
  - Elk River_change_detect.pdf
  - Guthrie Creek_change_detect.pdf
  - Humboldt Bay Tributaries_change_detect.pdf
  - Hunter Creek_change_detect.pdf
  - Illinois River_change_detect.pdf
  - Little River_change_detect.pdf
  - Lower Eel - Van Duzen Rivers_change_detect.pdf
  - Lower Klamath River_change_detect.pdf
  - Lower Rogue_change_detect.pdf

- Lower Trinity River_change_detect.pdf
- Mad River_change_detect.pdf
- Mainstem Eel River_change_detect.pdf
- Maple Creek - Big Lagoon_change_detect.pdf
- Mattole River_change_detect.pdf
- Middle Fork Eel River_change_detect.pdf
- Middle Klamath River_change_detect.pdf
- Middle Mainstem Eel River_change_detect.pdf
- Middle Rogue - Applegate Rivers_change_detect.pdf
- Mussel Creek_change_detect.pdf
- North Fork Eel River_change_detect.pdf
- Norton - Widow White Creek_change_detect.pdf
- Pistol River_change_detect.pdf
- Redwood Creek_change_detect.pdf
- Salmon River_change_detect.pdf
- Scott River_change_detect.pdf
- Shasta River_change_detect.pdf
- Smith River_change_detect.pdf
- South Fork Eel River_change_detect.pdf
- South Fork Trinity River_change_detect.pdf
- Strawberry Creek_change_detect.pdf

I.3 Example Images Created from the PDF Map Files

Figure I-1 and Figure I-2 show example images for the Mattole River created from the map files described above.

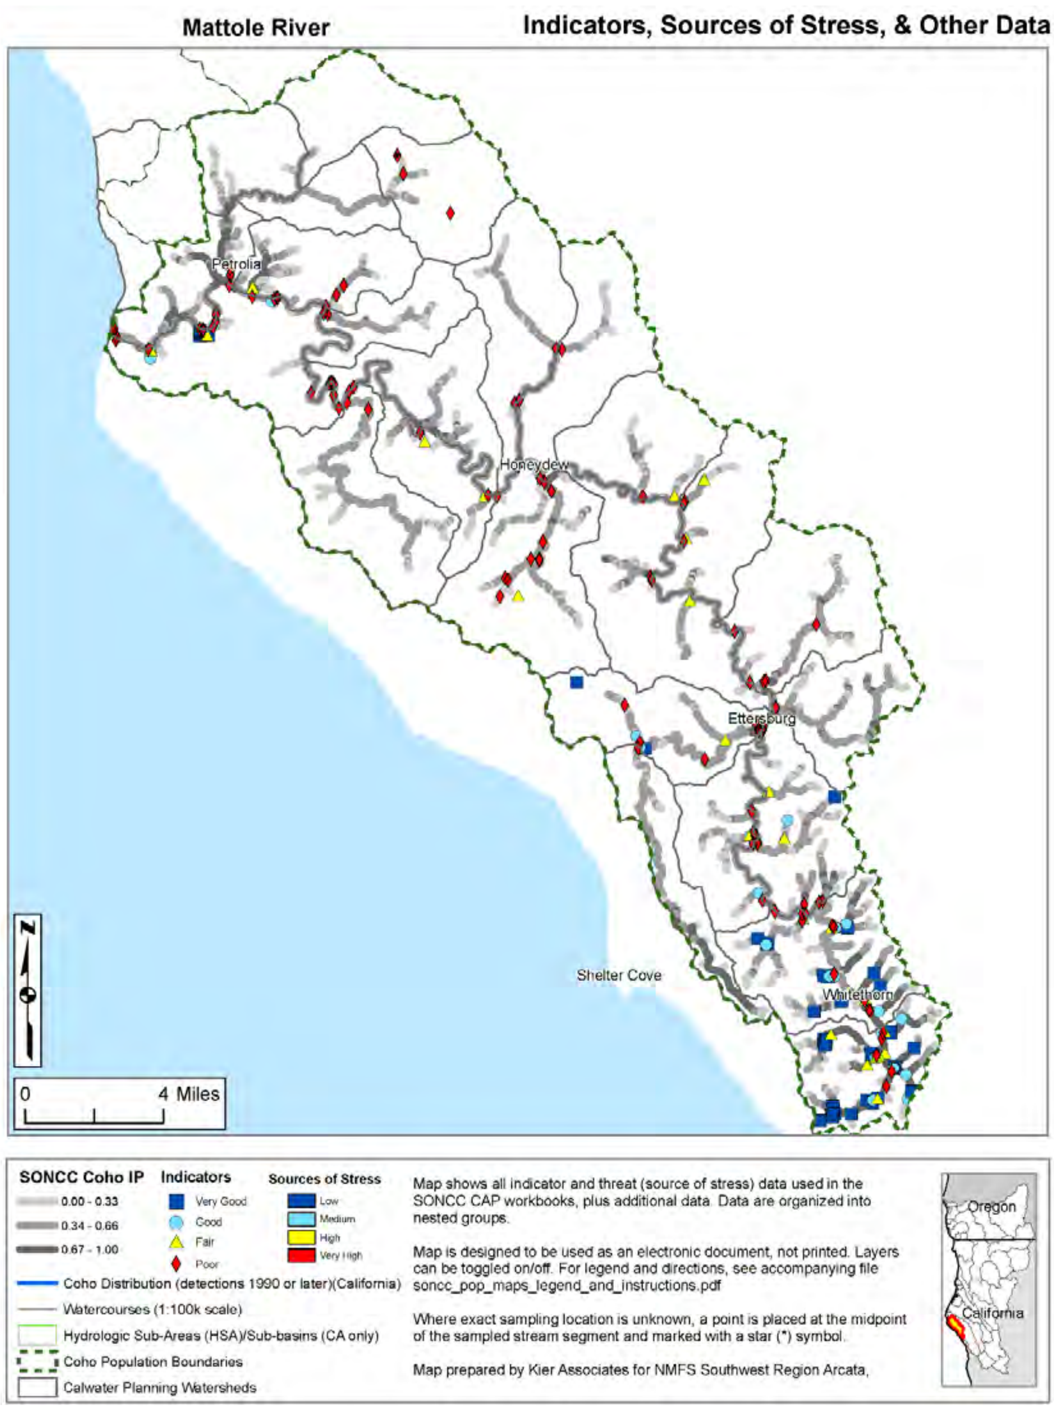

Figure I-1. Example image from map of Mattole River stress data. Map shows water temperature monitoring stations, modeled Intrinsic Potential (IP) of coho salmon habitat, and boundaries of Calwater Planning Watersheds (all other layers in map are turned off). These are just a few many data layers available in the "Mattole River_soncc_cap_indicators_sources.pdf" map file. Complete legend is available in "soncc_pop_maps_legend_and_instructions_2011_12_11.pdf".

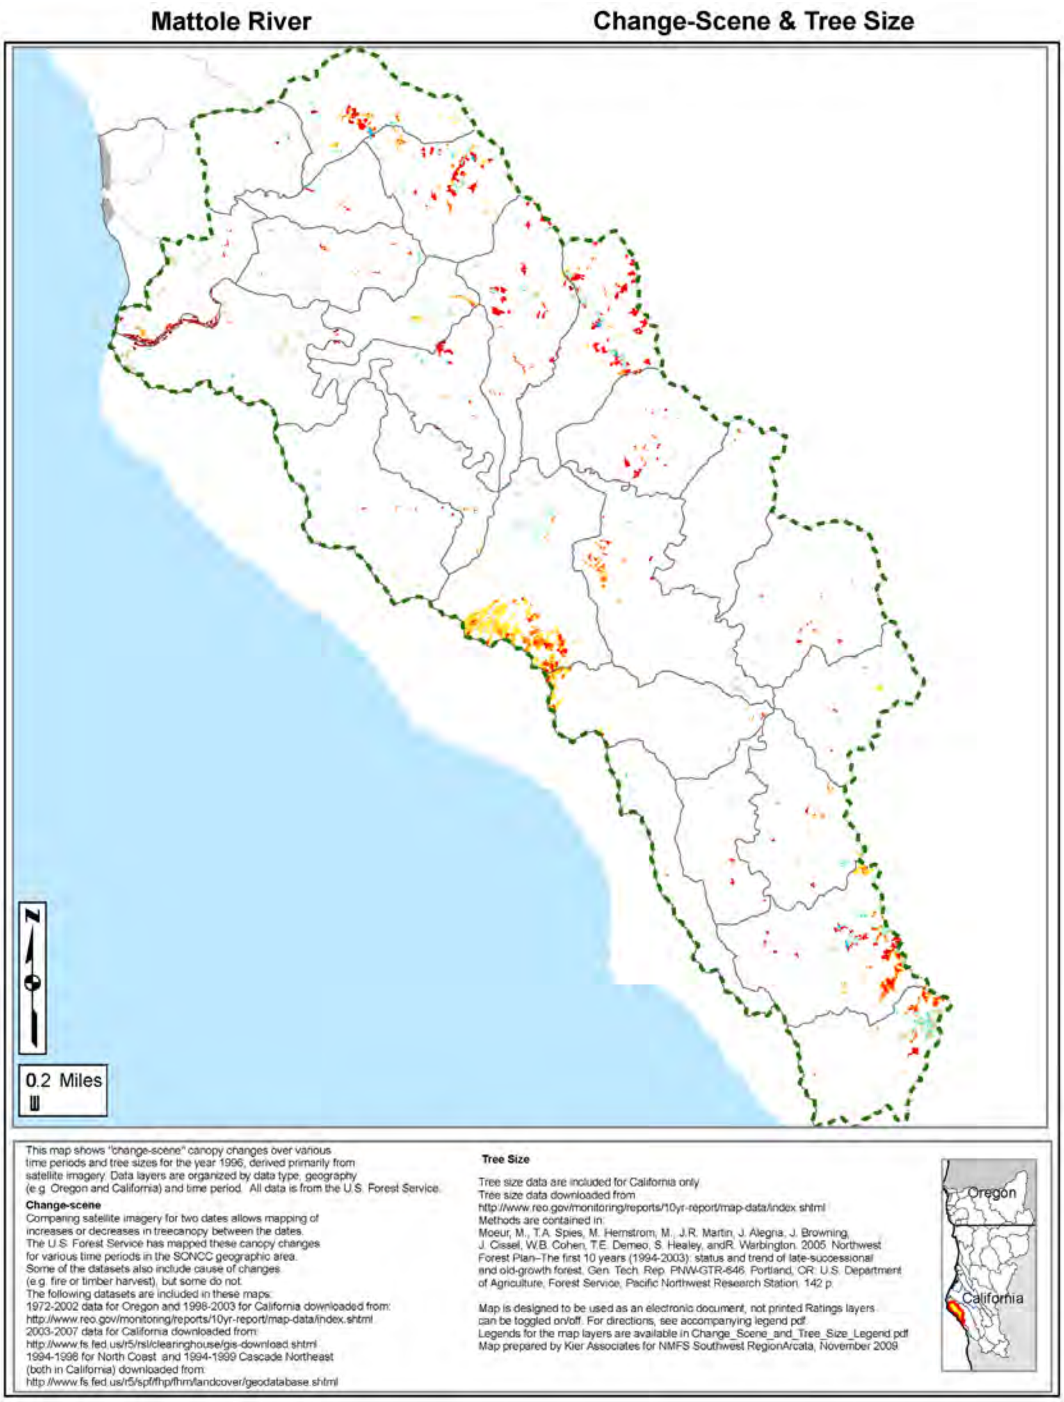

Figure I-2. Example image from PDF map of Mattole River canopy change and tree size data. Map shows areas where remote sensing detected canopy change in the years 1994 to 2007 and boundaries of Calwater Planning Watersheds (all other layers in map are turned off). These are just a few several data layers available in the “Mattole River_change_detect.pdf” map file. Complete legend is available in “change_detect_legend_and_instructions_2011_12_11.pdf”.

7. Elk River Population

Northern Coastal Stratum

Core, Functionally Independent Population

High Extinction Risk

Population likely below depensation threshold

2,400 Spawners Required for ESU Viability

93 mi^2 watershed (78% Federal ownership)

63 IP-km (39 IP-mi) (23% High)

Dominant Land Uses are Agriculture and Recreation

Key Limiting Stresses are 'Lack of Floodplain and Channel Structure' and 'Impaired Water Quality'

Key Limiting Threats are 'Agricultural Practices' and 'Channelization/Diking'

Highest Priority Recovery Actions

• Develop total maximum daily loads (TMDLs) for water bodies listed under Clean Water Act Section 303(d) • Increase large woody debris (LWD), boulders, or other instream structure • Increase instream flows	• Improve timber harvest practices by revising Oregon Forest Practices Act • Improve regulatory mechanisms regarding agricultural practices • Construct off channel ponds, alcoves, backwater habitat, and old stream oxbows

7.1 History of Habitat and Land Use

Historically, the lower Elk River provided the most important habitat for coho salmon in the population area. Large wood jams spanning the lower Elk River channel would dislodge and relocate with winter high flows. Impacts to the Elk River basin include timber harvest (and associated road-building) in the lower basin and extensive placer and hydraulic mining in the upper basin (Maguire 2001a). The legacy of mining in the Elk River basin may be substantial because hydraulic mining used water cannons to blast away alluvial deposits that caused potentially long lasting impacts on channel structure. Over time, settlement and associated agriculture encroached on the lower Elk River floodplain which confined the channel and reduced wetlands. These human settlements greatly reduced or eliminated wood jams and beaver that had previously helped form coho salmon rearing habitat. Basin-wide disturbances occurred from 1950 to 1990 and were associated with expansion of the road network and industrial timber harvest on public and private lands (U.S. Forest Service [USFS] 1998a). Extensive road networks were developed to support timber harvest, and these roads and timber harvesting practices greatly damaged the landscape surrounding the Elk River and impacted the water quality and habitat in the river and its tributaries. Between 1954 and 1989, over 300 million board feet of timber were removed from the Elk River population area and the cumulative effects to streams were substantial, particularly following large storm events (USFS 1998a). Between 1952 and 1986, road and harvest-related landslides within the basin delivered 2.2 times more fine sediment volume than naturally-occurring landslides (USFS 1998a). Currently, the Elk River is recognized as a Key Watershed under the Northwest Forest Plan, (USDA and USDI 1994) and much of the USFS land is managed as Late Successional Reserve or as part of the Copper Salmon Wilderness. Private timberlands are limited in the population area. In the last two decades, cranberry farming has expanded into lower tributary watersheds, where on and off-stream storage reservoirs have been built. Cranberry farming has contributed to the loss of function in three low gradient tributaries that were mostly high IP coho salmon habitat. Residential development has also increased in the lower basin.

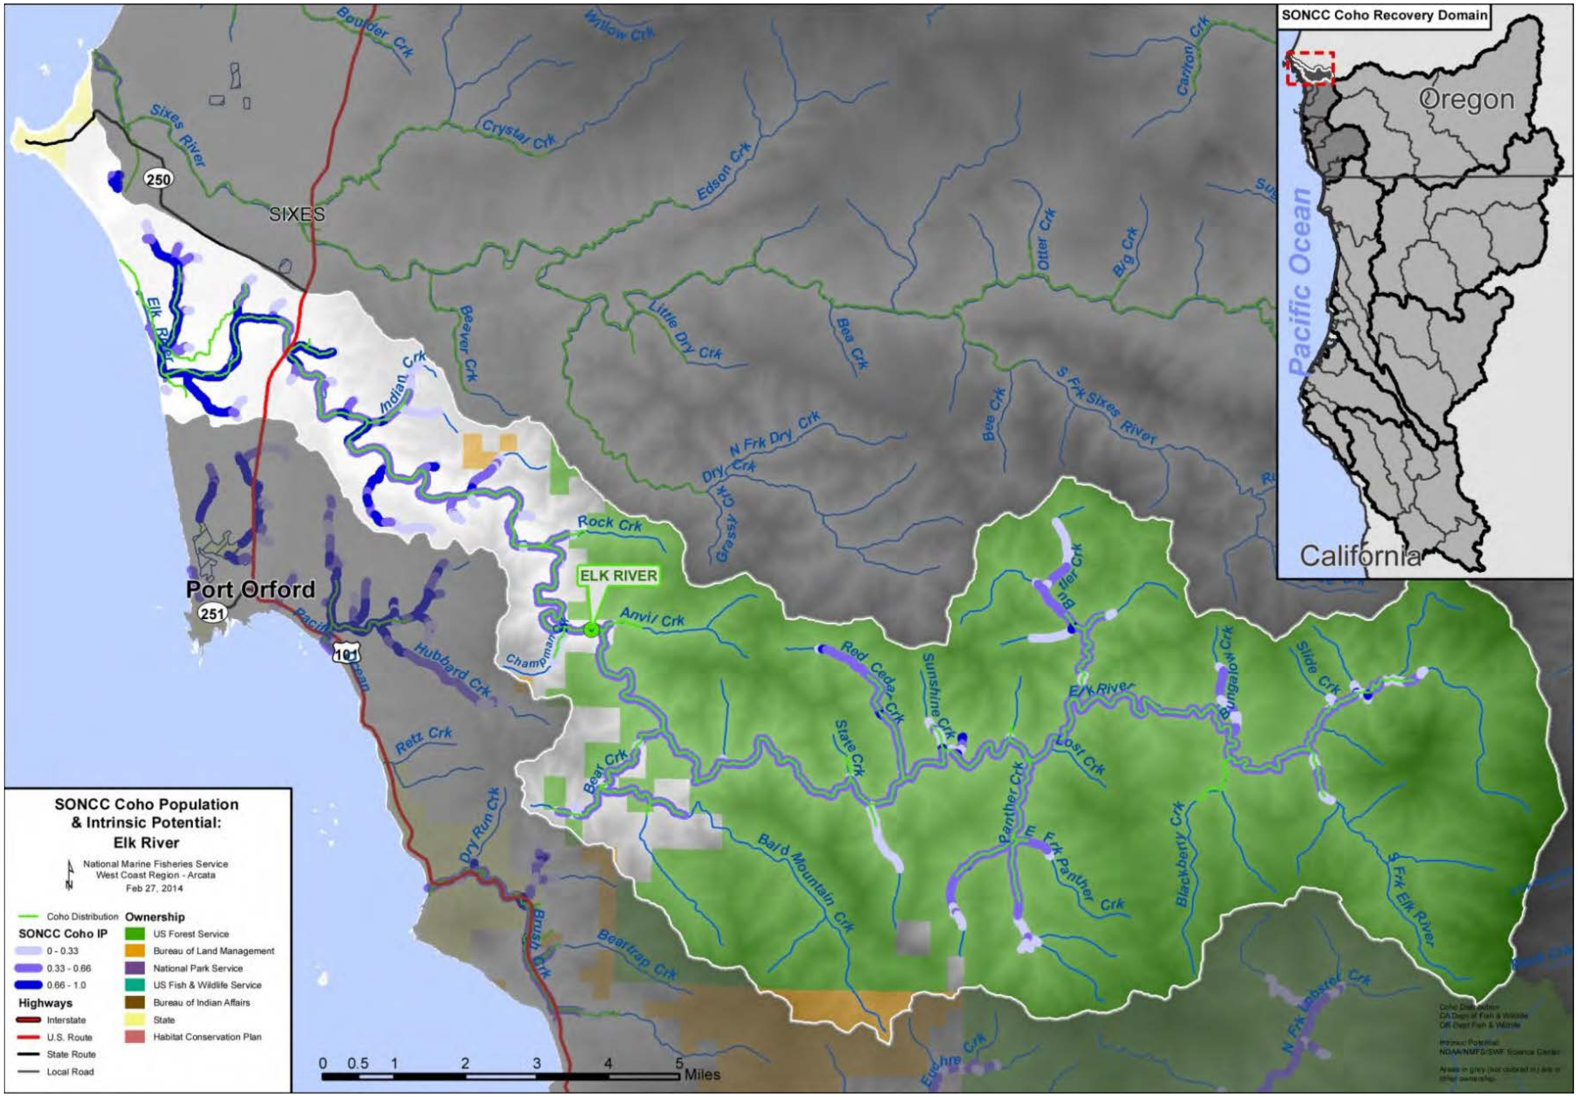

Figure 7-1. The geographic boundaries of the Elk River coho salmon population. Figure shows modeled Intrinsic Potential of habitat (Williams et al. 2006), land ownership, coho salmon distribution (ODFW 2013a), and location within the Southern-Oregon/Northern California Coast Coho Salmon ESU and the Northern Coastal diversity stratum (Williams et al. 2006). Grey areas indicate private ownership.

7.2 Historic Fish Distribution and Abundance

The Elk River basin has 63 total Intrinsic Potential-kilometers (IP-km) of coho salmon habitat (Williams et al. 2008). Approximately 7.7 km of IP habitat is currently inaccessible due to a dam. The coho salmon habitat with highest IP is concentrated in the lower Elk River, including all tributaries of the alluvial coastal plain downstream of Rock Creek (Williams et al. 2008) (Figure 7-1). Short, low gradient stream reaches in upper tributaries, such as the North Fork Elk River, Red Cedar Creek, Panther Creek and Butler Creek also have optimal IP habitat.

Historically, coho salmon were more abundant in the Elk River basin than they are today. Contemporary distribution of coho salmon is much reduced from the period of early Anglo-American settlement beginning in the 1850s. This reduction may be due to habitat modification in the lower reaches, including diking and channelization of the mainstem, which eliminated summer and winter rearing habitat (Maguire 2001a). Smaller tributaries, such as one near the mouth of Elk River and upstream of Highway 101, are now disconnected or dammed for agricultural water supply. In 1927, the gillnet catch from the Elk River was dominated by 13,334 pounds of coho salmon (USFS 1998a). Tributaries with the highest IP are shown in Table 7-1.

Table 7-1. Tributaries with high IP reaches (IP > 0.66) (Williams et al. 2006).

Stream Name	Stream Name	Stream Name
Lower Elk River and Estuary	Panther Creek	Sunshine Creek
Indian Creek	Red Cedar Creek	Butler Creek
Bagley Creek	Swamp Creek	

7.3 Status of Elk River Coho Salmon

Spatial Structure and Diversity

Oregon Department of Fish and Wildlife (ODFW) has conducted adult coho salmon carcass and redd counts (ODFW 2008a) and juvenile snorkel surveys (ODFW 2005a) in the mainstem Elk River and its tributaries. The South Coast Watershed Council (SCWC) conducted smolt trap surveys in 2012 in Swamp Creek and Cedar Creek (SCSC 2012). There are far more surveys with no sightings than those where coho salmon were found. Adult coho salmon were found in Anvil, Indian, Butler, and Red Cedar creeks as well as the mainstem Elk River between Sunshine Creek and Red Cedar Creek. Juvenile coho salmon were found in Panther, Red Cedar, Swamp, Cedar, and Blackberry creeks as well as the middle mainstem Elk River. USFS (1998a) identified Red Cedar, the North Fork Elk, Panther Creek, and Anvil Creeks as those most important for coho salmon production, as they appeared to account for most coho salmon production in the basin. The very low number of adult fish observed by ODFW and low density of juveniles in summer surveys indicates a very small population which would likely have restricted genetic diversity.

Population Size and Productivity

In 1997, adult coho salmon populations for the entire Elk River population area ranged between 100 and 200 (USFS 1998a). Estimated returns were zero in many years between 1998 and 2007, and at most 501 in 1998 (ODFW 2009a) (Table 7-2). Large differences in effort between years and incomplete survey coverage could account for observed differences in estimates. In addition, high flows may have occurred in some years, which could affect the ability to carry out sampling consistently or effectively.

Table 7-2. Estimates of annual spawning escapement of coho salmon for the Elk River (ODFW 2009a).

Year	Population Estimate	Year	Population Estimate	Year	Population Estimate
1998	501	2002	104	2006	0
1999	Not estimated	2003	187	2007	230
2000	0	2004	0	2008	Not estimated
2001	Not estimated	2005	0		

Extinction Risk

The Elk River population is at high risk of extinction because NMFS estimates the ratio of the three consecutive years of lowest abundance within the last twelve years to the amount of IP-km in a watershed is less than one, the criterion described by Williams et al. (2008). NMFS' determination of population extinction risk is based on the viability criteria provided by Williams et al. 2008 (Table 3, pg. 17). These viability criteria reflect population size and rate of decline. As Williams et al. (2008) provided no viability criteria for assessing moderate and high risk based on spatial structure and diversity, spatial structure and diversity were not considered in NMFS' determination of population extinction risk.

In addition, the areas where juvenile coho salmon currently rear are concentrated in the low gradient reaches of steeper upper basin tributaries, recognized by Frissell (1992) as alluviated canyons. These areas are prone to alteration by floods and populations dependent on them are vulnerable to periodic disturbance and habitat alterations. Therefore, even the low numbers of coho salmon observed in some years are at high risk of losing their habitat.

Role in SONCC Coho Salmon ESU Viability

The Elk River population is considered to be a core, Functionally Independent population within the Northern Coastal diversity stratum; historically having had a high likelihood of persisting in isolation over 100-year time scales, and with population dynamics or extinction risk over a 100-year time period that are not substantially altered by exchanges of individuals with other populations (Williams et al. 2006). To contribute to stratum and ESU viability, the Elk River core population needs to have at least 2,400 spawners. Sufficient spawner densities are needed to maintain connectivity and diversity within the stratum and continue to represent critical components of the evolutionary legacy of the ESU. Besides its role in achieving demographic goals and objectives for recovery, as a core population the Elk River population may serve as a source of spawner strays for nearby coastal populations. At present, the capacity of the Elk River coho salmon population to provide recruits to adjacent independent populations is limited due to its low spawner abundance. Conversely, recruits straying from nearby rivers may enhance recovery of the Elk River population.

7.4 Plans and Assessments

State of Oregon

Expert Panel on Limiting Factors for Oregon's SONCC coho salmon populations

ODFW (2008b) convened a panel of fisheries and watershed scientists as an initial step in their development of a recovery plan for Oregon's SONCC coho salmon populations. Deliberations of the expert panel provided ODFW with initial, strategic guidance on limiting factors and threats to recovery. Based on the input of panel members, concerns for the Elk River population are as follows:

> Key concerns were primarily loss of over-winter tributary and freshwater estuarine habitat complexity and floodplain connectivity for juveniles, especially in the lowlands which are naturally limited in this system and have been impacted by past and current agricultural practices. Secondary concerns were primarily related to high water temperatures in tributaries for summer parr (excluding the mainstem, where rearing is not expected) and loss of tributary habitat for juveniles and adults due to road crossings (especially in Bagley and Blackberry Creeks).

Oregon Plan for Salmon and Watersheds
http://www.oregon.gov/OPSW/about_us.shtml

The State of Oregon developed a conservation and recovery strategy for coho salmon in the SONCC and Oregon Coast ESUs (State of Oregon 1997). The Oregon Plan for coho salmon is a comprehensive plan that includes voluntary actions for all of the threats currently facing coho salmon in these ESUs and involves all relevant state agencies. Reforms to fishery harvest and hatchery programs were implemented by ODFW in the late 1990s. Many habitat restoration projects have occurred across the landscape in headwater habitat, lowlands, and the estuary.

Cumulative Effects of Southwest Oregon Coastal Land Use on Salmon Habitat

Oregon State University's Oak Creek Labs conducted a study funded by ODFW and the Oregon Department of Forestry to determine relationships between forest harvest and Pacific salmon productivity (Frissell 1992). The study assessed basins along the Oregon coast extending from the Sixes River to the southern border during the period from 1986 to 1992 with the most extensive research conducted in Euchre Creek to the south of the Elk River.

Oregon Clean Water Act 303(d) Impaired Water Body List

The mainstem Elk River and estuary, Bald Mountain Creek and Butler Creek are recognized as water quality impaired on the Oregon Clean Water Act 303(d) impaired water body list due to temperature problems and habitat modification. No TMDL has been approved.

U.S. Forest Service

Elk River Watershed Analysis (USFS 1998a)

The Elk River watershed analysis was developed to implement the Northwest Forest Plan and provides the watershed context for fishery protection, restoration, and enhancement efforts. The following is a summary of the most relevant findings: (1) Excessive sediment from natural and management activities has decreased pool depth; (2) Reduction of pool depth decreases available habitat and fish production and provides a competitive advantage to steelhead over other salmonids; (3) High road densities change hillslope hydrology, which contributes to elevated peak flows that damage streams; and (4) Over-winter survival for juvenile salmonids may be decreased due to low habitat complexity (i.e., no slow velocity marginal habitats behind large wood jams or old growth riparian trees).

Sufficiency Assessment: Forest Service and Bureau of Land Management Programs in Support of SONCC Coho Salmon Recovery (USFS and BLM 2011)

The USFS has adopted a Watershed Condition Framework assessment and planning approach (USFS and BLM 2011). The Watershed Condition Framework (WCF) is a comprehensive approach for proactively implementing integrated restoration on priority watersheds on national forests and grasslands. The WCF provides the Forest Service with an outcome-based performance measure for documenting improvement to watershed condition at forest, regional, and national scales. As part of the WCF, Upper Elk River was identified as a high priority 6th field sub-watershed in the Rogue-Siskiyou National Forest (USFS and BLM 2011).

South Coast Watershed Council

Elk River Watershed Assessment (Maguire 2001a)

The Elk River watershed assessment includes a compilation, summary, and synthesis of existing data and information pertaining to watershed conditions in the Elk River basin. Some findings relevant to coho salmon recovery include issues with water temperature, highly altered wetlands, weak riparian cover (especially in the lower sections), sediment sources (present and potential), and noxious weed invasions. The assessment describes variation in run timing of coho salmon in the Elk River basin, with “early” coho salmon entering streams beginning in about mid-November and spawning soon after, while “late” coho salmon delay spawning until as late as March or April.

Elk River Action Plan (Massingill 2001a)

The Elk River action plan is a companion to Maguire (2001a) and defines specific action items for restoration of the Elk River basin.

7.5 Stresses

Table 7-3. Severity of stresses affecting each life stage of coho salmon in the Elk River. Stress rank categories, assessment methods, and data used to assess stresses are described in Appendix B.

	Stresses	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Stress Rank
1	Lack of Floodplain and Channel Structure[1]	High	High	Very High[1]	Very High	Very High	Very High
2	Impaired Water Quality[1]		High	Very High[1]	High	Low	High
3	Degraded Riparian Forest Conditions	-	High	High	High	Medium	High
4	Impaired Estuary/Mainstem Function	-	Low	Medium	High	Low	Medium
5	Altered Hydrologic Function	Low	Low	High	High	High	High
6	Altered Sediment Supply	Medium	Medium	Medium	Low	Medium	Medium
7	Barriers	-	Medium	Medium	Low	Medium	Medium
8	Adverse Hatchery-Related Effects	Low	Low	Low	Low	Low	Low
9	Increased Disease/Predation/Competition	Low	Low	Low	Low	Low	Low
10	Adverse Fishery- and Collection-Related Effects	-	-	Low	Low	Low	Low

[1]Key limiting stresses and limited life stage.

Key Limiting Stresses, Life Stages, and Habitat

The juvenile life stage is most limited and quality winter rearing habitat, as well as summer rearing habitat, is lacking for the population. Lack of floodplain and channel structure and impaired water quality are the two most limiting stresses. Juvenile summer rearing habitat is impaired by high temperatures resulting from degraded riparian conditions and water withdrawals. Winter rearing habitat has been reduced by channelization, diking, and filling of wetlands. Timber removal has decreased the source of large wood, and most historically available habitat in the estuary has been altered by development, channelization, sedimentation, and diking. Overall, these findings are consistent with those of the Oregon Expert Panel (ODFW 2008b) (Section 7.4), but the expert panel considered water temperature to be only a secondary, not primary, concern.

The IP habitat in the Elk River basin is concentrated in the low gradient reaches of the basin near the ocean. No thermal refugia have been noted. Off-channel juvenile rearing habitat with suitable temperature is vital to coho salmon recovery in this river. Habitat currently occupied by coho salmon is at a premium and should be prioritized for protection.

Lack of Floodplain and Channel Structure

Lack of floodplain and channel structure is the greatest constraint to coho salmon production in the Elk River. The lower Elk River channel is disconnected from its floodplain, wetlands, and tributaries (Figure 7-2). This has significantly reduced what was once optimal habitat for coho salmon spawning, egg incubation, and rearing. The ODFW (2008b) Expert Panel found that loss of floodplain connectivity and access to off-channel habitat was a major limiting factor in this population. This stress applies to both freshwater and tidally-influenced freshwater areas. Tributary channels are also altered by agricultural activities, as evidenced in aerial photos (Figure 7-2). One entire fork of Swamp Creek is no longer discernible on aerial photos and has been completely filled in. Large woody debris was historically important and available in the lower Elk River but today there is little large wood (ODFW 2008b).

Figure 7-2. Aerial image from Google Earth of the Lower Elk River above and below Highway 101 (yellow line is highway). Rectangular beige shapes are cranberry bogs. Filled river meanders, cutoff wetlands and streams, and an irrigation pond on a tributary (right) are highlighted with red arrows.

Impaired Water Quality

Water temperature in the mainstem Elk River, Bald Mountain, Panther and Butler creeks does not meet the Oregon Department of Environmental Quality (ODEQ) maximum average weekly temperature (temperature) standard of 64 ºF. Water temperatures are suitable during the time of adult returns and when eggs are in the gravel. Data from the South Coast Watershed Council's monitoring program from 1991 to 2000 indicate that the warmest 7-day maximum recorded in the Elk River basin was 74.1 °F on the mainstem of the Elk River below Camp Creek. The water temperature at Bagley Creek is 3 to 4 °F warmer than that observed upstream at the National Forest boundary (Maguire 2001a). Butler, Bald Mountain, and Panther creeks were warm and ranged from 66 °F to 68 °F (USFS 1998a). Swamp Creek, a tributary to the estuary, also had impaired water temperature conditions of 69.7 °F (USFS 1998a). Fecal coliform levels exceeded standards in 8 out of 27 samples often during high flows, indicating moderately impaired conditions (Maguire 2001a). Phosphate levels exceeded the water quality standards 4 out of 28 samples (14.3 percent) during high flow events. All of these data (Maguire 2001a, USFS 1998a) are at least ten years old and so should not be considered a definitive description of current conditions. Effects of pesticides and herbicides on salmon are harmful (Ewing 1999), but there are no pesticide studies in the Elk River, nor any regional data available (Riley, S., pers. comm. 2009).

Degraded Riparian Forest Conditions

ODFW (2008b) noted problems with high water temperatures due to riparian shade loss and competition from non-native shrubs. Elk River riparian zones were once dominated by large conifers, but today are dominated by hardwoods and invasive non-native species including gorse and Himalayan blackberry (USFS 1998a, Maguire 2001a). In steeper channels of headwater streams, riparian trees may be removed by rapidly moving landslides known as debris torrents that move down channels (USFS 1998a).

Impaired Estuary/Mainstem Function

The main issues for coho salmon in the estuary are insufficient holding habitat for smolts and the barriers described below. Based on aerial photos, most of the land adjacent to the Elk River estuary has been converted to agricultural land, with associated channelization and diking that has disconnected small tributaries. A small amount of off-channel habitat remains near the mouth.

Altered Hydrologic Function

Diversion dams block water movement and restrict flows in a few lower river tributaries. Flow to the estuary from tributaries is completely disconnected. Wells for domestic and agricultural water supply in the lower Elk River and its tributaries have the potential to reduce surface water availability, which could substantially diminish coho salmon habitat in the smaller streams. Water diversions or surface water supply reductions both can directly reduce the amount of habitat available to coho salmon by drying up smaller streams and can increase water temperatures, making habitat unsuitable for coho salmon. The Elk River Watershed Assessment (Maguire 2001a) found that the minimum Oregon Water Rights Division instream-flow right of 45 cubic feet per second in the mainstem Elk River is usually met at the USGS gage at the Elk

River Hatchery. However, almost all of the water diversion is below the hatchery and no measurements are taken downstream or in tributaries with high IP. Therefore, compliance with the instream flow downstream of the hatchery has not been established. The significant number of cranberry bogs (Figure 7-2) alters hydrologic function by converting some tributaries to ponds and diverting many others. A golf course has been proposed on a terrace above Elk River. The proposal includes use of irrigation water from a tributary of lower Elk River. Increased peak flows in the watershed (USFS 1998a) can negatively affect redd stability and over-winter survival of fry and juveniles.

Altered Sediment Supply

Altered sediment supply poses an overall medium stress to coho salmon in the Elk River. Sediment contribution from landslides and erosion occurs naturally in the Elk River basin; however, roads, timber harvest, and bank erosion following removal of riparian vegetation have elevated fine sediment input. High sediment yield is of particular concern in those areas of the basin with decomposing diorite-type soil, such as at Bald Mountain Creek and Purple Mountain Creek (Maguire 2001a). Excess fine sediment directly impacts coho salmon egg viability and can reduce food for fry, juveniles and smolts. Poor pool frequency and depth throughout the Elk River basin (Maguire 2001a) are likely due to elevated levels of fine sediment partially filling pools, a lack of scour-forcing obstructions such as large wood, and, in some reaches, diminished scour due to channel widening.

Barriers

The most important barriers in the Elk River are three agricultural dams that block migration of coho salmon and contribute to excessively high water temperature. Two of the dams disrupt Swamp Creek, a tributary to the estuary. The Curry County Soil and Water Conservation District recently improved fish passage at these barriers by installing baffled culverts. They documented coho salmon smolts above the first dam, but fully unimpeded passage has not been confirmed (Swanson, M., pers. comm. 2013).

The third dam affects the small unnamed creek immediately upstream of Highway 101. In addition, diking and filling of river and estuarine tributaries constitute a great impediment to fish movement that is addressed as part of the channelization and diking stress. A few culverts are in need of modification to improve fish passage, as described in the “road-stream crossing barriers” threat description.

Adverse Hatchery Effects

The Elk River Hatchery releases approximately 295,000 Chinook salmon juveniles into Elk River each September and an additional 10,000 yearling Chinook in April (ODFW 2008c). The risk of competition between wild coho salmon and hatchery-produced steelhead and Chinook salmon is minimized by rearing fish to a sufficient size that smoltification occurs quickly and the stocked fish quickly leave the river for the ocean (ODFW 2008c). Due to temperature impairment below the hatchery, juvenile coho salmon rear mostly upstream of the hatchery. Due to these factors, the potential for competition between hatchery-released Chinook salmon and wild coho salmon is expected to be reduced. Adverse hatchery-related effects pose a medium risk to all life stages of coho salmon in the Elk River because of the ongoing in-basin stocking with Chinook salmon (Appendix B).

Disease/Predation/Competition

Water temperatures that are too high could elevate disease risk, although there are no recognized fish disease problems in the basin. Elk River Hatchery proactively manages disease risk and minimizes the risk of exposure of coho salmon to hatchery-related disease (ODFW 2008c).

Adverse Fishery- and Collection-Related Effects

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low stress to juveniles, smolts, and adults.

7.6 Threats

Table 7-4. Severity of threats affecting each life stage of coho salmon in the Elk River. Threat rank categories, assessment methods, and data used to assess threats are described in Appendix B.

	Threats	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Threat Rank
1	Agricultural Practices[1]	High	Very High	Very High[1]	Very High	Very High	Very High
3	Channelization/Diking[1]	High	High	High[1]	Medium	Medium	High
2	Dams/Diversions	Low	Medium	High	High	Medium	High
4	Road/Stream Crossing Barriers	-	Low	High	Medium	High	High
5	Roads	Low	Medium	Medium	Medium	Medium	Medium
6	Timber Harvest	Medium	Medium	Medium	Medium	Low	Medium
7	Invasive/Non-Native Alien Species	-	Medium	Medium	Medium	Medium	Medium
8	Climate Change	-	-	Medium	Medium	Medium	Medium

11	Mining/Gravel Extraction	Low	Low	Low	Low	Low	Low
12	Urban/Residential/Industrial Dev.	Low	Low	Low	Low	Low	Low
13	Fishing and Collecting	-	-	Low	Low	Low	Low

[1]Key limiting threats and limited life stage.

Key Limiting Threats

The two key limiting threats, those which most affect recovery of the population by influencing stresses, are agricultural practices and channelization/diking.

Agricultural Practices

Agricultural practices are the top threat for coho salmon because their impacts are concentrated in the lower basin, where the highest IP habitat exists and where all fish from the upper basin must pass. Agricultural impacts include the loss and filling of wetlands, water diversion, riparian alteration, polluted stormwater runoff, and blocked access to formerly productive tributaries. Areas of bare soil on terraces adjacent to the lower river and estuary, and newly cleared riparian forests, which are apparent in recent aerial photo images, suggest that agricultural activities may be expanding. The ODFW (2008b) expert panel found agricultural activities to be the causal mechanism for a number of factors limiting Elk River coho salmon production. Removal of riparian trees, particularly conifers, associated with agricultural activities decreases shade and promotes increased water temperature. Cattle grazing can degrade bank structure, initiate erosion, and lead to increases in nutrients and pollutants. Non-point source pollution from cranberry cultivation has not been assessed, but the South Coast Watershed Council is working with growers to consider value-added organic options.

Channelization and Diking

The ODFW (2008b) expert panel found that habitat simplification, resulting from straightening, channelizing, revetting, filling, and/or stream channel dredging, was the most limiting stress upon coho salmon in the Elk River. One entire fork of Swamp Creek has been filled. Much of the lower Elk River channel has been diked since the major floods of 1955 and 1964 (USFS 1998a). Channel confinement causes bed load mobility that disrupts redds which results in high stress to eggs. Fry and juveniles have difficulty over-wintering in confined channels because of elevated water velocities and a lack of off-channel refugia. The Lower Elk River lacks large wood jams that formerly provided shelter from winter high flows and complex summer rearing habitat. Streamside roads in the basin may also confine the channel, creating higher velocities.

Dams/Diversions

There are two main effects of diversions on coho salmon: passage impairment and reduced water in the river. The most problematic diversions are those to cranberry bogs and the small unnamed creek just upstream of Highway 101. These and other diversions facilitate movement of water away from juvenile rearing habitat. The USGS stream flow gage is upstream of the Elk River hatchery and flow data for the lower river are not available. This reach may be at risk from over-diversion, but there are insufficient data to evaluate.

Road-Stream Crossing Barriers

Road crossings on Bagley and Blackberry Creeks are high priority barriers (ODFW 2008b). Additional barriers are listed in Table 7-5.

Table 7-5. List of prioritized road-stream crossing barriers in the range of Elk River coho salmon.

Priority	Stream Name	Road Name	County	Miles of upstream habitat
High	Bagley Creek	N/A	Curry	N/A
High	Blackberry Creek	N/A	Curry	1.25
N/A	Chapman Creek	At intersection with Elk River	Curry	N/A

Roads

Some areas have road densities exceeding levels known to increase risk of fine sediment yield and altered hydrology. There are far more un-surfaced roads than paved roads in the Elk River basin, which can increase surface erosion. Road densities are highest in the lower Elk River, Panther Creek and Bald Mountain Creek watersheds. The number of road failures and landslides caused by roads is far greater on roads constructed before 1980 than more recently built roads (USFS 1998a). In 2009, the USFS designated the Copper Salmon Wilderness. Most of the USFS lands north of the mainstem Elk River were included. The USFS designated approximately 60 miles of road within this area to be decommissioned, thus reducing the future threat of roads.

Timber Harvest

Timber harvest poses a medium threat in the Elk River basin because of high rates of timber harvest on private lands. Private timberlands are located in the lower Elk River, in tributaries such as Indian and Bagley creeks, as well as in-holdings in the Bald Mountain and Panther Creek drainages. Harvest practices on private lands have been shown to increase movement of fine sediment to the Elk River, where the percentage of fine sediment from landslides delivered to streams was higher where trees had been harvested from riparian areas (USFS 1998a). High rates of timber harvest and high road densities in the lower Elk River are a concern because the tributary streams found there are important for coho salmon recovery.

Invasive Non-Native Species

Gorse, Himalayan blackberry, and scotch broom pose serious problems for agricultural land in the lower river. These species have colonized riparian zones and are inhibiting regeneration of native hardwoods and conifers that provide shade and channel stability and allow for long-term large wood recruitment. Japanese knotweed (*Polygonum cuspidatum*) has spread into areas near Port Orford and may be present in the Elk River (Oregon Department of Agriculture 2010). Japanese knotweed is aggressive, fast growing, and out-competes native vegetation in riparian areas. Scotch broom and gorse are also locally common and similarly invasive. If these plants replace conifers or hardwoods in riparian zones, coho salmon habitat will be substantially impacted.

Climate Change

Air temperatures during July are expected to increase by 0.0 – 0.5 °C at the coast and 1.5 to 2.0 °C in the eastern portion of the basin. January temperature rise is expected to be similar with an increase of 0.5 to 1.0 °C at the coast and 1.0 to 1.5 °C in the interior portion of the basin. The latter trend could reduce snow pack in higher elevations, diminishing this source of cold water for coho salmon juvenile rearing. Sea level rise could expand the estuary and the footprint of tidal wetlands, which could potentially benefit coho salmon.

High Severity Fire

The large amount of land owned by the USFS and managed as Wilderness and Late Successional Reserves means that the Elk River basin has more old growth coniferous forest and maturing stands than any other southwest Oregon coastal basin. Stands of this type have a low risk of stand-replacing fires, particularly in a coastal basin.

Hatcheries

Hatcheries pose a medium threat to all life stages of coho salmon in the Elk River. The rationale for these ratings is described under the “Adverse Hatchery-Related Effects” stress.

Mining/Gravel Extraction

There are 534 historic gold mining claims in the Elk River basin (Bredensteiner et al. 2001), and eight are active. There is currently no industrial scale gravel extraction. Minor amounts of aggregate are extracted for local use.

Urban/Residential/Industrial Development

There is some rural residential development in the lower Elk River. Residential development is concentrated in the lower basin, where the highest value coho salmon habitat occurs. Rural residential development can cause a variety of negative effects upon coho salmon and their habitats. These potential effects include, but are not limited to: increased road densities, increased densities of impervious surfaces, channel modification, reductions in riparian vegetation, reductions in riparian function, increased pollution and runoff, and reductions in in-stream water availability.

Fishing and Collecting

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low threat to juveniles, smolts, and adults.

7.7 Recovery Strategy

Deficiencies in the amount of suitable, juvenile rearing habitat are the most important factors limiting Elk River coho salmon recovery. The processes that create and maintain such habitat must be restored by increasing channel complexity and restoring flow. Channel complexity should be improved by constructing off-channel ponds or backwater habitat, restoring wetlands, and limiting development and fill. To increase instream structure, LWD should be added to stable channels to provide structure until natural sources of LWD (mature coniferous forests) are re-established next to the stream. Areas adjacent to the stream should be replanted to re-establish mature streamside forest as a source for LWD recruitment.

The most immediate need for habitat restoration and threat reduction in the Elk River are in those areas currently occupied by coho salmon, which are identified in this profile. Unoccupied areas must also be restored to provide enough habitats to allow for coho salmon recovery. Those areas with high IP habitat such as the Lower Elk River, Bagley Creek, Panther Creek, and Sunshine Creek are optimum candidates for recovery actions. The effects of fishing on this population's ability to meet its viability criteria should be evaluated.

Table 7-6 on the following page lists the recovery actions for the Elk River population.

Table 7-6. Recovery action implementation schedule for the Elk River population. Recovery actions for monitoring and research are listed in the tables at the end of Chapter 5.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-ElkR.12.1.41	Agricultural Practices	Yes	Improve agricultural practices	Improve regulatory mechanisms	Population wide	1
SONCC-ElkR.12.1.41.1	*Determine the best way to revise the Agricultural Water Quality Management Act (AWQMAP) so that it does not limit recovery of SONCC coho salmon and recommend appropriate revisions*					
SONCC-ElkR.12.1.41.2	*Ensure basin rules are specific and linked to implementing AWQMAP recommendations, including developing specific standards for riparian buffers*					
SONCC-ElkR.12.1.41.3	*Ensure that AWQMA plans address both impaired areas and proactive prevention of water quality impairment*					
SONCC-ElkR.12.1.41.4	*Adopt interim buffers equal to the buffer standards NMFS is recommending in Washington state until the state establishes its own buffers*					
SONCC-ElkR.12.1.41.5	*Change the complaint-based compliance monitoring process to a focused compliance program*					
SONCC-ElkR.2.8.4	Floodplain and Channel Structure	Yes	Improve timber harvest practices	Improve regulatory mechanisms	Private timberlands that include: tributaries of the alluvial coastal plain downstream of North Fork Elk River, Rock, Indian, Bagley, Red Cedar, Panther, and Butler creeks	1
SONCC-ElkR.2.8.4.1	*Determine how to revise Oregon Forest Practice Rules so that they do not limit recovery of SONCC coho salmon and make appropriate revisions*					
SONCC-ElkR.2.8.4.2	*Adopt rules for fish-bearing streams sufficient to protect both water quality and fish habitat*					
SONCC-ElkR.2.8.4.3	*Adopt rules to increase protection of non-fish-bearing streams that address practices that adversely impact water quality and fish habitat*					
SONCC-ElkR.2.8.4.4	*Ensure management measures for landslide prone areas include protection of water quality and fisheries habitat*					
SONCC-ElkR.2.8.4.5	*Until more permanent regulatory mechanisms can be put in place, immediately adopt interim rules that increase protection for salmon habitat in forested areas, including increased natural recruitment of large wood on perennial and intermittent streams likely to deliver wood downstream, increased shade on all perennials, and protective buffers on small intermittent streams*					
SONCC-ElkR.2.7.3	Floodplain and Channel Structure	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	Elk River, west of Indian Creek, between County Highway 207 and Elk River Road, and areas where coho would benefit immediately	2a
SONCC-ElkR.2.7.3.1	*Assess grazing impact on sediment delivery and riparian condition, identifying opportunities for improvement*					
SONCC-ElkR.2.7.3.2	*Develop grazing management plans to improve water quality and coho salmon habitat*					
SONCC-ElkR.2.7.3.3	*Plant vegetation to stabilize stream bank*					
SONCC-ElkR.2.7.3.4	*Fence livestock out of riparian zones*					
SONCC-ElkR.2.7.3.5	*Remove instream livestock watering sources*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-ElkR.2.1.6	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	All tributaries of the alluvial coastal plain downstream of Rock Creek, as well as Indian Cree, Bagley, Sunshine creeks, North Fork Elk River, Red Cedar, Panther, and Butler creeks	2a
SONCC-ElkR.2.1.6.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-ElkR.2.1.6.2	*Place instream structures, guided by assessment results*					
SONCC-ElkR.2.1.51	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	Population wide	2b
SONCC-ElkR.2.1.51.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-ElkR.2.1.51.2	*Place instream structures, guided by assessment results*					
SONCC-ElkR.2.2.5	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Private timberlands that include: Mainstem Elk River and tributaries of the alluvial coastal plain downstream of North Fork Elk River, Rock, Indian, Bagley, Red Cedar, Panther, and Butler creeks	2a
SONCC-ElkR.2.2.5.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-ElkR.2.2.5.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-ElkR.2.2.53	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Population wide	2b
SONCC-ElkR.2.2.53.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-ElkR.2.2.53.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-ElkR.10.2.15	Water Quality	Yes	Reduce pollutants	Set standard	Population wide	2a
SONCC-ElkR.10.2.15.1	*Develop TMDLs for water bodies listed under Clean Water Act Section 303(d)*					
SONCC-ElkR.10.1.37	Water Quality	Yes	Reduce water temperature, increase dissolved oxygen	Increase instream flows	All streams with ODFW water rights for fish	2a
SONCC-ElkR.10.1.37.1	*Secure adequate instream flows to fulfill ODFW water rights for fish*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-ElkR.2.2.49	Floodplain and Channel Structure	No	Reconnect the channel to the floodplain	Construct off channel ponds, alcoves, backwater habitat, and old stream oxbows	All streams where coho salmon would benefit immediately	2a
SONCC-ElkR.2.2.49.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-ElkR.2.2.49.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*

8. Brush Creek Population

Northern Coastal Stratum

Dependent Population

Recovery criteria: 80% of available IP habitat must be occupied in years following spawning of brood years with high marine survival

Habitat likely available to support all life stages

12 mi^2 watershed (35% Federal ownership)

6 IP-km (4 IP-mi) (18% High)

Dominant Land Uses are Recreation, Timber Harvest

Key Limiting Stresses are ‘Lack of Floodplain and Channel Structure’ and ‘Degraded Riparian Forest Conditions’

Key Limiting Threats are ‘Roads’ and ‘Timber Harvest’

Highest Priority Recovery Actions

• Improve timber harvest practices by revising Oregon Forest Practices Act • Reduce road-stream hydrologic connection • Reduce pollutants from runoff, minimize impervious surfaces	• Increase riparian vegetation • Reduce pollutants by increasing application of Low Impact Development (LID) techniques

8.1 History of Habitat and Land Use

Maguire (2001b) notes the Brush Creek watershed is poorly studied and the reported history of land use in the area is inconsistent. The creek bottom was the main trail north and south for Native Americans and then white settlers. A road was built through Brush Creek canyon just after 1920. The State of Oregon made its first purchase of land for Humbug Mountain State Park in 1926 and continued to expand the park to its current size (1800 acres) over the following 50 years. Maguire (2001b) could not substantiate whether there was a mill in middle Brush Creek reaches, but historic timber harvest was widespread. Although Maguire (2001b) did not mention recent timber harvest, it is evident in aerial photos because of the early seral conditions (Figure 8-1). The Highway 101 corridor confines the stream for long reaches and constitutes the most significant disturbance in the Brush Creek basin.

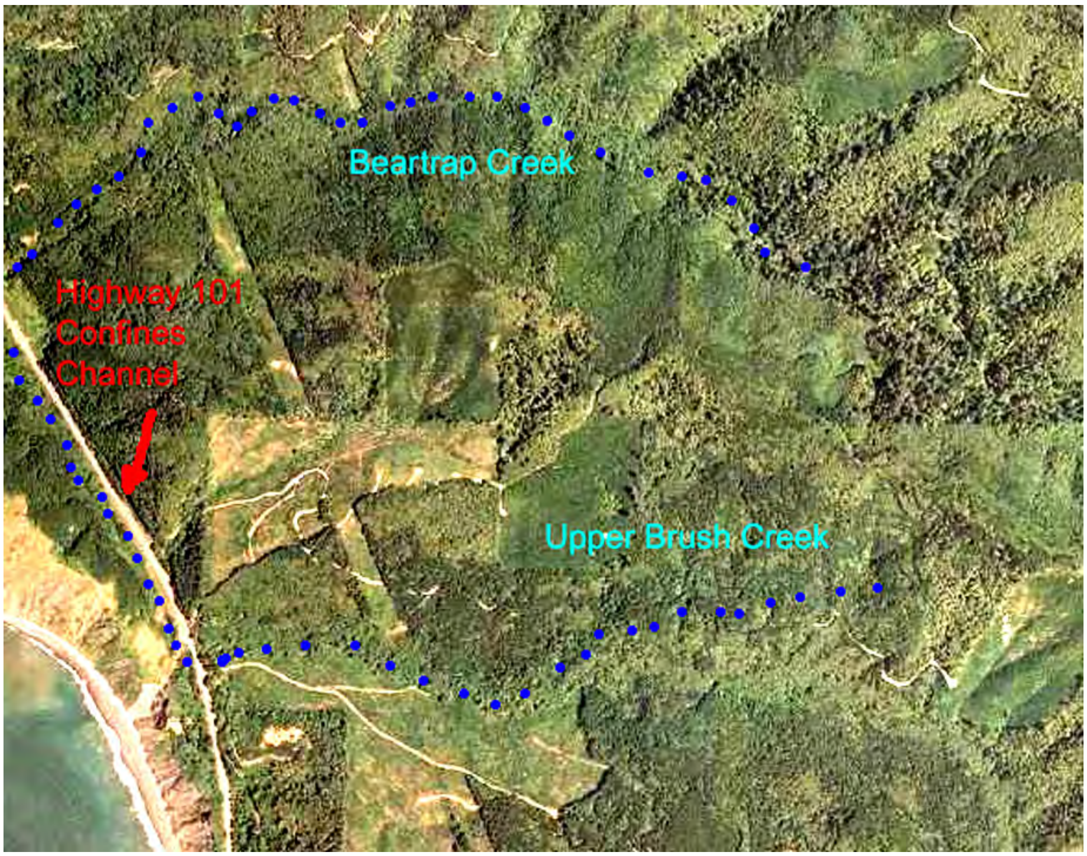

Figure 8-1. Upper Brush and tributary Beartrap Creek watersheds Photo shows power line corridor, extensive timber harvest and Highway 101 running right along the stream. Blue dots approximate USGS (1984) streams.

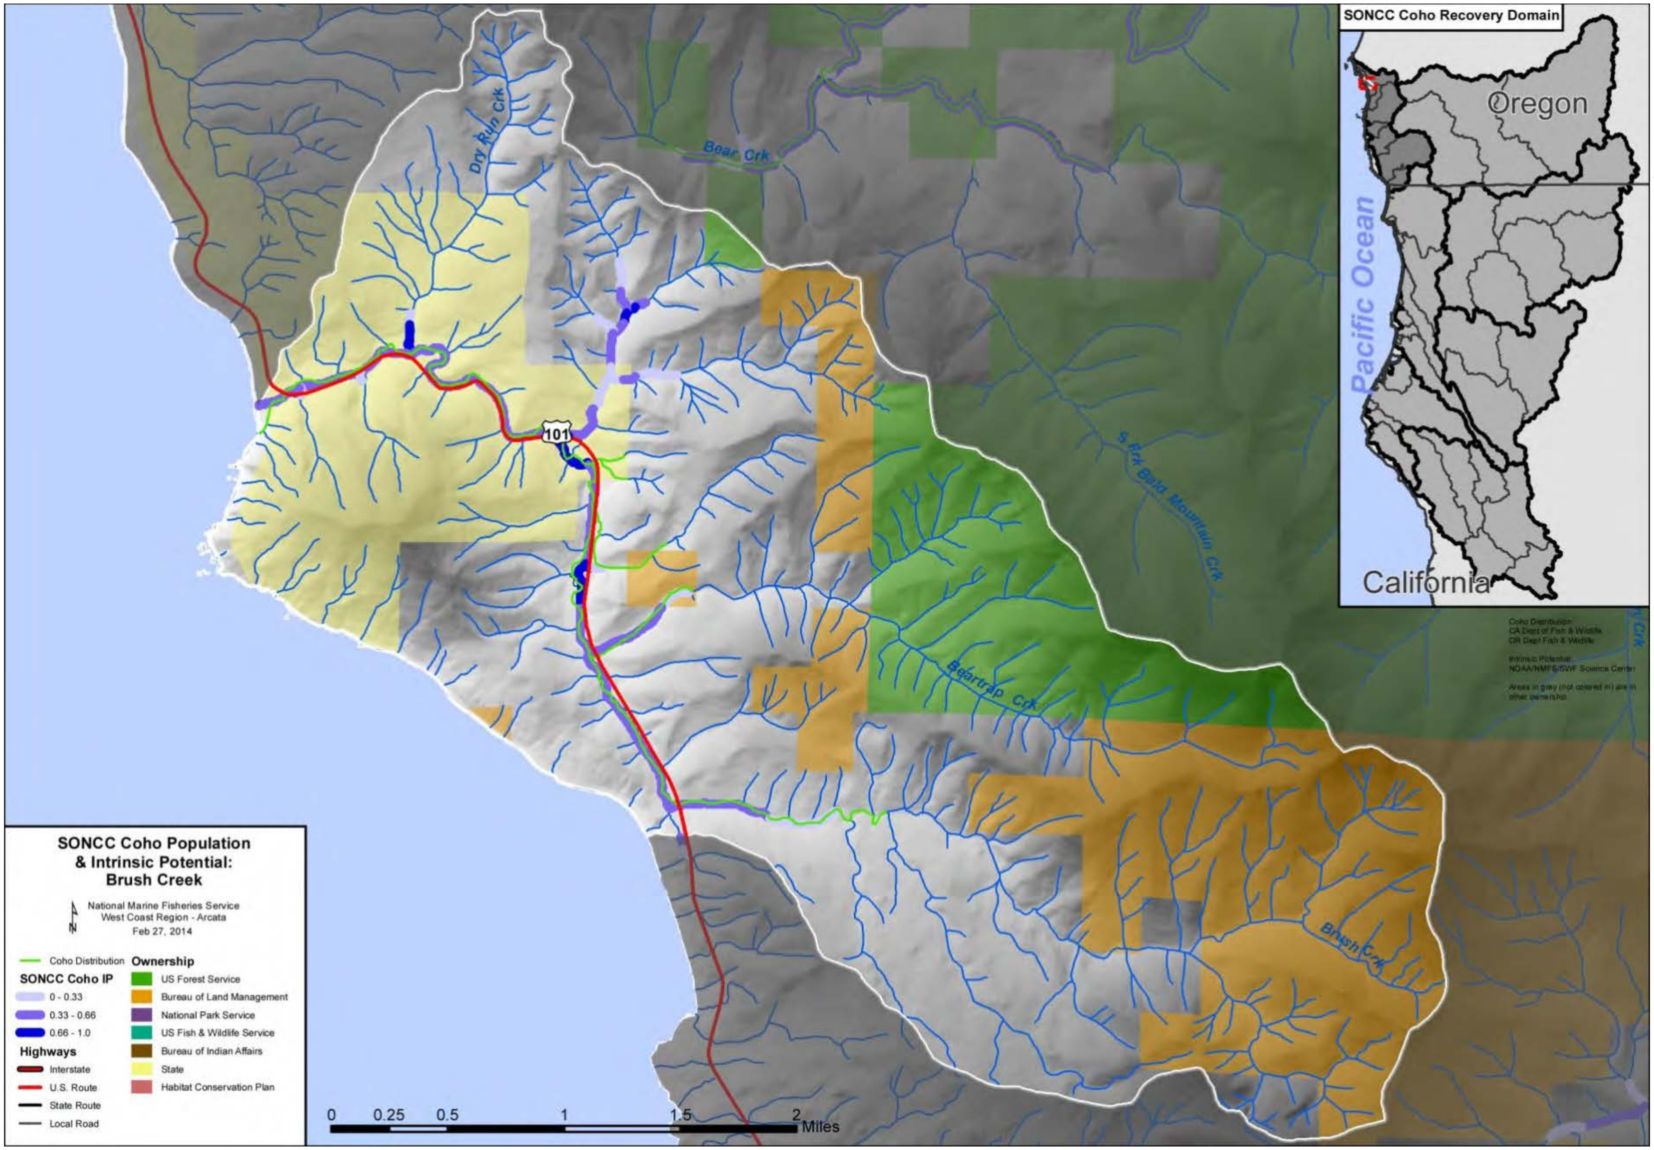

Figure 8-2. The geographic boundaries of the Brush Creek coho salmon population. Figure shows modeled Intrinsic Potential of habitat (Williams et al. 2006), land ownership, coho salmon distribution (ODFW 2013a), and location within the Southern-Oregon/Northern California Coast Coho Salmon ESU and the Northern Coastal diversity stratum (Williams et al. 2006). Grey areas indicate private ownership.

8.2 Historic Fish Distribution and Abundance

The Brush Creek basin is one of three coho salmon populations near Port Orford, Oregon (Maguire 2001b). Brush Creek has a higher gradient and greater natural valley confinement than its neighbor to the north, Hubbard Creek, with the bulk of high IP (>0.66) concentrated in the middle mainstem (Figure 8-2). Upper mainstem Brush Creek and the majority of Beartrap Creek are too steep for successful use by coho salmon. Table 8-1 lists the high intrinsic potential reaches and tributaries of Brush Creek.

Table 8-1. Tributaries with high IP reaches (IP > 0.66) (Williams et al. 2006).

Stream Name	Stream Name	Stream Name
Brush Creek mainstem	Dry Run Creek	Unnamed tributary (lower Brush)

8.3 Status of Brush Creek Coho Salmon

Spatial Structure and Diversity

The more restricted and fragmented the distribution of individuals within a population, and the more spatial distribution and habitat access have diverged from historical conditions, the greater the extinction risk. The confined mainstem channel conditions caused by Highway 101 restrict coho salmon use due to changes in stream velocity. ODFW (2005a) snorkeled two reaches, bracketing the area upstream and downstream of where Brush Creek first meets Highway 101, and found coho salmon in both reaches at very low densities (0.002 and 0.071 juveniles/m^2) in 2003 but did not find them in those same reaches in 2002. This suggests few adult spawners find suitable habitat in the Brush Creek basin, resulting in reduced diversity of the gene pool.

Population Size and Productivity

The very low density of coho salmon juveniles in Brush Creek found by ODFW in 2003 is likely associated with low adult population size caused by a reduction in the creek's carrying capacity due to channelization.

Extinction Risk

Not applicable because Brush Creek is not an independent population.

Role in SONCC Coho Salmon ESU Viability

The Brush Creek population is considered dependent because it does not have a high likelihood of sustaining itself over a 100-year time period in isolation and would likely receive sufficient immigration to alter its dynamics and extinction risk (Williams et al. 2006). Although such populations are not viable on their own, they do increase connectivity by allowing dispersal among independent populations and provide areas of refugia for other populations, acting as a source of colonists in some cases. The Brush Creek population likely interacts with other Northern Coastal dependent populations of coho salmon, such as Mussel Creek, as well as larger independent populations such as those in the Elk and Rogue rivers. Any restored habitat in

Brush Creek provides potential connectivity that assists metapopulation function in the SONCC ESU.

8.4 Plans and Assessments

State of Oregon

Expert Panel Limiting Factors Report for Southwest Oregon

ODFW (2008b) convened a panel of fisheries and watershed science experts as an initial step in their development of a recovery plan for Oregon's SONCC coho salmon populations. Deliberations of the expert panel provided ODFW with initial, strategic guidance on limiting factors and threats to recovery. Based on the input of panel members, ODFW (2008b) summarized the concerns for the Brush Creek population as follows:

Key concerns in Brush Creek were primarily loss of over-winter tributary habitat complexity and floodplain connectivity for juveniles, especially in the lowlands which are naturally very limited in this system and have been impacted by past and current urban, rural residential, and forestry development and practices. A diversion that flows over a cliff and into the ocean is also a key concern. Secondary concerns were related to a loss of over-winter, lowland habitat complexity due to past and current agricultural practices. In addition, high water temperatures in the summer due to a loss of riparian function and channel straightening, stress coho salmon juveniles.

Oregon Plan for Salmon and Watersheds
http://www.oregon.gov/OPSW/about_us.shtml

The state of Oregon developed a conservation and recovery strategy for coho salmon in the SONCC and Oregon Coast ESUs (State of Oregon 1997). The Oregon Plan for coho salmon is comprehensive and includes voluntary actions for all of the threats currently facing coho salmon in these ESUs and involves all relevant state agencies. Reforms to fishery harvest and hatchery programs were implemented by ODFW in the late 1990s. Many habitat restoration projects have occurred across the landscape in headwater habitat, lowlands, and the estuary. The action plans, implementation, and annual reports can be found at the web site.

South Coast Watersheds Council

Port Orford Watershed Assessment

The Port Orford Watershed Assessment (Maguire 2001b) is a summary of conditions, historic changes, and restoration needs for Mill, Hubbard, and Brush creeks.

Port Orford Action Plan

The Port Orford Action Plan (Massingill 2001b) is a companion document to the Watershed Assessment. The action plan describes a restoration strategy with specific recommended actions.

8.5 Stresses

Table 8-2. Severity of stresses affecting each life stage of coho salmon in Brush Creek. Stress rank categories, assessment methods, and data used to assess stresses are described in Appendix B.

	Stresses[2]	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Stress Rank
1	Lack of Floodplain and Channel Structure[1]	Very High	Very High	Very High[1]	Very High	Very High	Very High
2	Degraded Riparian Forest Conditions[1]	-	Very High	Very High[1]	High	High	Very High
3	Altered Hydrologic Function	Medium	High	High	High	High	High
4	Altered Sediment Supply	Low	Medium	High	Medium	Low	Medium
5	Impaired Estuary/Mainstem Function	-	Low	Low	Medium	Low	Low
6	Impaired Water Quality	Low	Low	Low	Low	Low	Low
7	Barriers	-	Low	Low	Low	Low	Low
8	Adverse Fishery- and Collection- Related Effects	-	-	Low	Low	Low	Low
9	Adverse Hatchery-Related Effects	Low	Low	Low	Low	Low	Low

[1]Key limiting stresses and limited life stage.
[2]Increased Disease/Predation/Competition is not a considered a stress for this population.

Key Limiting Stresses, Life Stages, and Habitat

The juvenile life stage is most limited and quality winter rearing habitat is lacking. The key limiting stresses for this population are lack of floodplain and channel structure and degraded riparian forest conditions. Degraded riparian conditions eliminated the source of large wood recruitment. Most historically available habitat in the estuary has been altered by development, channelization, and diking. These findings are consistent with those of the Oregon Expert Panel (ODFW 2008b).

Lack of Floodplain and Channel Structure

Highway 101 has caused major alterations to the Brush Creek channel, including relocation and confinement. This channel confinement resulted in increased velocity, which compromises adult coho salmon passage and decreases the quality of summer and winter rearing habitat. These high velocities could also increase bedload movement in confined reaches, leading to bed scour and loss of eggs and alevins. Large wood supply in Brush Creek is limited according to ODFW habitat data, and pool frequency is low. Where large wood has been restored to the channel, it has increased pool depth and created more complex habitats.

Degraded Riparian Forest Conditions

There are few large conifers in the riparian zone of Brush Creek above Humbug Mountain State Park, except for large trees in the headwaters of Brush Creek which are well above the range of coho salmon. The remainder of Brush Creek's riparian zone is comprised of hardwoods, including willow and alder. These species do not provide long lasting large wood for channel forming processes (Cederholm et al. 1997). Riparian development is impeded by the highway in some channelized sections. ODFW found the lower mainstem of Brush Creek has poor riparian conditions (<75 conifers 36" diameter at breast height/1000 feet) due to development of campgrounds and recreational access.

Altered Sediment Supply

Altered sediment supply poses an overall medium stress to coho salmon in Brush Creek. Sediment contribution from landslides and erosion occurs naturally in the Brush Creek basin; however, roads, timber harvest, and bank erosion following removal of riparian vegetation have elevated fine sediment input. Habitat surveys in the lower section of Brush Creek found poor (>17 percent fines) silt/sand surface conditions except in reaches confined by Highway 101, where scores rose to good levels (12 to 15 percent fines). Excess fine sediment directly impacts coho salmon egg viability and can reduce food for fry, juveniles and smolts. Poor pool frequency and depth throughout the Brush Creek basin is likely due to elevated levels of fine sediment partially filling pools, a lack of scour-forcing obstructions such as large wood, and in some reaches diminished scour due to channel widening.

Impaired Estuary/Mainstem Function

Estuary function is important to the population because of its unique role in the life history and survival of coho salmon (Miller and Sadro 2003, Koski 2009). Brush Creek meets the Pacific Ocean after passing through a narrow canyon opening spanned by Highway 101. The estuary is surrounded by very steep and unstable land at the base of Humbug Mountain and along the creek to the north. Although small, this estuary remains in good condition, with land being protected within Humbug Mountain State Park. The estuary/lagoon currently has little cover and complexity and has very little salmon rearing habitat. Because the estuary is naturally small, this lack of rearing habitat is not considered a threat for juveniles. However, lagoon breaching during the summer months may be affected by excess fine sediment and cause stress to outmigrating smolts.

Figure 8-3. Mouth of Brush Creek. Photo shows poorly developed estuary/lagoon, visible as a depression in the sandy beach that affords little opportunity for salmonid juvenile rearing.

Impaired Water Quality

Brush Creek's maximum floating weekly average water temperature (MWMT) value of less than 16 °C is well under the ODEQ criteria of 18.4 °C (64° F). Pesticide and herbicide use on both public and private lands contribute deleterious effects to water quality in Brush Creek. More significantly, Brush Creek's immediate adjacency to Highway 101 along most of its main stem makes it particularly vulnerable to herbicides from the Oregon Department of Transportation's vegetation management program for invasive weed control.

Barriers

Maguire (2001b) reports only one potential barrier to juvenile salmonids in the Brush Creek basin, which is at the mouth of Dry Run Creek.

Altered Hydrologic Function

There are no dams or low-flow diversions in Brush Creek other than for use at Humbug Mountain State Park. However, timber harvest and associated roads may result in altered peak flows (Grant et al. 2008). In addition, to prevent flooding of Highway 101 high flows greater than a 15 year event are diverted off a cliff into the ocean through an overflow channel about 3 miles upstream of the mouth (NMFS 2005a) (see Dams/Diversions section below). Runoff from Highway 101 enters Brush Creek directly and significantly adds to storm flow intensities.

Adverse Fishery- and Collection-Related Effects

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low stress to juveniles, smolts, and adults.

Adverse Hatchery-Related Effects

There are no operating hatcheries in the Brush Creek population area. Hatchery-origin adults may stray into the population area; however, the proportion of adults that are of hatchery origin is likely less than five percent and there is no hatchery in the basin producing other species of salmonids. Therefore, adverse hatchery-related effects pose a low risk to all life stages (Appendix B).

8.6 Threats

Table 8-3. Severity of threats affecting each life stage of coho salmon in Brush Creek. Threat rank categories, assessment methods, and data used to assess threats are described in Appendix B.

	Threats[2]	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Threat Rank
1	Roads[1]	Very High	Very High	Very High[1]	Very High	Very High	Very High
2	Channelization/Diking	High	High	High	High	High	High
3	Timber Harvest[1]	High	High	High[1]	High	Medium	High
4	Climate Change	Low	Low	Medium	Medium	Medium	Medium
5	High Severity Fire	Low	Low	Low	Low	Low	Low
6	Urban/Residential/Industrial Dev.	Low	Low	Low	Low	Low	Low
7	Road-Stream Crossing Barriers	-	Low	Low	Low	Low	Low
8	Dams/Diversions	Low	Medium	Medium	Medium	Low	Medium
9	Fishing and Collecting	-	-	Low	Low	Low	Low
10	Hatcheries	Low	Low	Low	Low	Low	Low

[1]Key limiting threats and limited life stage.
[2]Agricultural Practices, Mining/Gravel Extraction, and Invasive and Non-Native/Alien Species are not considered threats to this population.

Key Limiting Threats

The two key limiting threats, those which most affect recovery of the population by influencing stresses, are roads and timber harvest.

Roads

A greater problem than high overall road densities is the fact that Highway 101 follows and confines almost the entire mainstem of Brush Creek.

Channelization/Diking

Channelization and diking pose a high threat to Brush Creek coho salmon because of the effects of Highway 101, which runs adjacent to most of the creek's mainstem. The highway causes confinement, accelerated currents and channel simplification, all of which adversely affect coho salmon. Development of campgrounds and day use recreation areas on the former flood terrace of the stream also confine the channel.

Timber Harvest

Timber harvesting in Brush Creek between 1972 and 1992 was less than 10 percent, except for patches of more intense activity where elevated road densities are also apparent (Bredensteiner et al. 2003). Maguire (2001b) produced a timber harvest map (Figure 8-4) that shows outlines of logged areas but does not provide information on when harvests took place or the harvest methods. Timber harvests in riparian zones and in headwater areas are likely to have played a role in decreased large wood supply. Forestry practices, past and present, in rain-dominated watersheds may combine to increase hydrologic risk as past practices may still be influencing the routing of water and causing channel modifications or increased fine sediment routing and turbidity (Maguire 2001b).

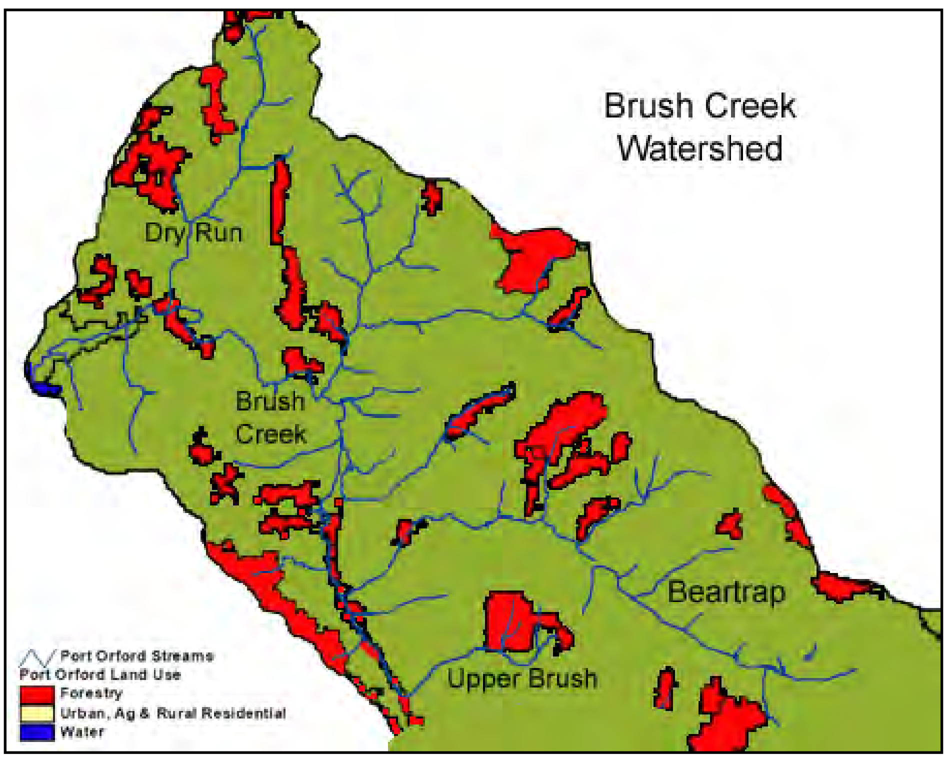

Figure 8-4. Map of timber harvest. This map was adapted from the Port Orford Watershed Assessment (Maguire 2001b) with polygons of timber harvests filled in with red. No metadata are available to understand harvest methods or dates.

Climate Change

There is low risk of change in average precipitation over the next 50 years (Appendix B). Modeled regional average temperature shows a moderate increase over the next 50 years (Appendix B). Average temperature could increase by up to 1^{o} C in the summer and by a similar amount in the winter. The risk of sea level rise is high (Thieler and Hammer-Klose 2000), which may impact the quality and extent of wetland juvenile and smolt habitat. Adults may be negatively impacted by climate-related ocean acidification, changes in ocean conditions, and prey availability (see Independent Science Advisory Board 2007, Feely et al. 2008, Portner and Knust 2007).

High Severity Fire

Brush Creek lies within the immediate coastal strip of southern Oregon and is subject to marine temperature mediation resulting in moist cool summers and high rainfall during fall, winter and spring. These attributes combine for a generally wet environment year-round and as a result a low threat score for fire.

Urbanization/Residential/Industrial Development

There is a relatively low level of urban and rural residential development in the Brush Creek basin.

Road-stream Crossing Barriers

A potential road-stream crossing barrier for juvenile coho salmon and other salmonids has been identified at the mouth of Dry Run Creek (Maguire 2001b).

Dams/Diversions

Near where Brush Creek first meets Highway 101, an overflow channel diverts peak flows from Brush Creek off a steep cliff into the ocean (NMFS 2005a). The overflow reduces roadway flooding downstream, but is unscreened and any coho entrained are killed. The overflow is now triggered during flows greater than 700 cubic feet per second (cfs), which are expected to occur on average once every 15 years.

Fishing and Collecting

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low threat to juveniles, smolts, and adults.

Hatcheries

Hatcheries pose a low threat to all life stages of coho salmon in the Brush Creek population area. The rationale for these ratings is described under the “Adverse Hatchery-Related Effects” stress.

8.7 Recovery Strategy

The most immediate need for habitat restoration and threat reduction in Brush Creek is in those areas currently occupied by coho salmon, which according to the limited available data is the mainstem of Brush Creek. Unoccupied areas must also be restored to provide enough habitat for coho salmon to complete their life cycle.

The Brush Creek population is considered dependent and therefore cannot be viable on its own; however, restoring habitat within the basin is necessary so that the basin can support all life stages of coho salmon and provide connectivity between other populations in the ESU. The recovery criterion for this population is that 80% of available IP habitat must be occupied in years following spawning of brood years with high marine survival. Despite impaired habitat conditions, Brush Creek has maintained use by coho salmon, possibly through straying from larger independent populations like the Elk River and Rogue River nearby. Highway 101, which is not likely to be relocated, is the major impediment to achieving full coho salmon potential in Brush Creek.

The most important factor limiting recovery of coho salmon in Brush Creek is a deficiency in the amount of suitable rearing habitat for juveniles. The processes that create and maintain such habitat must be restored by increasing habitat complexity within the channel, re-establishing off-channel rearing areas, restoring riparian forests, and reducing threats to instream habitat. The effects of fishing on this population's ability to meet its viability criteria should be evaluated.

Table 8-4 on the following page lists the recovery actions for the Brush Creek population.

Table 8-4. Recovery action implementation schedule for the Brush Creek population. Recovery actions for monitoring and research are listed in tables at the end of Chapter 5.

Action ID / *Step ID*	Target	KLS/T	Strategy / *Step Description*	Action Description	Area	Priority
SONCC-BruC.2.1.29	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	Population wide	2c
SONCC-BruC.2.1.29.1			*Assess habitat to determine beneficial location and amount of instream structure needed*			
SONCC-BruC.2.1.29.2			*Place instream structures, guided by assessment results*			
SONCC-BruC.19.1.2	Timber Harvest	Yes	Improve timber harvest practices	Improve regulatory mechanisms	Population wide	2b
SONCC-BruC.19.1.2.1			*Determine how to revise Oregon Forest Practice Rules so that they do not limit recovery of SONCC coho salmon and make appropriate revisions*			
SONCC-BruC.19.1.2.2			*Adopt rules for fish-bearing streams sufficient to protect both water quality and fish habitat*			
SONCC-BruC.19.1.2.3			*Adopt rules to increase protection of non-fish-bearing streams that address practices that adversely impact water quality and fish habitat*			
SONCC-BruC.19.1.2.4			*Ensure management measures for landslide prone areas include protection of water quality and fisheries habitat*			
SONCC-BruC.19.1.2.5			*Until more permanent regulatory mechanisms can be put in place, immediately adopt interim rules that increase protection for salmon habitat in forested areas, including increased natural recruitment of large wood on perennial and intermittent streams likely to deliver wood downstream, increased shade on all perennials, and protective buffers on small intermittent streams.*			
SONCC-BruC.2.1.1	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	Mainstem within Humbug Mountain State Park, and all streams where coho salmon would benefit immediately	2b
SONCC-BruC.2.1.1.1			*Assess habitat to determine beneficial location and amount of instream structure needed*			
SONCC-BruC.2.1.1.2			*Place instream structures, guided by assessment results*			
SONCC-BruC.28.2.11	Roads	Yes	Reduce pollutants and stormflow	Educate stakeholders	Highway 101 and campgrounds	2b
SONCC-BruC.28.2.11.1			*Develop stormwater management plan, consistent with ODEQ specifications, to minimize non-point source pollution from entering Brush Creek from HWY 101 and campgrounds*			
SONCC-BruC.2.1.18	Floodplain and Channel Structure	Yes	Increase channel complexity	Improve regulatory mechanisms	Population wide	2c
SONCC-BruC.2.1.18.1			*Improve protective regulations for beaver and develop guidelines for relocation that are practical for restoration groups*			
SONCC-BruC.2.2.9	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	All streams where coho salmon would benefit immediately	2c
SONCC-BruC.2.2.9.1			*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*			
SONCC-BruC.2.2.9.2			*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*			

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-BruC.2.2.31	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Population wide	2d
SONCC-BruC.2.2.31.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-BruC.2.2.31.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-BruC.2.2.3	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	Lower mainstem	2c
SONCC-BruC.2.2.3.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for landowners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-BruC.2.2.3.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-BruC.2.2.3.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					
SONCC-BruC.2.2.30	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	Population wide	2d
SONCC-BruC.2.2.30.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for landowners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-BruC.2.2.30.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-BruC.2.2.30.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					
SONCC-BruC.28.2.20	Roads	Yes	Reduce pollutants and stormflow	Increase regulatory oversight	Population wide	2c
SONCC-BruC.28.2.20.1	*Strengthen city and county ordinances to minimize new impervious surfaces and require treatment to current standards*					
SONCC-BruC.28.2.20.2	*Strengthen city and county ordinances to require treatment to current standards when existing impervious surfaces are expanded, reconditioned, reconstructed or replaced*					
SONCC-BruC.28.2.20.3	*Develop local regulatory mechanisms that limits development and reduces amount of total impervious area through incentives*					
SONCC-BruC.8.1.10	Sediment	No	Reduce delivery of sediment to streams	Reduce road-stream hydrologic connection	All areas where coho salmon would benefit immediately	2c
SONCC-BruC.8.1.10.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-BruC.8.1.10.2	*Decommission roads, guided by assessment*					
SONCC-BruC.8.1.10.3	*Upgrade roads, guided by assessment*					
SONCC-BruC.8.1.10.4	*Maintain roads, guided by assessment*					
SONCC-BruC.8.1.33	Sediment	No	Reduce delivery of sediment to streams	Reduce road-stream hydrologic connection	Population wide	2d
SONCC-BruC.8.1.33.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-BruC.8.1.33.2	*Decommission roads, guided by assessment*					
SONCC-BruC.8.1.33.3	*Upgrade roads, guided by assessment*					
SONCC-BruC.8.1.33.4	*Maintain roads, guided by assessment*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-BruC.7.1.6	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Increase conifer riparian vegetation	Lower mainstem, estuary/lagoon	3c
SONCC-BruC.7.1.6.1	*Develop an appropriate timber harvest management plan for benefits to coho salmon habitat*					
SONCC-BruC.7.1.6.2	*Thin, or release conifers, guided by the plan*					
SONCC-BruC.7.1.6.3	*Plant conifers, guided by the plan*					
SONCC-BruC.7.1.19	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Increase regulatory oversight	All coho bearing streams	3c
SONCC-BruC.7.1.19.1	*Strengthen city and county ordinances to limit development within the 100 year channel migration zone*					
SONCC-BruC.7.1.19.2	*Strengthen city and county ordinances to limit development within the 50 year flood elevation*					
SONCC-BruC.5.1.7	Passage	No	Improve access	Remove barriers	Mouth of Dry Run Creek	3c
SONCC-BruC.5.1.7.1	*Assess and prioritize barrier*					
SONCC-BruC.5.1.7.2	*Remove barrier, based on evaluation*					
SONCC-BruC.5.1.32	Passage	No	Improve access	Remove barriers	Population wide	3d
SONCC-BruC.5.1.32.1	*Assess and prioritize barriers using the ODFW fish passage barrier database*					
SONCC-BruC.5.1.32.2	*Remove barriers, based on evaluation*					
SONCC-BruC.10.7.27	Water Quality	No	Restore nutrients	Add marine-derived nutrients to streams	All streams where coho salmon would benefit immediately	3c
SONCC-BruC.10.7.27.1	*Develop a plan to supply appropriate amounts of marine-derived nutrients to streams (e.g. carcass placement, pellet dispersal)*					
SONCC-BruC.10.7.27.2	*Supply marine-derived nutrients to streams guided by the plan*					
SONCC-BruC.10.7.28	Water Quality	No	Restore nutrients	Add marine-derived nutrients to streams	Population wide	3d
SONCC-BruC.10.7.28.1	*Develop a plan to supply appropriate amounts of marine-derived nutrients to streams (e.g. carcass placement, pellet dispersal)*					
SONCC-BruC.10.7.28.2	*Supply marine-derived nutrients to streams guided by the plan*					
SONCC-BruC.10.2.17	Water Quality	No	Reduce pollutants	Increase regulatory oversight	Population wide	3d
SONCC-BruC.10.2.17.1	*Increase application of Low Impact Development (LID) techniques through education and incentives*					
SONCC-BruC.10.2.17.2	*Incorporate LID in Clean Water Act permits for projects that result in stormwater discharge*

9. Mussel Creek Population

Northern Coastal Stratum

Dependent Population

Recovery criteria: 80% of IP habitat must be occupied in years following spawning of brood years with high marine survival

Habitat likely available to support all life stages

14 mi^2 watershed (2% Federal ownership)

6 IP-km (4 IP-mi) (50% High)

Dominant Land Uses are Timber Harvest and Recreation

Key Limiting Stresses are 'Lack of Floodplain and Channel Structure' and 'Degraded Riparian Forest Conditions'

Key Limiting Threats are 'Timber Harvest' and 'Channelization/Diking'

Highest Priority Recovery Actions

• Increase large woody debris (LWD), boulders, or other instream structure • Construct off-channel habitats, alcoves, backwater habitat, and old stream oxbows • Improve timber harvest practices by revising Oregon Forest Practices Act	• Increase beaver abundance • Improve grazing practices • Reduce pollutants, minimize impervious surfaces

9.1 History of Habitat and Land Use

Mussel Creek empties into the Pacific Ocean just south of Port Orford between Brush and Euchre creeks. Historically, a trail likely passed through the lower basin, and became a road for automobiles in the 1920s prior to eventually becoming Highway 101 (Maguire 2001b). The roadway has caused the South Fork of Mussel Creek to be realigned, which resulted in a loss of habitat suitability for coho salmon. Tourist attractions, such as the Prehistoric Gardens and the Arizona Beach campground, are in the floodplain of lower Mussel Creek and Myrtle Creek.

Data for timber harvest on private lands are not available for the Mussel Creek basin, but aerial photos indicate timber has been harvested from most of the basin except for a small patch below Highway 101, adjacent to Prehistoric Gardens. Active timber harvest continues and road densities are high in this basin. In addition, Mussel Creek has very steep slopes, which likely facilitated sediment transport to the creeks during and after land disturbing activities. Myrtle Creek serves as an example of these channel changes; it loses surface flow in late summer and early fall possibly due to excessive fine sediment loads from steep, managed land near the headwaters. Additionally, the stream channel has been straightened and channelized to maximize space for camping and recreation. These impacts have made approximately 50 percent of the area with high intrinsic potential for coho salmon habitat currently uninhabitable and difficult to restore.

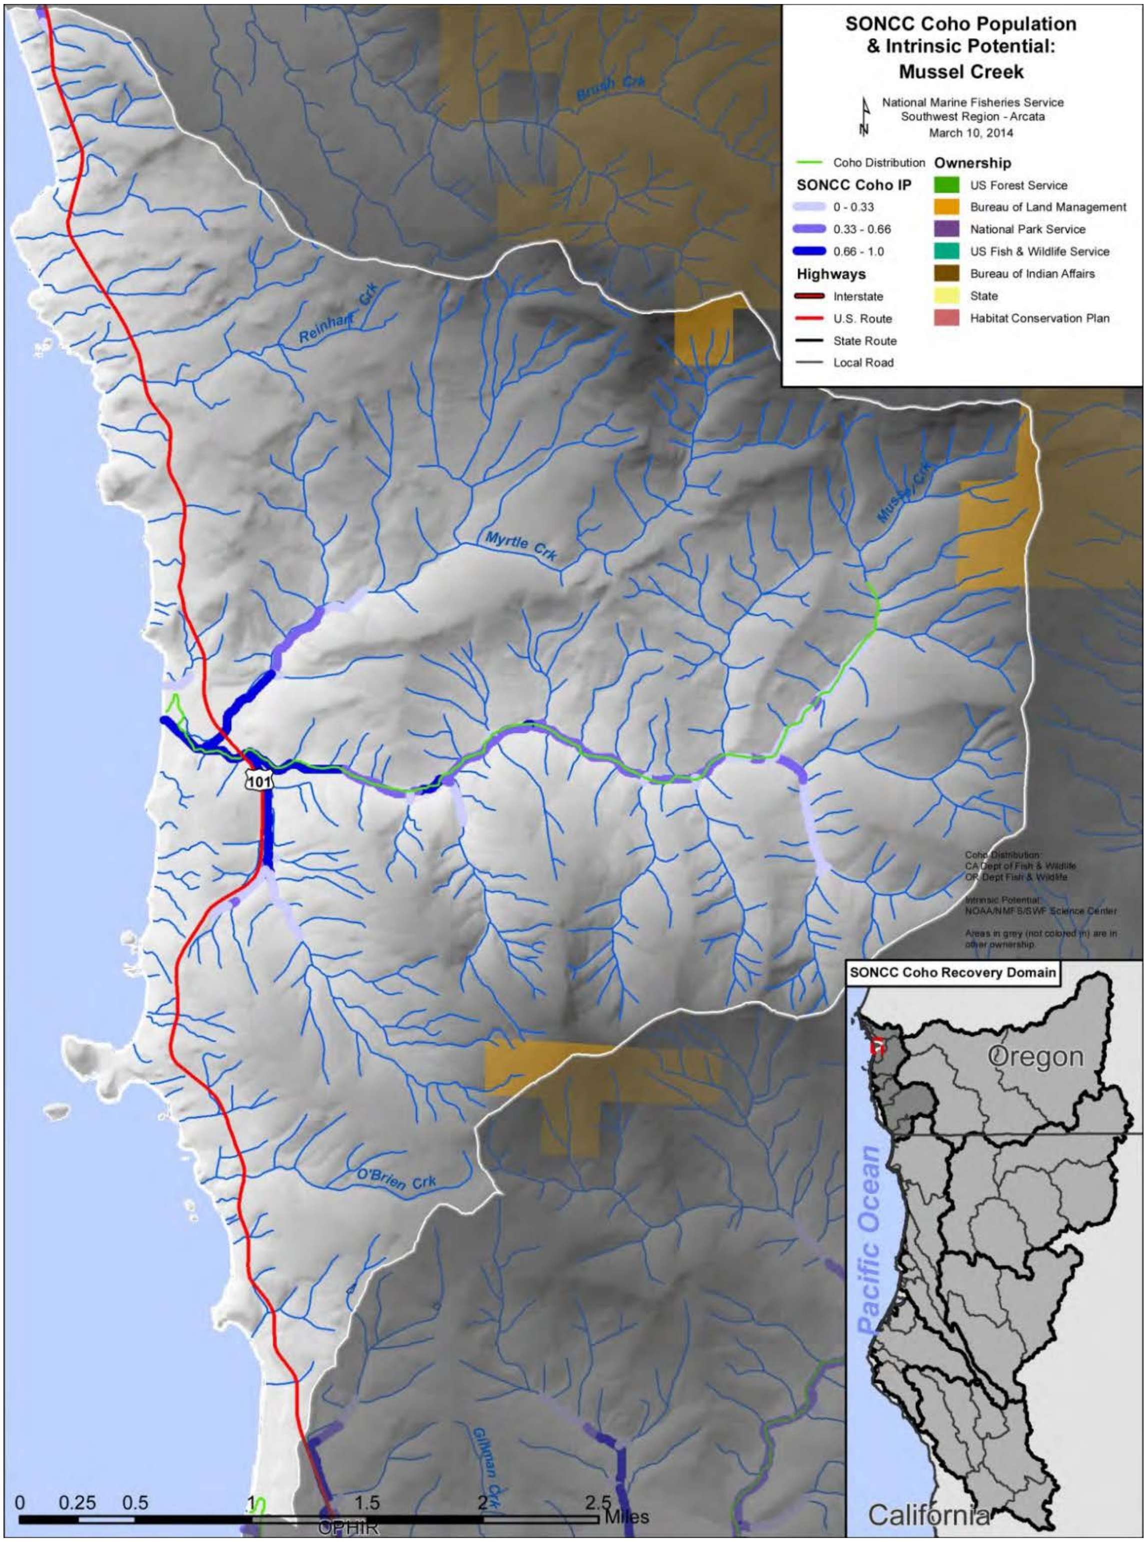

Figure 9-1. The geographic boundaries of the Mussel Creek coho salmon population. Figure shows modeled Intrinsic Potential of habitat (Williams et al. 2006), land ownership, coho salmon distribution (ODFW 2013a), and location within the Southern-Oregon/Northern California Coast Coho Salmon ESU and the Northern Coastal diversity stratum (Williams et al. 2006). Grey areas indicate private ownership.

9.2 Historic Fish Distribution and Abundance

No information is available about the historic distribution and abundance of coho salmon in Mussel Creek.

Table 9-1. Tributaries with high IP reaches (IP > 0.66) (Williams et al. 2006).

Stream Name	Stream Name	Stream Name
Lower Mussel Creek	Myrtle Creek	South Fork Mussel Creek

9.3 Status of Mussel Creek Coho Salmon

Spatial Structure and Diversity

Much of the high IP in Mussel Creek is not currently suitable because the South Fork is channelized and re-routed by Highway 101. The major tributary, Myrtle Creek, is also channelized and loses surface flows during the summer and fall. Approximately 50 percent of high IP in the basin has been degraded due to channelization and straightening. Additionally, mainstem Mussel Creek lacks sufficient depth and other channel features necessary to be fully functional for coho salmon rearing. Available data show coho salmon are restricted to mainstem Mussel Creek when present, and that no coho salmon were observed during recent juvenile surveys in 2002 and 2003 (Oregon Department of Fish and Wildlife [ODFW] 2005a). The small population size in Mussel Creek suggests restricted genetic diversity.

Population Size and Productivity

The Mussel Creek population is presumed to be nearly extirpated based on recent juvenile surveys, impaired habitat conditions, and the lack of any other information to indicate that coho salmon currently spawn or rear in the basin. The productivity and size of this population is driven not only by the dynamics of the Mussel Creek population, but by those of nearby populations as well, which contribute spawners as strays. However, the supply of strays to Mussel Creek is not expected to be substantial or consistent in the near term because most adjacent populations in the SONCC coho salmon ESU are at low levels.

Extinction Risk

Not applicable because Mussel Creek is not an independent population.

Role in SONCC Coho Salmon ESU Viability

The Mussel Creek population is considered dependent because it does not have a high likelihood of sustaining itself over a 100-year time period in isolation and would likely receive sufficient immigration to alter its dynamics and extinction risk (Williams et al. 2006). Although such populations are not viable on their own, they do increase connectivity by allowing dispersal among independent populations and provide areas of refugia for other populations, acting as a source of colonists in some cases. Historically the Mussel Creek population would have interacted with other Northern Coastal dependent populations of coho salmon, such as those in

Brush Creek, as well as larger independent populations such as those in the Elk and Rogue Rivers. Any restored habitat in Mussel Creek provides potential connectivity that assists metapopulation function in the ESU.

9.4 Plans and Assessments

State of Oregon

Oregon Plan for Salmon and Watersheds
http://www.oregon.gov/OPSW/about_us.shtml

The State of Oregon developed a conservation and recovery strategy for coho salmon in the SONCC and Oregon Coast ESUs (State of Oregon 1997). The Oregon Plan for coho salmon is a comprehensive plan that includes voluntary actions to address all of the threats currently facing coho salmon in these ESUs and involves all relevant state agencies. Reforms to fishery harvest and hatchery programs described in the Oregon Plan were implemented by ODFW in the late 1990s. Many habitat restoration projects have occurred across the landscape in headwater habitat, lowlands, and the estuary.

Report of the Oregon Expert Panel on Limiting Factors

ODFW (2008b) convened a panel of fisheries and watershed science experts as an initial step in their development of a recovery plan for Oregon's SONCC coho salmon populations. Deliberations of the expert panel provided ODFW with initial, strategic guidance on limiting factors and threats to recovery. Based on the input of panel members, ODFW (2008b) summarized the concerns for the Mussel Creek population as follows:

> Key concerns in Mussel Creek were primarily loss of over-winter tributary habitat complexity and floodplain connectivity for juveniles, especially in the lowlands which are naturally very limited in these systems and have been impacted by past and current urban, rural residential, and forestry development and practices. Secondary concerns were related to a loss of over-winter, lowland habitat complexity due to past and current agricultural practices. In addition, high water temperatures exist for summer parr due to a loss of riparian function and channel straightening.

Cumulative Effects of Southwest Oregon Coastal Land Use on Salmon Habitat

Oregon State University (OSU) Oak Creek Labs conducted a study funded by ODFW and the Oregon Department of Forestry (ODF) to determine relationships between forest harvest and Pacific salmon productivity (Frissell 1992). The study assessed basins along the Oregon coast extending from the Sixes River to the southern border during the period from 1986 to 1992.

9.5 Stresses

Table 9-2. Severity of stresses affecting each life stage of coho salmon in Mussel Creek. Stress rank categories, assessment methods, and data used to assess stresses are described in Appendix B.

	Stresses[2]	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Stress Rank
1	Lack of Floodplain and Channel Structure[1]	Low	Very High	Very High[1]	Very High	Very High	Very High
2	Degraded Riparian Forest Conditions[1]	-	Very High	Very High[1]	Very High	Very High	Very High
3	Altered Sediment Supply	High	High	High	High	High	High
4	Impaired Estuary/Mainstem Function	-	Medium	High	High	Medium	High
5	Impaired Water Quality	Medium	Medium	Medium	Low	Low	Medium
6	Barriers	-	Low	Low	Low	Low	Low
7	Altered Hydrologic Function	Low	Medium	High	High	Low	High
8	Adverse Fishery- and Collection- Related Effects	-	-	Low	Low	Low	Low
9	Adverse Hatchery-Related Effects	Low	Low	Low	Low	Low	Low

[1] Key limiting stresses and limited life stage.
[2] Increased Disease/Predation/Competition is not considered a stress for this population.

Key Limiting Stresses, Life Stages, and Habitat

The juvenile life stage is most limited and quality winter rearing habitat, as well as summer rearing habitat, is lacking as vital habitat for the population. The key limiting stresses for this population are lack of floodplain and channel structure and degraded riparian forest condition. Winter rearing habitat is often formed by instream large wood, but is also found in estuaries and floodplain wetlands. Timber removal has decreased the source of large wood, and much of the historically available habitat in the estuary and floodplain wetlands has been altered by development and channelization. The IP habitat in the Mussel Creek basin is concentrated in the flattest parts of the basin, near the ocean, which is where the development occurs. Off-channel juvenile rearing habitat with suitable temperature is vital to coho salmon recovery in this creek, but is very impaired. These findings are consistent with those of the Oregon Expert Panel (Section 9.4).

Lack of Floodplain and Channel Structure

In many areas, the creek and its tributaries are disconnected from the floodplain. Channelization of Myrtle Creek and the South Fork Mussel Creek eliminated meanders and side channels that would have provided summer and winter coho salmon rearing habitat. Coho salmon juveniles prefer pools formed by large wood, but habitat surveys show less than one key piece per 100 meters in the middle reach of Mussel Creek upstream of the highest IP habitat, which rates as poor according to ODFW standards. The upper reach of Mussel Creek had 1 to 2 key pieces of large wood per 1000 feet, which rates as fair.

Figure 9-2. Photo of the Myrtle Creek channel. View is looking downstream just above its convergence with Mussel Creek. Surface flow has been lost, and the stream has been channelized. Photo taken on 9/18/2008.

Pool frequency in the upper reach of Mussel Creek was rated as (10 to 20 percent) according to ODFW standards. The good rating (20 to 35 percent) in the middle reach of Mussel Creek likely represents a substantial reduction in pool frequency from historic conditions, given the level of disturbance in the basin. Pool depth is poor (average less than 2 feet) in the entire sampled area.

Degraded Riparian Forest Conditions

Without proper riparian forests, Mussel Creek has no mechanism for recruitment of large wood, which would trap fine sediment and enhance habitat complexity (Chapter 3). Lack of riparian cover also decreases shade and thermal buffering, and reduces formation of undercut banks. Habitat surveys of riparian conditions in the middle reaches of Mussel Creek found the area to be devoid of large conifers (>36" diameter at breast height), which translates to a poor riparian condition score using the ODFW criteria (<75 large conifers per 1000 feet of stream). Lack of large conifers in the riparian zone of much of the lower creek is also apparent. One short reach of Mussel Creek downstream Highway 101 contains a patch of late seral forest with a mature riparian canopy (Figure 9-3).

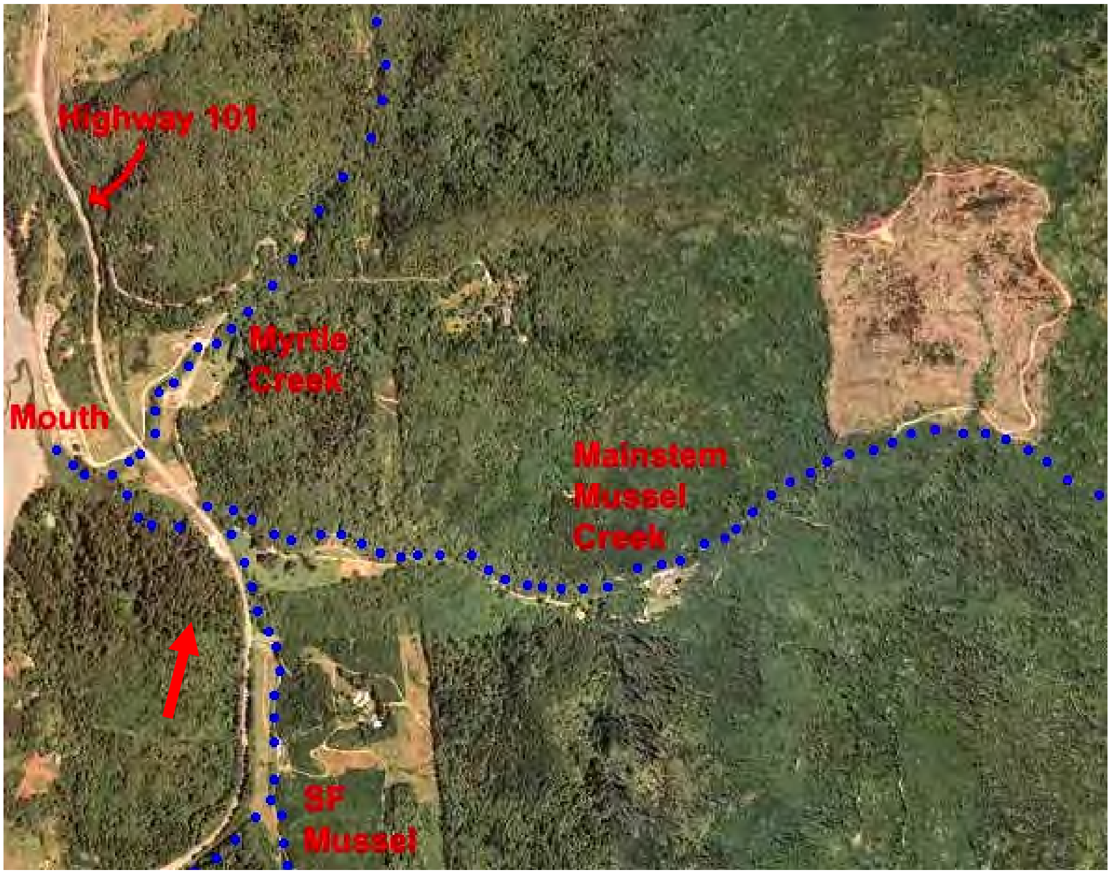

Figure 9-3. The lower reaches of Mussel, South Fork Mussel and Myrtle creeks in June 2005. Note the power line corridor in upper Myrtle riparian, Highway 101 confining South Fork, and a clearcut upper mainstem Mussel Creek. Arrow at lower-left points to patch of large trees, possibly old growth.

Altered Sediment Supply

Sediment contribution from landslides and erosion occurs naturally in the Mussel Creek basin. However, roads, timber harvest, and bank erosion following removal of riparian vegetation have elevated fine sediment input. While the steeper reach further upstream rated good for surface fines (<12 percent), habitat surveys in the middle reaches of Mussel Creek found poor (>17 percent surface fines) silt/sand surface conditions. These middle reaches are where the high IP is located. The high percentage of industrial timberlands, high harvest rates and associated roads has increased the amount of fine sediment delivered to the streams. Excess fine sediment directly impacts coho salmon egg viability and can reduce food for fry, juveniles and smolts. Poor pool frequency and depth throughout the Mussel Creek basin is likely due to elevated levels of fine sediment partially filling pools, a lack of scour-forcing obstructions such as large wood, and in some reaches diminished scour due to channel widening.

Impaired Estuary/Mainstem Function

Little is known about the historic extent of estuarine area in Mussel Creek, but it is likely that development adjacent to the current estuary has reduced habitat. Currently the estuarine portion of Mussel Creek is confined to less than 10 acres of tidal sand and mudflat, and a few acres of tidal wetland habitat west of Highway 101 (Figure 9-4). Based on the natural drainage pattern and elevations in the area, much of the historical estuarine tidal area that once existed has likely been diked and filled to accommodate the highway, other small roads, and residential and agricultural development. Remaining habitat is largely degraded and provides little cover and foraging habitat.

Figure 9-4. Lagoon at the mouth of Mussel Creek. View is looking north. A sand bar blocks exchange of salt and fresh waters during periods of low flow. The lagoon is shallow, lacks cover, and likely provides limited habitat for juvenile salmonid rearing. (9/18/2008).

Impaired Water Quality

There are no water quality data available for Mussel Creek. Temperature problems are unlikely in Mussel Creek due to the proximity to the coast, topographic shading, short transit time, and likely contributions of groundwater from hollows throughout this steep basin. Turbidity is likely high during winter due to high road density and timber harvest in the basin. Potential sources of chemical water pollutants would be use of herbicides on industrial timberlands and leakage from septic systems at the campground, resorts, or the small number of rural residences in the basin.

Barriers

There are no known structural barriers to coho salmon passage in Mussel Creek. The dry reach of lower Myrtle Creek poses a potential seasonal impediment to passage.

Altered Hydrologic Function

The complex hydrology of Mussel Creek has been severely disrupted by Highway 101, debris torrents down Myrtle Creek, and development on the floodplain. Increased peak discharge is likely in the Mussel Creek basin, due to high road densities and widespread timber harvest. These peak flows can scour eggs and flush fry, juveniles, and smolts from the river system.

Adverse Fishery- and Collection-Related Effects

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low stress to juveniles, smolts, and adults.

Adverse Hatchery-Related Effects

Hatchery-origin coho salmon may stray into Mussel Creek; however, the proportion of adults that are of hatchery origin is likely less than five percent and there are no hatcheries in the basin. Therefore, adverse hatchery-related effects pose a low risk to all life stages (Appendix B).

9.6 Threats

Table 9-3. Severity of threats affecting each life stage of coho salmon in Mussel Creek. Threat rank categories, assessment methods, and data used to assess threats are described in Appendix B.

	Threats[2]	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Threat Rank
1	Timber Harvest[1]	Very High	Very High	Very High[1]	Very High	Medium	Very High
2	Channelization/Diking[1]	High	Very High	Very High[1]	Very High	Very High	Very High
3	Roads	High	Very High	Very High	Very High	Very High	Very High
4	Urban/Residential/Industrial Dev.	High	High	High	High	High	High
5	Agricultural Practices	Medium	Medium	Medium	Medium	Medium	Medium
6	Dams/Diversion	Low	Low	Medium	Low	Low	Low
7	Climate Change	Low	Low	Low	Low	Medium	Low
8	High Severity Fire	Low	Low	Low	Low	Low	Low
9	Road-Stream Crossing Barriers	-	Low	Low	Low	Low	Low
10	Fishing and Collecting	-	-	Low	Low	Low	Low
11	Hatcheries	Low	Low	Low	Low	Low	Low

[1]Key limiting threats and limited life stage.
[2]Invasive Non Native/Alien Species and Mining/Gravel Extraction are not considered threats to this population.

Key Limiting Threats

The two key limiting threats, those which most affect recovery of the population by influencing stresses, are timber harvest and channelization/diking.

Timber Harvest

Recent private timber harvest data are not readily available. However, Mussel Creek has the highest percentage of industrial timberlands managed under the Oregon Forest Practices Act. Active timber harvest on private lands within the Mussel Creek basin is widespread and occurring rapidly with the expectation it will continue. The high harvest rates and associated roads impact multiple aspects of coho salmon habitat. Studies of adjacent southwest Oregon basins found that "downstream, cumulative impacts of human activity are pervasive in southwest Oregon, wherever logging has occurred over an extensive portion of a drainage basin or has involved operations on steep, unstable slopes. The downstream effects of channel sedimentation and aggradation can severely damage streams even where buffer zones of riparian vegetation have been retained, and such effects persist more than 20-30 years after logging activities have ceased (Frissell 1992)."

Channelization/Diking

Highway 101 caused the relocation and straightening of most of the South Fork Mussel Creek channel, which altered more than 20 percent of the high IP in the Mussel Creek basin. The highway is not likely to be relocated and is a major impediment to restoring habitat in South Fork Mussel Creek; however, there is a meadow east of the creek that could potentially provide space for creation of a more complex channel. Myrtle Creek has also been channelized through the lower reach near the campground. A parking lot for beach access was constructed by rearranging deposited materials, which created a functional dike along the eastern lagoon border and reduced the lagoon area. While the number of developed properties is low (Prehistoric Gardens and a few rural residences), they overlap with the highest IP habitat. These most important reaches of Myrtle Creek, Mussel Creek and South Fork Mussel Creek have been pushed to the sides of their floodplains, channelized and diked.

Roads

Road densities in the Mussel Creek basin are over thresholds recognized as contributing to increased fine sediment yield and elevated peak flows. Roads are expected to cause fine sediment delivery into Mussel Creek because the basin is very steep and the geology is relatively unstable. The construction of Highway 101 has resulted in the channelization and realignment of the South Fork Mussel Creek, as well as parts of the mainstem Mussel Creek and Myrtle Creek. These impacts, along with excessive sedimentation from upslope activities, have altered the hydrology of these creeks and made them less suitable for coho salmon spawning and rearing. In addition, because of the small size of the Mussel Creek basin and the significant impacts of Highway 101 to high IP habitat in the basin, the highway continues to be a major threat to coho salmon in this basin.

Urban/Residential/Industrial Development

A resort (Prehistoric Gardens), a campground, and a day use recreation area (Arizona Beach) are operated in the floodplain of Mussel Creek. Additionally, an electrical power transmission line runs north-south across the South Fork and lower mainstem Mussel Creek and parallels the riparian zone of upper Myrtle Creek (Figure 9-3). Periodically, along this corridor all vegetation is removed. Other than the power lines, the existing developments are relatively small and are not expected to expand significantly. The recent acquisition and conversion of Arizona Beach from a privately operated campground facility to a state park should improve conditions in the basin.

Agricultural Practices

Cattle grazing occurs in the lower Mussel Creek floodplain adjacent to high IP. In the rest of the basin, agriculture is not a significant activity.

Dams/Diversions

No dams are known to exist in the valley and few water diversions are presently active.

Climate Change

There is low risk of average temperature increase, or change in average precipitation, over the next 50 years (Appendix B). The risk of sea level rise is moderate (Appendix B, Thieler and Hammer-Klose 2000). Adults may be negatively impacted by climate-related ocean acidification, changes in ocean conditions, and prey availability (see Independent Science Advisory Board 2007, Feely et al. 2008, Portner and Knust 2007).

High Severity Fire

The proximity of the Mussel Creek basin to the coast is a strong moderating factor on fire risk.

Road-Stream Crossing Barriers

Road-stream crossing barriers are not a significant threat to coho salmon in Mussel Creek based on the lack of known barriers that exist in the basin. Given the amount of timber harvest that has occurred in the basin and the density of roads in the lower basin, there are likely many partial or total barriers that have yet to be identified on private land. Based on the projected population growth in this area, an increase in road-stream crossings is not likely unless significant timber harvest resumes in roadless areas.

Fishing and Collecting

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low stress to juveniles, smolts, and adults.

Hatcheries

Hatcheries pose a low threat to all life stages of coho salmon in the Mussel Creek population area. The rationale for these ratings is described under the “Adverse Hatchery-Related Effects” stress.

9.7 Recovery Strategy

Restoration efforts should be focused on lower Mussel Creek, South Fork Mussel Creek, and Myrtle Creek, which all have high IP (Figure 9-1).

The Mussel Creek population is considered dependent and therefore cannot be viable on its own; however, restoring habitat within the basin is necessary so that the basin can support all life stages of coho salmon and provide connectivity between other populations in the ESU. The recovery criterion for this population is that 80% of available IP habitat must be occupied in years following spawning of brood years with high marine survival. The most important factor limiting recovery of coho salmon in Mussel Creek is a deficiency in the amount of suitable rearing habitat for juveniles. The processes that create and maintain such habitat must be restored by increasing habitat complexity within the channel, re-establishing off-channel rearing areas, restoring riparian forests, increasing summer flow, and reducing threats to instream habitat. The effects of fishing on this population's ability to meet its viability criteria should be evaluated.

Table 9-4 on the following page lists the recovery actions for the Mussel Creek population.

Table 9-4. Recovery action implementation schedule for the Mussel Creek population. Recovery actions for monitoring and research are listed in tables at the end of Chapter 5.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-MusC.19.3.3	Timber Harvest	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve timber harvest practices	Population wide	2b
SONCC-MusC.19.3.3.2	*Determine how to revise Oregon Forest Practice Rules so that they do not limit recovery of SONCC coho salmon and make appropriate revisions*					
SONCC-MusC.19.3.3.3	*Adopt rules for fish-bearing streams sufficient to protect both water quality and fish habitat*					
SONCC-MusC.19.3.3.4	*Adopt rules to increase protection of non-fish-bearing streams that address practices that adversely impact water quality and fish habitat*					
SONCC-MusC.19.3.3.5	*Ensure management measures for landslide prone areas include protection of water quality and fisheries habitat*					
SONCC-MusC.19.3.3.6	*Until more permanent regulatory mechanisms can be put in place, immediately adopt interim rules that increase protection for salmon habitat in forested areas, including increased natural recruitment of large wood on perennial and intermittent streams likely to deliver wood downstream, increased shade on all perennials, and protective buffers on small intermittent streams.*					
SONCC-MusC.2.1.6	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	State park in lower mainstem and streams where coho salmon would benefit immediately	2b
SONCC-MusC.2.1.6.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-MusC.2.1.6.2	*Place instream structures, guided by assessment results*					
SONCC-MusC.2.1.35	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	Population wide	2c
SONCC-MusC.2.1.35.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-MusC.2.1.35.2	*Place instream structures, guided by assessment results*					
SONCC-MusC.2.2.4	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Lower mainstem and estuary, and streams where coho salmon would benefit immediately	2b
SONCC-MusC.2.2.4.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-MusC.2.2.4.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-MusC.2.2.36	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Population wide	2c
SONCC-MusC.2.2.36.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-MusC.2.2.36.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-MusC.2.2.5	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	Lower Mainstem and streams where coho salmon would benefit immediately	2b
SONCC-MusC.2.2.5.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for land owners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-MusC.2.2.5.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-MusC.2.2.5.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					
SONCC-MusC.2.2.37	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	Population wide	2c
SONCC-MusC.2.2.37.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for land owners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-MusC.2.2.37.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-MusC.2.2.37.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					
SONCC-MusC.7.1.1	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve long-range planning	Lower mainstem and estuary	2c
SONCC-MusC.7.1.1.1	*Review General Plan or County Ordinances to ensure coho salmon habitat needs are accounted for. Revise if necessary*					
SONCC-MusC.7.1.1.2	*Develop watershed-specific guidance for managing riparian vegetation. Consider larger riparian buffers in coho occupied habitat*					
SONCC-MusC.2.2.31	Floodplain and Channel Structure	No	Reconnect the channel to the floodplain	Improve regulatory mechanisms	Population wide	2c
SONCC-MusC.2.2.31.1	*Improve protective regulations for beaver and develop guidelines for relocation that are practical for restoration groups*					
SONCC-MusC.7.1.19	Riparian	No	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	Private lands and all areas where coho salmon would benefit immediately	3b
SONCC-MusC.7.1.19.1	*Assess grazing contribution to sediment delivery, pollutants, and impaired riparian conditions*					
SONCC-MusC.7.1.19.2	*If problems are identified, develop and implement grazing management strategy that decreases delivery of sediment and pollutants to streams and improves riparian condition*					
SONCC-MusC.7.1.19.3	*Monitor effectiveness of grazing management to ensure grazing does not limit recovery of SONCC coho salmon*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-MusC.7.1.40	Riparian	No	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	Population wide	3d
SONCC-MusC.7.1.40.1	*Assess grazing contribution to sediment delivery, pollutants, and impaired riparian conditions*					
SONCC-MusC.7.1.40.2	*If problems are identified, develop and implement grazing management strategy that decreases delivery of sediment and pollutants to streams and improves riparian condition*					
SONCC-MusC.7.1.40.3	*Monitor effectiveness of grazing management to ensure grazing does not limit recovery of SONCC coho salmon*					
SONCC-MusC.7.1.20	Riparian	No	Improve wood recruitment, bank stability, shading, and food subsidies	Increase regulatory oversight	All coho salmon bearing streams	3b
SONCC-MusC.7.1.20.1	*Strengthen city and county ordinances to limit development within the 100 year channel migration zone*					
SONCC-MusC.7.1.20.2	*Strengthen city and county ordinances to limit development within the 50 year flood elevation*					
SONCC-MusC.22.1.21	Urban, Residential, Industrial Development	No	Reduce pollutants	Increase regulatory oversight	Population wide	3b
SONCC-MusC.22.1.21.1	*Strengthen city and county ordinances to minimize new impervious surfaces and require treatment to current standards*					
SONCC-MusC.22.1.21.2	*Strengthen city and county ordinances to require treatment to current standards when existing impervious surfaces are expanded, reconditioned, reconstructed or replaced*					
SONCC-MusC.22.1.21.3	*Develop local regulatory mechanisms that limits development and reduces amount of total impervious area through incentives*					
SONCC-MusC.5.1.8	Passage	No	Improve access	Remove barriers	All streams where coho salmon would benefit immediately	3c
SONCC-MusC.5.1.8.1	*Use ODFW and SCWC fish passage barrier database to remove barriers based on known coho use or data identifying suitable habitat conditions above barriers*					
SONCC-MusC.5.1.39	Passage	No	Improve access	Remove barriers	Population wide	3d
SONCC-MusC.5.1.39.1	*Use ODFW and SCWC fish passage barrier database to remove barriers based on known coho use or data identifying suitable habitat conditions above barriers*					
SONCC-MusC.3.1.18	Hydrology	No	Improve flow timing or volume	Increase instream flows	All streams with ODFW water rights for fish, and all streams where coho salmon would benefit immediately	3c
SONCC-MusC.3.1.18.1	*Secure adequate instream flows to fulfill ODFW water rights for fish*					
SONCC-MusC.3.1.38	Hydrology	No	Improve flow timing or volume	Increase instream flows	Population wide	3d
SONCC-MusC.3.1.38.1	*Secure adequate instream flows to fulfill ODFW water rights for fish*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-MusC.8.1.11	Sediment	No	Reduce delivery of sediment to streams	Reduce road-stream hydrologic connection	All areas where coho salmon would benefit immediately	3c
SONCC-MusC.8.1.11.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-MusC.8.1.11.2	*Decommission roads, guided by assessment*					
SONCC-MusC.8.1.11.3	*Upgrade roads, guided by assessment*					
SONCC-MusC.8.1.11.4	*Maintain roads, guided by assessment*					
SONCC-MusC.8.1.41	Sediment	No	Reduce delivery of sediment to streams	Reduce road-stream hydrologic connection	Population wide	3d
SONCC-MusC.8.1.41.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-MusC.8.1.41.2	*Decommission roads, guided by assessment*					
SONCC-MusC.8.1.41.3	*Upgrade roads, guided by assessment*					
SONCC-MusC.8.1.41.4	*Maintain roads, guided by assessment*					
SONCC-MusC.10.7.33	Water Quality	No	Restore nutrients	Add marine-derived nutrients to streams	All streams where coho salmon would benefit immediately	3c
SONCC-MusC.10.7.33.1	*Develop a plan to supply appropriate amounts of marine-derived nutrients to streams (e.g. carcass placement, pellet dispersal)*					
SONCC-MusC.10.7.33.2	*Supply marine-derived nutrients to streams guided by the plan*					
SONCC-MusC.10.7.34	Water Quality	No	Restore nutrients	Add marine-derived nutrients to streams	Population wide	3d
SONCC-MusC.10.7.34.1	*Develop a plan to supply appropriate amounts of marine-derived nutrients to streams (e.g. carcass placement, pellet dispersal)*					
SONCC-MusC.10.7.34.2	*Supply marine-derived nutrients to streams guided by the plan*					
SONCC-MusC.22.1.7	Urban, Residential, Industrial Development	No	Reduce pollutants	Educate stakeholders	Population wide	3d
SONCC-MusC.22.1.7.1	*Develop an educational program that teaches landowners about avoiding pollution from septic systems, backyard pesticides, fuels, and nutrients*					
SONCC-MusC.22.1.17	Urban, Residential, Industrial Development	No	Reduce pollutants	Increase regulatory oversight	Population wide	3d
SONCC-MusC.22.1.17.1	*Increase application of Low Impact Development (LID) techniques through education and incentives*					
SONCC-MusC.22.1.17.2	*Incorporate LID in Clean Water Act permits for projects that result in stormwater discharge*

10. Lower Rogue River Population

Northern Coastal Stratum

Non-Core 1, Potentially Independent Population

High Extinction Risk

Population likely below depensation threshold

320 Spawners Required for ESU Viability

198 mi^2 watershed (58% Federal ownership)

81 IP-km (50 IP-mi) (24% High)

Dominant Land Uses are Timber Harvest and Agriculture

Key Limiting Stresses are ‘Lack of Floodplain and Channel Structure’ and ‘Impaired Water Quality’

Key Limiting Threats are ‘Roads’ and ‘Urban/Residential/Industrial Development’

Highest Priority Recovery Actions

• Improve timber harvest practices by revising Oregon Forest Practices Act	• Increase large woody debris (LWD), boulders, or other instream structure
• Reduce road-stream hydrologic connection	• Increase instream flows
• Re-connect and restore estuarine habitat	• Reduce impacts of mining

10.1 History of Habitat and Land Use

Historically, beaver ponds created ideal habitat for coho salmon and likely existed in side channels of the valley floor and in the lowlands of tributaries all the way to the estuary [Oregon Department of Fish and Wildlife (ODFW) 2005b]. Timber near the coast was in stands separated by large meadows, which were regularly burned by Native Americans (Hicks 2005). Anglo-American settlement began with the gold rush in 1853. Canneries were established as early as 1861 (Hicks 2005) on the shores of the estuary and thrived until salmon stocks were depleted around 1930. Around the same time, larger wood jams which interfered with net fishing or shipping were removed (Hicks 2005). Grazing was once widespread in the Lower Rogue River watershed (Hicks 2005), with tens of thousands of sheep and cattle feeding in upland prairies. In the early to mid-1900s, agricultural use shifted to development of dairies, which led to the clearing of riparian vegetation from river terraces for conversion to pasture (Hicks 2005). Streams with mild gradient and broad valleys (ideal coho salmon habitat) were ideal pasture land, so forests were cleared to accommodate grazing which led to simplified channels.

The most profound change to the Lower Rogue River resulted from timber harvest after World War II (U.S. Forest Service (USFS) 2000a). Most old growth timber in the Lower Rogue River sub-basin has been logged (USFS 1996b,USFS 1996a and 2000a; Hicks 2005), with remnant patches scattered on federal lands in basins like Quosatana, Silver, and Lobster creeks as well as in inner gorge tributaries of the mainstem Rogue River below Agness. The flood of 1964 devastated Lower Rogue River tributary channels and a wave of sediment swept through the lower mainstem (USFS 2000a). Low gradient streams (formerly the best sites for coho salmon spawning and rearing) were the most impacted by sediment depositions. Timber harvest on public lands resumed after 1970 and another wave of sediment was unleashed (USFS 1996b). The Lower Rogue continues to be impacted by the timber harvest that occurred on National Forest land during the 1970s and 1980s. During this period, harvests and expanding road networks were increasingly located on steep ground, and subsequent landslides during storm events contributed massive inputs of fine sediments into streams (USFS 2000a). Aquatic habitat remains compromised by elevated water temperatures and sediment levels decades after the initial impacts.

Mainstem Rogue River flow was diminished due to construction of Lost Creek Dam in the Upper Rogue in the 1970s (Figure 10-1), but flows from the dam were later increased to prevent the loss of spring-run Chinook salmon and are now thought to be adequate for mainstem ecosystem function of the Lower Rogue (Hicks 2005). Before disturbance, the estuary occasionally barred up and formed a lagoon (Hicks 2005). The Rogue River mouth now remains open due to the construction of jetties in 1960 to maintain navigability, which changed the estuary circulation and accelerated currents (Hicks 2005). Marina development eliminated the largest track of saltwater wetlands, and levees further upstream cut off access to tributaries and sloughs. The human population of Gold Beach is modest (1,847) and not believed to be increasing. Effects of urbanization and residential development in the Lower Rogue River sub-basin are moderate (Hicks 2005), but domestic water use and wastewater treatment related to rural development are regional concerns (Southwest Oregon Resource Conservation and Development Council (SO RC&D) 2003).

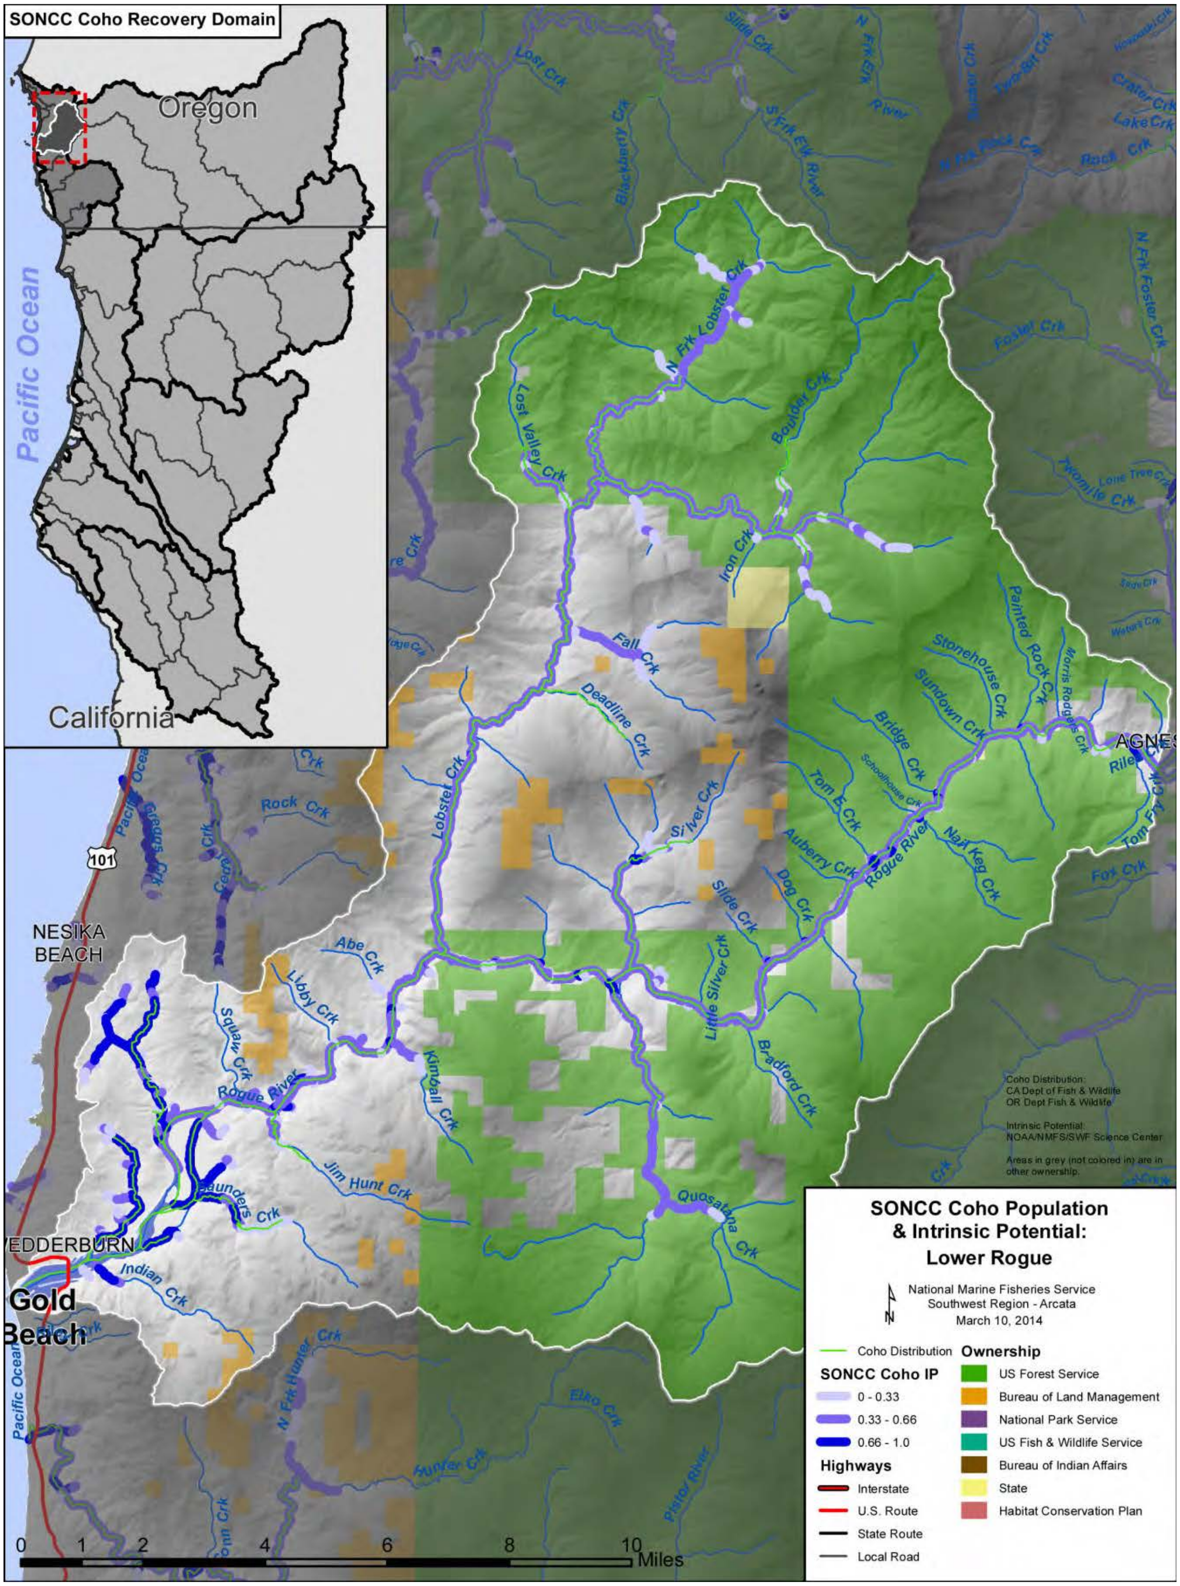

Figure 10-1. The boundaries of the Lower Rogue River coho salmon population. Figure shows modeled Intrinsic Potential of habitat (Williams et al. 2006), land ownership, coho salmon distribution (ODFW 2013a), and location within the Southern-Oregon/Northern California Coast Coho Salmon ESU and the Northern Coastal diversity stratum (Williams et al. 2006). Grey areas indicate private ownership.

10.2 Historic Fish Distribution and Abundance

While the Rogue River basin still produces many coho salmon, the indigenous stock adapted to the Lower Rogue River sub-basin is diminished in range and abundance (USFS 2000a). Meengs and Lackey (2005) used the cannery data from near the mouth of the Rogue River in the late 1880s to estimate annual catches of 114,000 adult coho salmon; however, there is no way to know how many of these fish were returning specifically to the lower Rogue River area. Because this sub-basin constitutes about 6 percent of the entire Rogue watershed area, approximately 7,000 coho salmon could have spawned in the Lower Rogue River. Williams et al. (2006) used models to estimate that the Lower Rogue had 80.9 intrinsic-potential kilometers (IP-km) of coho salmon habitat, with the highest IP habitats concentrated mostly in tributaries near the estuary (Figure 10-1). An estimated 37 coho salmon spawners would be needed to fully utilize each IP-km, and would have produced an annual coho salmon population of 3,000 adults (Williams et al. 2008).

The highest IP (IP >0.66) habitat for coho salmon in the Lower Rogue River is in Indian, Saunders, God Wants You, Jerrys Draw, Ranch and Edson creeks (Figure 10-1). Jim Hunt Creek has a small patch of high IP at its confluence with the mainstem Rogue River. Steep tributaries upstream of Lobster Creek, such as Silver, Quosatana and Tom Fry creeks also have high IP reaches just above their confluence with the mainstem Rogue River. Table 10-1 lists all tributaries with the highest IP coho salmon habitat. Alluvial flats of the Lower Rogue mainstem also have segments of high IP habitat all the way up to Agnes, especially downstream of tributaries that add coarse sediment for spawning and flatten stream gradient locally.

Table 10-1. Tributaries with high IP reaches (IP > 0.66) Williams et al. (2006).

Stream Name	Stream Name	Stream Name
Edson Creek	Kimball	Rogue River- Lower Mainstem
God Wants You Creek	Ranch Creek	Saunders Creek
Indian Creek	Quosatana Creek	Silver Creek
Jerrys Draw	Rogue River- Estuary	Tom Fry Creek
Jim Hunt		

10.3 Status of Lower Rogue River Coho Salmon

Spatial Structure and Diversity

Although they contain high IP (>0.66) habitat, Jim Hunt Creek, Kimball Creek, Ranch Creek and Indian Creek are not known to currently support coho salmon. Monitoring reports for the years 1998 through 2004 indicated that coho salmon are well distributed but at low levels in Lobster Creek, Quosatana Creek, Silver Creek, and Tom Fry Creek (ODFW 2005a). The Lower Rogue Watershed Council (2010) also found coho salmon in Edson Creek, Ranch Creek, and Saunders Creek. However, coho salmon spawners have not been seen in Ranch Creek since 2002, which indicates the potential presence of a new barrier (Lower Rogue Watershed Council 2010). Many reaches in these streams are not prime coho salmon habitat due to the steep gradient (USFS

2000a). Genetic diversity has likely diminished as coho salmon have disappeared from productive tributaries and the population has declined.

Population Size and Productivity

In 2001, there were an estimated 32,962 adult coho salmon in the Rogue Basin (Oregon State University [OSU] 2009, ODFW 2009b). Using a different methodology, ODFW (2013b) estimated a maximum of 235 spawners in the Lower Rogue River during the period 2000 to 2008 (Table 10-2). These escapement estimates suggest one year class may be weaker than the others – that observed in 2000, 2003, and 2006. The highest three year running average in the period 2000-2008 was 172 (from 2001 to 2003).

Table 10-2. Estimates of coho salmon escapement for the Lower Rogue River (ODFW 2013b)

. Year	Population Estimate	Year	Population Estimate	Year	Population Estimate
1998	0	2003	75	2008	184
1999	0	2004	127	2009	193
2000	59	2005	127	2010	0
2001	235	2006	35	2011	44
2002	205	2007	193	2012	0

Surveys completed from 1998 to 2003 (Hicks 2005) in the Lower Rogue River sub-basin found coho salmon spawners in lower Lobster Creek (19 individuals), South Fork Lobster Creek (46 individuals), Silver Creek (18 individuals), and Quosatana Creek (5 individuals). During juvenile coho salmon surveys (ODFW 2005a) in the Lobster Creek watershed from 1998 to 2004, fish were present in zero of four years in Boulder Creek, one of two years in Deadline Creek, one of seven years in North Fork Lobster Creek, and four of six years in lower Lobster Creek. South Fork Lobster Creek, on National Forest land, is the only site with observed annual juvenile coho salmon presence, but juvenile density there is very low (0.000 to 0.110 coho salmon per m^2) (ODFW 2005a). The growth rate of the Lower Rogue River coho salmon population is unknown but likely negative, given that successful recruitment is consistent only in the South Fork Lobster Creek.

The number of adult coho salmon is estimated using a seine-recapture method at Huntley Park in the Lower Rogue River (river mile 8). These data provide the most robust and precise estimates of adult coho salmon abundance in the Rogue River (ODFW 2013b). It is impossible to determine, with existing information, how many of the estimated coho salmon at Huntley Park are returning to the Lower Rogue River as opposed to other sub-basins in the Rogue River basin. However, the trend in abundance at Huntley Park can inform whether the population is at high risk of extinction according to the population decline criterion (Williams et al. 2008). The number of adults estimated at Huntley Park has declined at an annual rate of 11% over the last 12 years (Figure 10-2), greater than the 10% decline associated with a high risk of extinction (Williams et al. 2008). Therefore, the population is at high risk of extinction due to its sharply declining productivity.

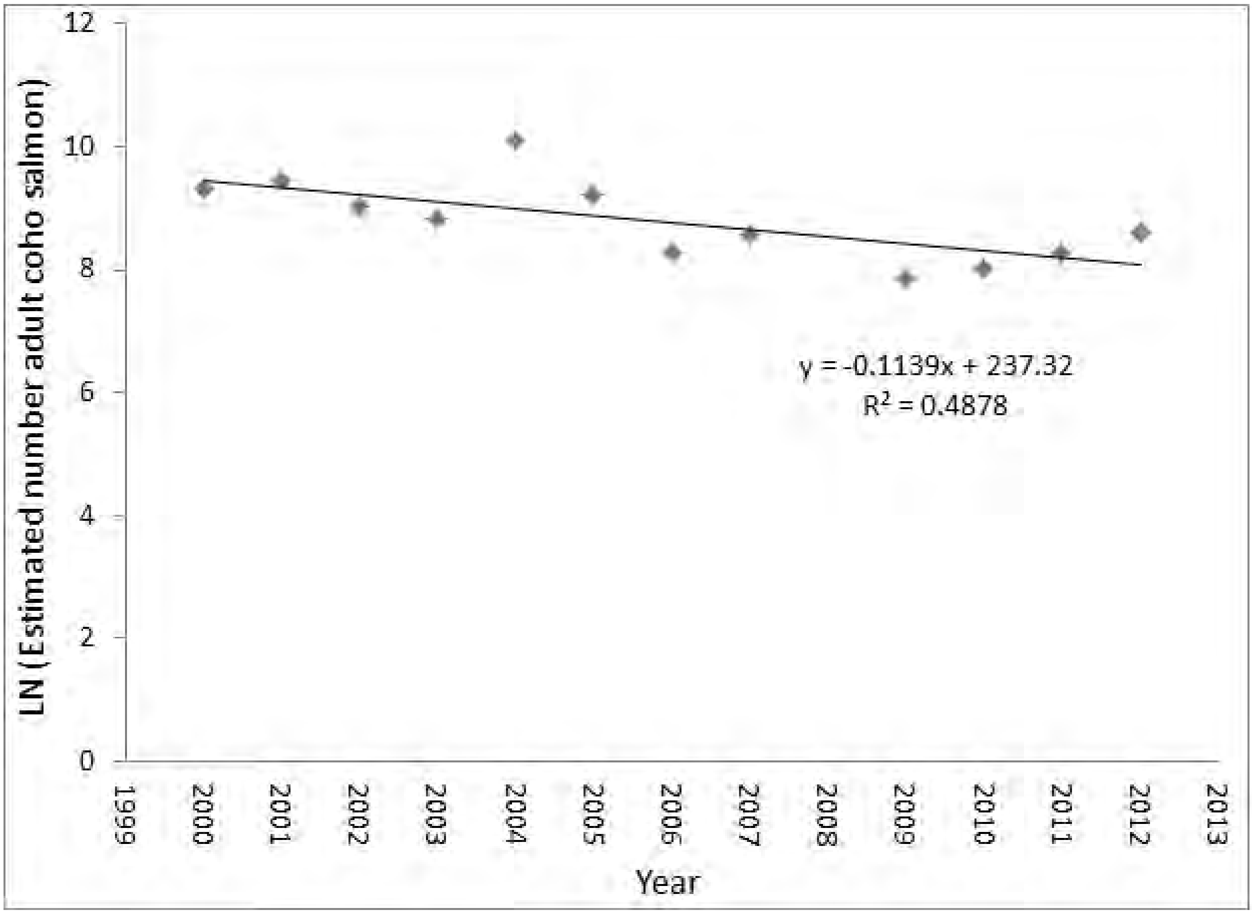

Figure 10-2. Rate of decline of estimated population abundance at Huntley Park. Data source: ODFW 2013b.

Extinction Risk

The Lower Rogue River population is at high risk of extinction because the ratio of the three consecutive years of lowest abundance within the last twelve years to the amount of IP-km in a watershed is less than one, the criterion described by Williams et al. (2008). NMFS' determination of population extinction risk is based on the viability criteria provided by Williams et al. 2008 (Table 3, pg. 17). These viability criteria reflect population size and rate of decline. As Williams et al. (2008) provided no viability criteria for assessing moderate and high risk based on spatial structure and diversity, spatial structure and diversity were not considered in NMFS' determination of population extinction risk.

Role in SONCC Coho Salmon ESU Viability

The Lower Rogue River population is a non-core, Potentially Independent population within the Northern Coastal diversity stratum; historically having had a high likelihood of persisting in isolation over 100-year time scales, but strongly influenced by immigration from other populations such that they did not exhibit independent dynamics (Williams et al. 2006). The Lower Rogue River population is strongly influenced by upstream populations in the Rogue River basin, as well as coastal populations such as the Chetco River. Adult strays from these populations spawn and interact with coho salmon in the Lower Rogue River. To contribute to stratum and ESU viability, the Lower Rogue River non-core population needs to have at least 320 spawners. Sufficient spawner densities are needed to maintain connectivity and diversity within the stratum and continue to represent critical components of the evolutionary legacy of the ESU. Furthermore, the Lower Rogue River population will contribute toward stratum and ESU viability by providing rearing, migratory, and refugia habitat to other nearby populations.

10.4 Plans and Assessments

State of Oregon

Expert Panel on Limiting Factors for Oregon's SONCC coho salmon populations

ODFW (2008b) convened a panel of fisheries and watershed scientists as an initial step in their development of a recovery plan for Oregon's SONCC coho salmon populations. Deliberations of the expert panel provided ODFW with initial, strategic guidance on limiting factors and threats to recovery. Based on the input of panel members, concerns for the Lower Rogue River are as follows:

> Key concerns for the Lower Rogue River were primarily loss of over-winter tributary habitat for juveniles, especially in the lowlands which are naturally very limited in this system and have been impacted by past and current forestry practices and rural residential development. Another key concern is limited habitat complexity for pre-smolts due to a loss of large wood transport into the freshwater portions of the estuary. Secondary concerns were related to high water temperatures in tributaries for summer parr (excluding the mainstem, where rearing is not expected) due to land management and reduced estuarine habitat for pre-smolts and smolts due to past and current forestry practices and rural residential development.

Rogue River TMDL

The Rogue River TMDL (Oregon Department of Environmental Quality 2008) includes an extensive treatise on the water quality impairment of the Upper Rogue River and its tributaries and describes mechanisms that drive pollution of different types, including bacteria, temperature, sedimentation, pH, and dissolved oxygen.

Lobster Creek TMDL and Water Quality Management Plan

The Lobster Creek TMDL and Water Quality Management Plan (ODEQ 2002b) were developed to abate temperature problems in this major Lower Rogue River tributary. A shade model was used in the TMDL process to gauge needs for recovery of riparian zones. ODEQ (2002b) also acknowledged that sediment contributions play a role in channel changes and increased water temperature.

Cumulative Effects of Southwest Oregon Coastal Land Use on Salmon Habitat

OSU Oak Creek Labs conducted a study funded by ODFW and the Oregon Department of Forestry (ODF) to determine relationships between forest harvest and Pacific salmon productivity (Frissell 1992). The study evaluated watersheds along the Oregon coast extending from the Sixes River to the California-Oregon border from 1986 to 1992. The principal findings were as follows: (1) Compared to streams draining mature old growth forests, streams in heavily logged basins had one third less pool area, supported a reduced diversity of Pacific salmon species, and were more likely to have actively eroding banks; (2) Channel instability in heavily logged basins coincided with high failure rates for in-stream structures; (3) Erosion rates have increased basin wide, contributing to chronic habitat damage in downstream alluvial valleys leading to depression or elimination of mainstem spawning populations of Pacific salmon; and (4) With timber harvest rotations of 30 to 50 years, large portions of drainage basins are deforested and made vulnerable to increased erosion before aquatic habitat and fish populations have recovered from the previous episode of disturbance.

Southwest Oregon Salmon Restoration Initiative

The Southwest Oregon Salmon Restoration Initiative provides the framework for coho salmon recovery in southwest Oregon (Prevost et al. 1997) and helped foster formation of watershed councils. This document was prepared as part of a Memorandum of Understanding between ODFW and the National Marine Fisheries Service (NMFS). Many of the recommended restoration measures have been carried out, but others are pending. Prevost et al. (1997) also identified ‘core areas’ for coho salmon recovery that overlap with areas of high coho salmon density and habitat quality. Streams with this designation include the upper South Fork of Lobster Creek, Quosatana Creek, and Silver Creek.

Oregon Plan for Salmon and Watersheds
http://www.oregon.gov/OPSW/about_us.shtml

The state of Oregon developed a conservation and recovery strategy for coho salmon in the SONCC and Oregon Coast ESUs (State of Oregon 1997). The Oregon Plan for coho salmon is comprehensive and includes voluntary actions for all of the threats currently facing coho salmon in these ESUs and involves all relevant state agencies. Reforms to fishery harvest and hatchery programs were implemented by ODFW in the late 1990s. Many habitat restoration projects have occurred across the landscape in headwater habitat, lowlands, and the estuary. The action plans, implementation, and annual reports can be found at the web site.

Lower Rogue Watershed Council

Lower Rogue Watershed Assessment

This extensive assessment on the Lower Rogue River sub-basin (Hicks 2005) includes historical accounts, descriptions of land use and aquatic habitat, and a wealth of information on factors that might limit coho salmon and restoration opportunities.

10.5 Stresses

Table 10-3. Severity of stresses affecting each life stage of coho salmon in the Lower Rogue River. Stress rank categories, assessment methods, and data used to assess stresses are described in Appendix B.

	Stresses	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Stress Rank
1	Lack of Floodplain and Channel Structure[1]	Medium	Very High	Very High[1]	Very High	High	Very High
2	Impaired Water Quality[1]	Medium	Very High	Very High[1]	Very High	Medium	Very High
3	Impaired Estuary/Mainstem Function	-	High	High[1]	Very High	High	Very High
4	Altered Sediment Supply	High	High	High	High	High	Very High
5	Degraded Riparian Forest Conditions	-	High	High	High	Medium	High
6	Adverse Hatchery-Related Effects	Medium	Medium	Medium	Medium	Medium	Medium
7	Altered Hydrologic Function	Medium	Medium	Medium	Low	Low	Medium
8	Increased Disease/Predation/Competition	Low	Low	Low	Low	Low	Low
9	Barriers	Low	Medium	Medium	Medium	Medium	Medium
10	Adverse Fishery- and Collection-Related Effects	-	-	Low	Low	Medium	Low

[1]Key limiting stresses and limited life stage.

Key Limiting Stresses, Life Stages, and Habitat

The primary stresses to SONCC coho salmon in the Lower Rogue River are the lack of floodplain and channel structure, degraded water quality resulting from high water temperature, and impaired estuarine function. Juveniles are the most limited life stage, due to insufficient summer and winter rearing habitat. Recovery is extremely unlikely without additional summer and winter rearing habitat. Overall, these findings are consistent with those of the Oregon Expert Panel (ODFW 2008b), but the expert panel considered water temperature to be only a secondary, not primary, concern. The highest historic IP coho salmon habitat is in the western part of the watershed (Williams et al. 2008), where the land is privately owned and land management is likely to be more intensive. The greatest effects of this management are the loss of rearing habitat when wetlands were filled, and degradation of the remaining habitat by high water temperatures resulting from the lack of mature trees in the riparian zone and the reduction of the amount of water in the river by diversions.

Lack of Floodplain and Channel Structure

The floodplain and channel structure of the Lower Rogue River is highly impaired and constitutes a major limiting stress for coho salmon. Edson Creek has been channelized in many reaches and lacks large wood and pool-riffle structure necessary to support juvenile coho salmon.

Libby Creek is one of the most altered Lower Rogue River tributaries due to the dam constructed above its confluence with the Lower Rogue River to create a recreational fishing pond. Channel structure and transport capacity has been completely disrupted in lower Jim Hunt Creek and Kimball Creek.

ODFW habitat surveys show poor pool frequency for the upper South Fork Lobster Creek (<10 percent) and fair (10 to 20 percent) conditions in the upper-most reach of the North Fork and one of its tributaries. Pool frequencies increase to good (20 to 35 percent) in the lower reaches of the North Fork (NF) and South Fork (SF) Lobster Creek. The average maximum pool depths ranged from less than 2 feet deep to 3.3 feet deep, with the deepest pools located in lower Lobster and Quosatana creeks. Quosatana Creek has re-developed pool depths of up to 10 feet (USFS 1996a).

Impaired Water Quality

Water quality in the Lower Rogue River is very poor and constitutes a major limiting stress for coho salmon (USFS 1996b, 2000a; ODEQ 2002b, 2008; Hicks 2005). Coho salmon have a low tolerance for elevated water temperatures (McCullough 1999) and this factor consequently poses a very high level of stress for Lower Rogue coho salmon fry, juveniles and smolts. The ODEQ (2002b, 2008) limit for maximum weekly maximum water temperature (MWMT) is 64° Fahrenheit, which is compatible with coho salmon recovery. Only 36 percent of Lower Rogue locations surveyed met this standard (SO RC&D 2003), and cooler locations were in headwater areas that are too steep for coho salmon to access (USFS 2000a). Inner gorge tributaries of the mainstem Rogue River below Agness have recovered to optimal salmonid rearing temperatures (e.g., Bradford Creek at 59.5 to 61.7° F), providing critical summer refugia. Tom Fry Creek also has a half-mile reach above the mouth that is suitable for coho salmon rearing (USFS 2000a). The Quosatana Creek MWMT from 1991 to 1999 ranged from a low of 66.4° F to a high of 70.9° F (USFS 2000a). Recovery of pool depth in Quosatana Creek (USFS 1996a) may help re-establish cool water temperatures, due to seepage of groundwater from adjacent alluvial deposits, which have been shown to create a deep layer of cold water in healthy streams (U.S. Environmental Protection Agency (USEPA) 2003a, ODEQ 2008).

The Lower Rogue River is recognized as having elevated nutrient levels (i.e., phosphorous; ODEQ 2010), but because the source of these nutrients is upstream, solutions to the problem are described in other Rogue River basin profiles. Libby Pond in the Lower Rogue sub-basin appears highly enriched with nutrients and has substantial algae blooms. Conditions are conducive to the proliferation of toxic algae, a recognized problem in other Oregon lakes (Jones et al. 2008).

The Oregon Department of Agriculture (Riley, S., pers. comm. 2009) currently has no pesticide data for the south coast Oregon, yet this may be a significant but little recognized region-wide problem for salmonids (Ewing 1999, Laetz et al. 2009).

Impaired Estuary/Mainstem Function

The Rogue River estuary is highly altered and retains little of its historic function downstream of Highway 101 (Figure 10-3; Hicks et al. 2008). Studies elsewhere in Oregon show estuarine tributaries and sloughs can be some of the most important habitat types for rearing coho salmon juveniles (Koehler and Miller 2003, Miller and Sadro 2003, Koski 2009). The lack of habitat in the Rogue River estuary that can be used for refugia likely results in high rates of predation from birds, fish, and pinnipeds. Numerous barriers in tributaries flowing into the estuary prevent use of these important rearing habitats and inhibit proper tidal exchange and greatly diminish opportunities for non-natal rearing in cooler coastal climates. The tributary on the north side of the estuary has been completely channelized and all of the wetlands near its mouth have been filled. Fine sediment from Saunders Creek has also partially filled Snag Patch Slough at its mouth (Hicks 2005).

Figure 10-3. Aerial photo of the Rogue River estuary. Photo shows the boat basin (right), jetties, levees and shoreline development. Photo from Hicks (2005).

Altered Sediment Supply

Altered sediment supply poses an overall high stress to coho salmon in the Lower Rogue River. Sediment contribution from landslides and erosion occurs naturally in the Lower Rogue River basin; however, roads, timber harvest, and bank erosion following removal of riparian vegetation have elevated fine sediment input. Excess fine sediment reduces coho salmon egg viability and may reduce food for fry, juveniles and smolts. Accumulation of excess fine sediment has caused several creeks in the Lower Rogue River sub-basin (Quosatana Creek, Jim Hunt Creek, and Kimball Creek) to flow subsurface. Low pool frequency and depth throughout the Lower Rogue River basin are likely due to elevated levels of fine sediment partially filling pools, a lack of scour-forcing obstructions such as large wood, and in some reaches diminished scour due to channel widening. The USFS (1996b, 2000a) and Hicks (2005) recognize elevated fine sediment transport as a major Lower Rogue River limiting stress for salmonids.

Degraded Riparian Forest Conditions

Degraded riparian forest conditions are recognized as the major driving force of water temperature problems in the Rogue River basin (ODEQ 2002b, 2008). These conditions also contribute to the lack of large wood in stream channels in the Lower Rogue (USFS 1996a, 2000a; Hicks 2005). The lack of large woody debris and high water temperatures contribute to the limiting stresses for this population – lack of floodplain and channel structure and impaired water quality. Past land use has led to replacement of riparian conifers with hardwoods on both public and private forest lands in the Lower Rogue River sub-basin (USFS 1996a, 2000a; Hicks 2005). Additionally, one of the more important riparian species (Port Orford Cedar) is experiencing a disease epidemic causing loss of this important riparian species in Quosatana Creek (USFS 1996a), and Frissell (1992) recognized the loss of this species as regionally significant.

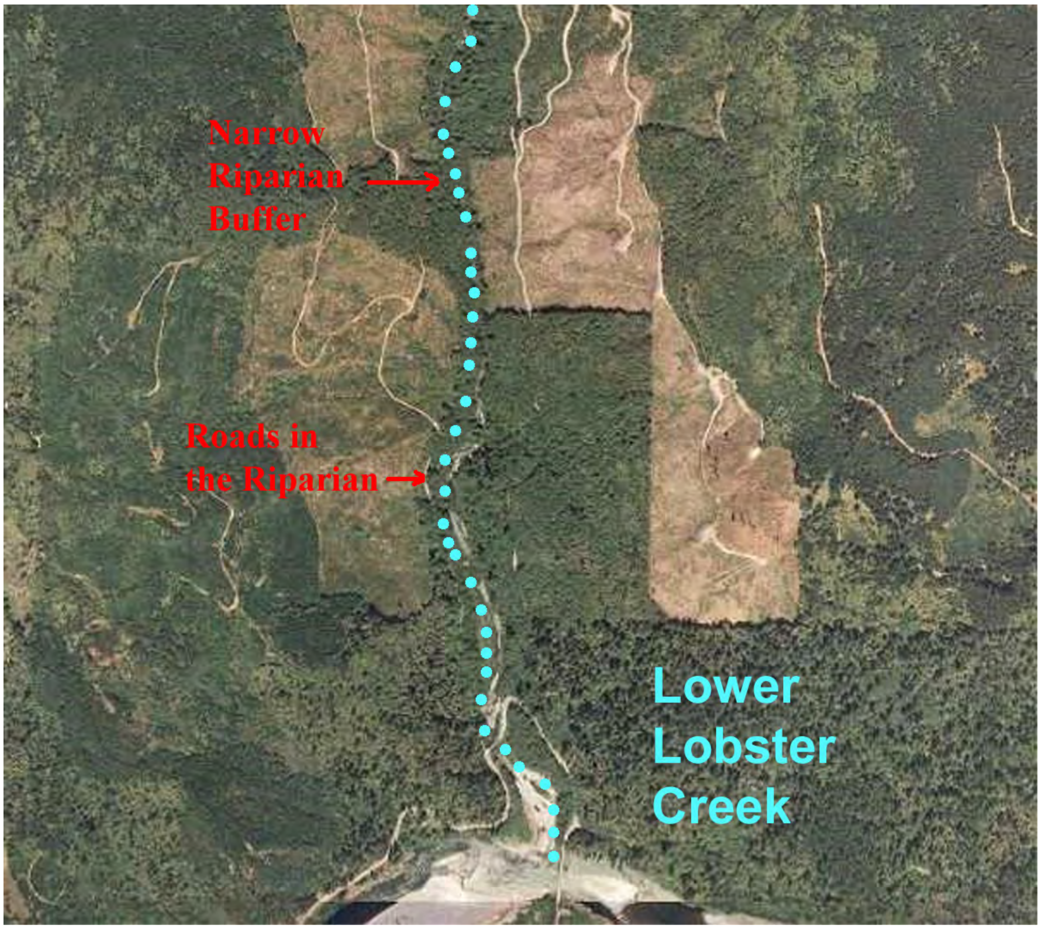

Figure 10-4. Aerial photo of Lower Lobster Creek at its convergence with the mainstem Rogue River. Convergence is at bottom of photo, which shows clear cuts, insufficient buffer widths, high road density and near stream roads. The stream course is shown in blue dots. (Terra Server, www.terraserver.com).

Adverse Hatchery-Related Effects

No hatcheries or artificial propagation occur in the Lower Rogue population area, but there is an active hatchery in the Rogue River basin. Cole Rivers Hatchery is downstream of William L. Jess Dam (RM 157) in the Upper Rogue River sub-basin. Genetic stress due to introduction of out-of-basin genetic material is not a current concern, because broodstock are currently selected from those fish which return to the hatchery (ODFW 2008d). Hatchery fish are stocked under conditions designed to make them leave the system quickly (ODFW 2008d), but are nonetheless expected to influence wild smolts to some degree. Eighty-two percent of coho spawners observed in Lower Rogue River tributaries in 2001 were of hatchery origin (Jacobs et al. 2002).

Adverse hatchery-related effects pose a medium risk to all life stages, due to the presence of Cole Rivers Hatchery in the Rogue River basin (Appendix B).

Altered Hydrologic Function

Water used for agriculture and residential developments in the Lower Rogue River sub-basin is modest relative to mainstem flows. The USFS (2000a) rated hydrologic risk as moderate due to timber harvest and road construction, particularly in the transient snow zone. Extensive timber harvest and road building have been hypothesized to diminish summer base flows (Montgomery and Buffington 1993) and likely contributed to increased peak flows. The loss of surface flow in creeks like Jim Hall and Kimball creeks may be due to aggradation, changes in net water yield, or a combination of the two. There is a side channel in the main river at the confluence with Edson Creek, which is the upper extent of the estuary, and cool flows from the tributary may create important refugia that could be diminishing with increasing residential water use.

Increased Disease/Predation/Competition

Although above-optimal water temperatures can elevate disease risk for coho salmon (McCullough 1999), there are currently no documented problems in the Lower Rogue River. Hicks (2005) raised questions about predation in the simplified estuary, because the lack of cover reduces their ability to avoid predators. Port Orford Cedar root-rot is a disease which is negatively impacting this important riparian species region-wide (Frissell 1992).

Barriers

High road densities on private lands in the Lower Rogue River sub-basin result in a high number of road-stream crossings that are potential juvenile and adult migration barriers. However, surveys have already identified most of the problems in potential coho salmon streams and many of these passage issues have been addressed or have plans in place to be addressed in the near future (Prevost et al. 1997, Hicks 2005). The USFS (2000a) addressed all fish passage problems related to culverts in the NF and SF Lobster Creek and will continue to improve fish passage at road-stream crossings as funds become available. Myers (2001) reported successful fish passage projects on private land in Lobster and Silver creeks. There is likely a barrier issue on Ranch Creek, which contains a substantial amount of high IP coho salmon habitat in a strategic location low in the basin. After implementing passage projects in upper Ranch Creek, the Lower Rogue Watershed Council found coho salmon spawning in 2001 and 2002 (Lower Rogue Watershed Council 2010). But the council did not find spawners from 2003 through 2012 and attribute it likely to presence of a barrier downstream (Lower Rogue Watershed Council 2010).

Adverse Fishery- and Collection-Related Effects

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a medium stress to adults and a low stress to juveniles and smolts.

10.6 Threats

Table 10-4. Severity of threats affecting each life stage of coho salmon in the Lower Rogue River. Threat rank categories, assessment methods, and data used to assess threats are described in Appendix B.

Threats		Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Threat Rank
1	Roads[1]	Medium	Very High	Very High[1]	Very High	Medium	Very High
2	Timber Harvest	High	High	High	High	Medium	High
3	Urban/Residential/Industrial Dev.[1]	Medium	High	High[1]	High	Medium	High
4	Channelization/Diking	Low	High	High	High	Low	High
5	Mining/Gravel Extraction	Low	Low	Medium	Medium	Medium	Medium
6	Hatcheries	Medium	Medium	Medium	Medium	Medium	Medium
7	Agricultural Practices	Low	Medium	Medium	Medium	Low	Medium
8	Dams/Diversion	Low	Medium	Medium	Medium	Low	Medium
9	Climate Change	Low	Low	Medium	Medium	Medium	Medium
10	High Severity Fire	Low	Low	Low	Low	Low	Low
11	Road-Stream Crossing Barriers	-	Low	Low	Low	Low	Low
12	Invasive Non-Native/Alien Species	-	Low	Medium	Medium	-	Medium
13	Fishing and Collecting	-	-	Low	Low	Medium	Low

[1]Key limiting threats

Key Limiting Threats

The two key limiting threats, those which most affect recovery of the population by influencing stresses, are roads and urban/residential/industrial development.

Roads

High road densities, numerous road-stream crossings, and roads on steep slopes combine to pose a critical threat to most coho salmon life history phases in the Lower Rogue River sub-basin. The road density in the Lower Rogue River exceeds 2.5 miles of road per square mile (mi/mi^2) of watershed. NMFS (1995) set a limit for road density of 2 mi/mi^2 to protect anadromous salmonids in the interior Columbia River basin to limit sources of fine sediment mobilization. Roads have contributed substantially to increased landsliding and fine sediment yield, including failures at stream crossings (USFS 1996a, 2000a). The most severe erosion potential is when multiple road-stream crossings fail in a single tributary. This occurs when a crossing washes out and creates a slug of debris and fine sediments that wash out crossings further downstream. Miles of Lower Rogue channels have been scoured by these debris torrents, resulting in flattened stream profiles that may require decades to recover. The loss of riparian conifers will require even more time to replace. Private lands feature large numbers of near-stream roads and roads on slopes of greater than 50 percent (Hicks 2005). Most timber haul roads are not surfaced, and chronically contribute fine sediment to streams, although measures are being taken to remedy the problem in Lobster Creek (ODEQ 2002b).

Timber Harvest

Sixty percent of the Lower Rogue River watershed is in federal ownership, and this land currently has low levels of timber harvest. Reeves et al. (1993) found that the rate of timber harvest in Oregon coastal watersheds should not exceed 25 percent of a watershed to minimize risks and disturbances to aquatic resources. The study covered a period of 30 years (Reeves, G., pers. comm. 2003) and watersheds exceeding that level of harvest did not maintain channel integrity or Pacific salmon species diversity. Timber harvest on public land is now largely restricted to selective harvests in previously logged areas in order to improve forest health. The greatest risk from timber harvest is on private industrial timberlands that are managed under the Oregon Forest Practices Act. Intense harvest rates on private lands in Lobster Creek (see Figure 10-4) and Silver Creek are double or triple the rates recommended by Reeves et al. (1993). It is likely the effects from these harvest practices are why juveniles were not present in Lobster Creek 4 of 6 years in the ODFW juvenile sampling (ODFW 2005a).

Urban/Residential/Industrial Development

The city of Gold Beach encroaches on the estuary of the Rogue River. Impervious surfaces related to development contribute stormwater runoff and non-point source pollution, as observed elsewhere in the Rogue River basin (ODEQ 2008). Commercial development along the north bank confines the lower estuary. Residential development also occurs in the Lower Rogue River riparian zone upstream to Lobster Creek and likely contributes pollutants from leaking septic systems. The high severity of this threat is due to concentrated impacts in areas of the highest IP coho salmon habitat, specifically in Edson Creek, Indian Creek, Saunders Creek, and in the estuary.

Channelization and Diking

Channelization and diking has greatly altered low gradient Lower Rogue River tributaries, the lower mainstem, and the estuary. Channel alteration of Edson Creek and Ranch Creek have had the greatest impact on coho salmon production in the Lower Rogue River sub-basin because of the extent of high potential coho salmon habitat occurring there. Levees and dikes have been constructed to protect residential or commercial property in the lower seven miles of the Rogue River, decreasing summer and winter coho salmon juvenile rearing habitat and disconnecting the river from its floodplain. Some remaining side channels located in the lower portions of the population area maintain some rearing habitat capacity (Hicks 2005). Side channels cannot reform on the north side of the upper estuary, because of the levees that protect grazing land and a gravel mining operation. Nearly all of the tidal wetlands have been channelized or diked and are no longer available to coho salmon. Development of the boat basin and marina along the south side of the river eliminated valuable tidal wetlands that provided off-channel habitat for coho salmon rearing and holding.

Mining/Gravel Extraction

Gravel mining is ongoing on the terrace of the Lower Rogue River estuary. There is a gravel operation on the south bank of the estuary. There was an operation of the north bank, but it has not removed from the river for several years. These areas have some of the best restoration opportunities for creating mainstem rearing refugia for coho salmon. The USFS has 9 gold mining claims on their land in Lobster Creek.

Hatcheries

Hatcheries pose a medium threat to all life stages in the Lower Rogue River sub-basin. The rationale for these ratings is described under the “Adverse Hatchery-Related Effects” stress.

Agricultural Practices

Livestock have been eliminated from prairies on public land (USFS 2000a), but on private land grazing may have significant effects on coho salmon. Pasture in the historic estuarine floodplain restricts side channel development that could provide refugia for rearing coho salmon. Across the sub-basin, channel changes caused by conversion of forest to pasture in the highest IP coho salmon habitat are a major inhibitor of coho salmon recovery. Ongoing livestock grazing only contributes to the threat. The primary stream reaches impacted are Ranch Creek and Edson Creek. The Oregon Department of Agriculture currently has no means of tracking pesticide use near the Lower Rogue River (Riley, S., pers. comm. 2009), but agricultural use of these substances could be affecting coho salmon (see Water Quality).

Dams/Diversions

Libby Pond on Libby Creek is the only known impoundment within the Lower Rogue River sub-basin that prevents access to historical coho salmon habitat. Concerns related to diversions, water use, and stream flows are restricted to Edson and Indian creeks. Problems with the base flow of Edson Creek are likely a combination of surface flow and groundwater extraction for agricultural and residential water use. The City of Gold Beach has a 0.77 cfs water right on Indian Creek (USFS 2000a). Flow depletion is a factor known to contribute to stream warming (Poole and Berman 2001), resulting in loss of potential coho salmon habitat.

Climate Change

Climate change in this region will have the greatest impact on juveniles, smolts, and adults. Although the current climate is generally cool, modeled regional average temperature shows a moderate increase over the next 50 years (see Appendix B for modeling methods). Average temperature could increase by up to 1.5 °C in the summer and by 1 °C in the winter. Annual precipitation in this area is predicted to stay within the natural range of current variability however seasonal patterns in precipitation likely will occur (Mote and Salathe 2010). Overall, the range and degree of variability in temperature and precipitation are likely to increase in all populations. The vulnerability of the estuary and coast to sea level rise is moderate to high in this population. Juvenile and smolt rearing and migratory habitat are most at risk to climate change. Rising sea level may impact the quality and extent of wetland rearing habitat by inundating freshwater marshes or wetlands with saltwater.

High Severity Fire

Proximity to the coast and high rainfall make fire risk less of an issue in the Lower Rogue River than in watersheds like the Applegate or Illinois in the interior of the Rogue River basin. Crowded stands of small-diameter trees have increased fire danger (SO RC&D 2003), and such stands are common on private timber lands.

Road-Stream Crossing Barriers

Coho salmon can access most of the Lower Rogue River watershed. Surveys of barriers have been conducted in all lower tributaries and in Lobster and Silver creeks (Hicks 2005) and most issues with fish passage at road-stream crossings have been resolved (Myers 2001). The Libby Pond is a current barrier although it is not a road-stream crossing.

Fishing and Collecting

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a medium threat to adults and a low stress to juveniles and smolts.

Invasive Non-Native/Alien Species

New Zealand mud snails are known to be present in the Lower Rogue River population area. The mud snail is a parthenogenic (i.e., asexual) livebearer with high reproductive potential, often reaching densities greater than 100,000/m² in suitable habitat (Portland State University (PSU) 2011). Due to the rapid population growth rates, New Zealand mud snails may account for the majority of the invertebrate biomass in colonized areas. This species is known to out-compete native invertebrates and contributes little food value to salmonids.

10.7 Recovery Strategy

The most important factor limiting recovery of coho salmon in the Lower Rogue River is the amount of suitable rearing habitat for juveniles. The processes that create and maintain such habitat must be restored. Channel complexity should be improved by constructing off-channel ponds or backwater habitat, reconnecting the wetlands and estuary to the river, restoring wetlands, and limiting development and fill. To increase instream structure, large wood should be added where the channel is stable, to provide structure until natural sources of large wood (mature coniferous and hardwood forests) are re-established next to the stream. Areas adjacent to the stream should be replanted and subsequently thinned to re-establish mature streamside forest as a source of large wood recruitment.

The most immediate need for habitat restoration and threat reduction in the Lower Rogue River is in those areas currently occupied by coho salmon, such as Snag Patch Slough in the estuary, the oxbow at the mouth of Edson Creek, and upper Lobster Creek. The least disturbed aquatic habitat would be a good place to start for restoring vital rearing habitat. Unoccupied areas must also be restored to provide habitat for coho salmon recovery, and the least disturbed areas with IP should be considered first for restoration: South Fork Lobster Creek, North Fork Lobster Creek, Indian Creek, and Saunders Creek (Reeves et al. 1995). The effects of fishing on this population's ability to meet its viability criteria should be evaluated.

Table 10-5 on the following page lists the recovery actions for the Lower Rogue River population.

Table 10-5. Recovery action implementation schedule for the Lower Rogue River population. Recovery actions for monitoring and research are listed in tables at the end of Chapter 5.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	***Step Description***					
SONCC-LRR.7.1.4	Riparian	No	Improve wood recruitment, bank stability, shading, and food subsidies	Improve timber harvest practices	Population wide, primarily Lobster Creek	1
SONCC-LRR.7.1.4.1	*Determine how to revise Oregon Forest Practice Rules so that they do not limit recovery of SONCC coho salmon and make appropriate revisions*					
SONCC-LRR.7.1.4.2	*Adopt rules for fish-bearing streams sufficient to protect both water quality and fish habitat*					
SONCC-LRR.7.1.4.3	*Adopt rules to increase protection of non-fish-bearing streams that address practices that adversely impact water quality and fish habitat*					
SONCC-LRR.7.1.4.4	*Ensure management measures for landslide prone areas include protection of water quality and fisheries habitat*					
SONCC-LRR.7.1.4.5	*Until more permanent regulatory mechanisms can be put in place, immediately adopt interim rules that increase protection for salmon habitat in forested areas, including increased natural recruitment of large wood on perennial and intermittent streams likely to deliver wood downstream, increased shade on all perennials, and protective buffers on small intermittent streams*					
SONCC-LRR.2.1.9	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	All streams where coho salmon would benefit immediately	2a
SONCC-LRR.2.1.9.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-LRR.2.1.9.2	*Place instream structures, guided by assessment results*					
SONCC-LRR.2.1.50	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	Population wide	2b
SONCC-LRR.2.1.50.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-LRR.2.1.50.2	*Place instream structures, guided by assessment results*					
SONCC-LRR.2.2.10	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	All streams where coho salmon would benefit immediately	2a
SONCC-LRR.2.2.10.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for land owners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-LRR.2.2.10.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-LRR.2.2.10.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-LRR.2.2.51	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	Population wide	2b
SONCC-LRR.2.2.51.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for land owners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-LRR.2.2.51.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-LRR.2.2.51.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					
SONCC-LRR.10.2.26	Water Quality	Yes	Reduce pollutants	Reduce point- and non-point source pollution	All streams where coho salmon would benefit immediately	2a
SONCC-LRR.10.2.26.1	*Identify pollution sources, and develop a strategy to minimize input to stream channels*					
SONCC-LRR.10.2.26.2	*Implement strategy to minimize pollution*					
SONCC-LRR.10.2.49	Water Quality	Yes	Reduce pollutants	Reduce point- and non-point source pollution	Population wide	2b
SONCC-LRR.10.2.49.1	*Identify pollution sources, and develop a strategy to minimize input to stream channels*					
SONCC-LRR.10.2.49.2	*Implement strategy to minimize pollution*					
SONCC-LRR.28.1.1	Roads	Yes	Reduce sediment delivery to streams	Reduce road-stream hydrologic connection	SF and NF Lobster, Silver, Saunders, Indian creeks, and all areas where coho salmon would benefit immediately	2a
SONCC-LRR.28.1.1.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-LRR.28.1.1.2	*Decommission roads, guided by assessment*					
SONCC-LRR.28.1.1.3	*Upgrade roads, guided by assessment*					
SONCC-LRR.28.1.1.4	*Maintain roads, guided by assessment*					
SONCC-LRR.28.1.57	Roads	Yes	Reduce sediment delivery to streams	Reduce road-stream hydrologic connection	Population wide	2b
SONCC-LRR.28.1.57.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-LRR.28.1.57.2	*Decommission roads, guided by assessment*					
SONCC-LRR.28.1.57.3	*Upgrade roads, guided by assessment*					
SONCC-LRR.28.1.57.4	*Maintain roads, guided by assessment*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-LRR.2.4.8	Floodplain and Channel Structure	No	Improve estuarine habitat	Restore estuarine habitat	Areas of the estuary where coho salmon would benefit immediately	2a
SONCC-LRR.2.4.8.1	*Assess coho use of different estuarine habitats and develop a plan to enhance those habitats (i.e. brackish wetlands, tidal sloughs, salt marshes, and tidally influenced freshwater)*					
SONCC-LRR.2.4.8.2	*Restore tidally influenced habitats, guided by the plan*					
SONCC-LRR.2.4.53	Floodplain and Channel Structure	No	Improve estuarine habitat	Restore estuarine habitat	Population wide	2b
SONCC-LRR.2.4.53.1	*Assess coho use of different estuarine habitats and develop a plan to enhance those habitats (i.e. brackish wetlands, tidal sloughs, salt marshes, and tidally influenced freshwater)*					
SONCC-LRR.2.4.53.2	*Restore tidally influenced habitats, guided by the plan*					
SONCC-LRR.2.5.6	Floodplain and Channel Structure	No	Improve tidal exchange of water	Reconnect estuarine habitat	Mouth of Ranch Creek and areas of the estuary where coho salmon would benefit immediately	2a
SONCC-LRR.2.5.6.1	*Assess the tidal wetland habitat and develop a plan to reconnect the tributary*					
SONCC-LRR.2.5.6.2	*Reconnect tidal wetlands, guided by the plan*					
SONCC-LRR.2.5.54	Floodplain and Channel Structure	No	Improve tidal exchange of water	Reconnect estuarine habitat	Population wide	2b
SONCC-LRR.2.5.54.1	*Assess the tidal wetland habitat and develop a plan to reconnect the tributary*					
SONCC-LRR.2.5.54.2	*Reconnect tidal wetlands, guided by the plan*					
SONCC-LRR.2.7.33	Floodplain and Channel Structure	No	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	All streams on private lands where coho salmon would benefit immediately	2a
SONCC-LRR.2.7.33.1	*Assess grazing contribution to sediment delivery, pollutants, and impaired riparian conditions*					
SONCC-LRR.2.7.33.2	*If problems are identified, develop and implement grazing management strategy that decreases delivery of sediment and pollutants to streams and improves riparian condition*					
SONCC-LRR.2.7.33.3	*Monitor effectiveness of grazing management to ensure grazing does not limit recovery of SONCC coho salmon*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-LRR.2.7.55	Floodplain and Channel Structure	No	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	Population wide	2b
SONCC-LRR.2.7.55.1	*Assess grazing contribution to sediment delivery, pollutants, and impaired riparian conditions*					
SONCC-LRR.2.7.55.2	*If problems are identified, develop and implement grazing management strategy that decreases delivery of sediment and pollutants to streams and improves riparian condition*					
SONCC-LRR.2.7.55.3	*Monitor effectiveness of grazing management to ensure grazing does not limit recovery of SONCC coho salmon*					
SONCC-LRR.2.2.48	Floodplain and Channel Structure	No	Reconnect the channel to the floodplain	Construct off channel ponds, alcoves, backwater habitat, and old stream oxbows	All streams where coho salmon would benefit immediately	2a
SONCC-LRR.2.2.48.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-LRR.2.2.48.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-LRR.2.2.52	Floodplain and Channel Structure	No	Reconnect the channel to the floodplain	Construct off channel ponds, alcoves, backwater habitat, and old stream oxbows	Population wide	2b
SONCC-LRR.2.2.52.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-LRR.2.2.52.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-LRR.22.3.36	Urban, Residential, Industrial Development	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Increase regulatory oversight	All coho salmon bearing streams	2b
SONCC-LRR.22.3.36.1	*Strengthen city and county ordinances to limit development within the 100 year channel migration zone*					
SONCC-LRR.22.3.36.2	*Strengthen city and county ordinances to limit development within the 50 year flood elevation*					
SONCC-LRR.28.1.2	Roads	Yes	Reduce sediment delivery to streams	Improve regulatory mechanisms	Population wide	2b

11. Hunter Creek Population

Northern Coastal Stratum

Dependent Population

Recovery criteria: 80% of available IP habitat must be occupied in years following spawning of brood years with high marine survival

Habitat likely available to support all life stages

44.5 mi^2 watershed (38% Federal ownership)

15 IP-km (9 IP-mi) (13% High)

Dominant Land Uses are Timber Harvest and Urban/Rural Development

Key Limiting Stresses are 'Lack of Floodplain and Channel Structure' and 'Degraded Riparian Forest Conditions'

Key Limiting Threats are 'Roads' and 'Timber Harvest'

Highest Priority Recovery Actions

• Increase streamflows • Reconnect estuarine habitat by installing new bridge at Highway 101 • Construct off-channel habitats, alcoves, backwater habitat, and old stream oxbows	• Remove, setback, or reconfigure levees and dikes • Increase large woody debris (LWD), boulders or other instream structure • Improve timber harvest practices by revising Oregon Forest Practices Act

11.1 History of Habitat and Land Use

Hunter Creek enters the Pacific Ocean just south of the town of Gold Beach, which is located at the mouth of the Rogue River. Farming and ranching on the lower terraces began in the 1850s. Some coho salmon habitat was likely impacted, although basin-wide productivity remained high. Only about 20 people lived in lower Hunter Creek through the 1930s (Massingill 2001d), but today there are hundreds of residents as rural development has spread outward from Gold Beach.

Forestry is the dominant land use in the Hunter Creek basin. Like most southwest Oregon river basins, Hunter Creek was extensively logged after World War II (EA Engineering, Science, and Technology 1998). In the 1950s, there were as many as 17 active mills in the Gold Beach/Hunter Creek area (Massingill 2001d). Private timber land was substantially logged by 1960, and reforestation was limited (Maguire 2001d). U.S. Forest Service (USFS) and Bureau of Land Management (BLM) lands in the headwaters of the upper mainstem and North Fork of Hunter Creek were logged from the 1950s to the 1980s (EA Engineering, Science, and Technology 1998). Damage in Hunter Creek from the floods of 1955 and 1964 was extensive.

In 1995, an area of lower Hunter Creek with a human population of about 414 people was annexed to the City of Gold Beach (Maguire 2001d). Residential development is concentrated in the lower basin. Residential, commercial, and industrial development in lower Hunter Creek and the estuary have also contributed to coho salmon habitat degradation.

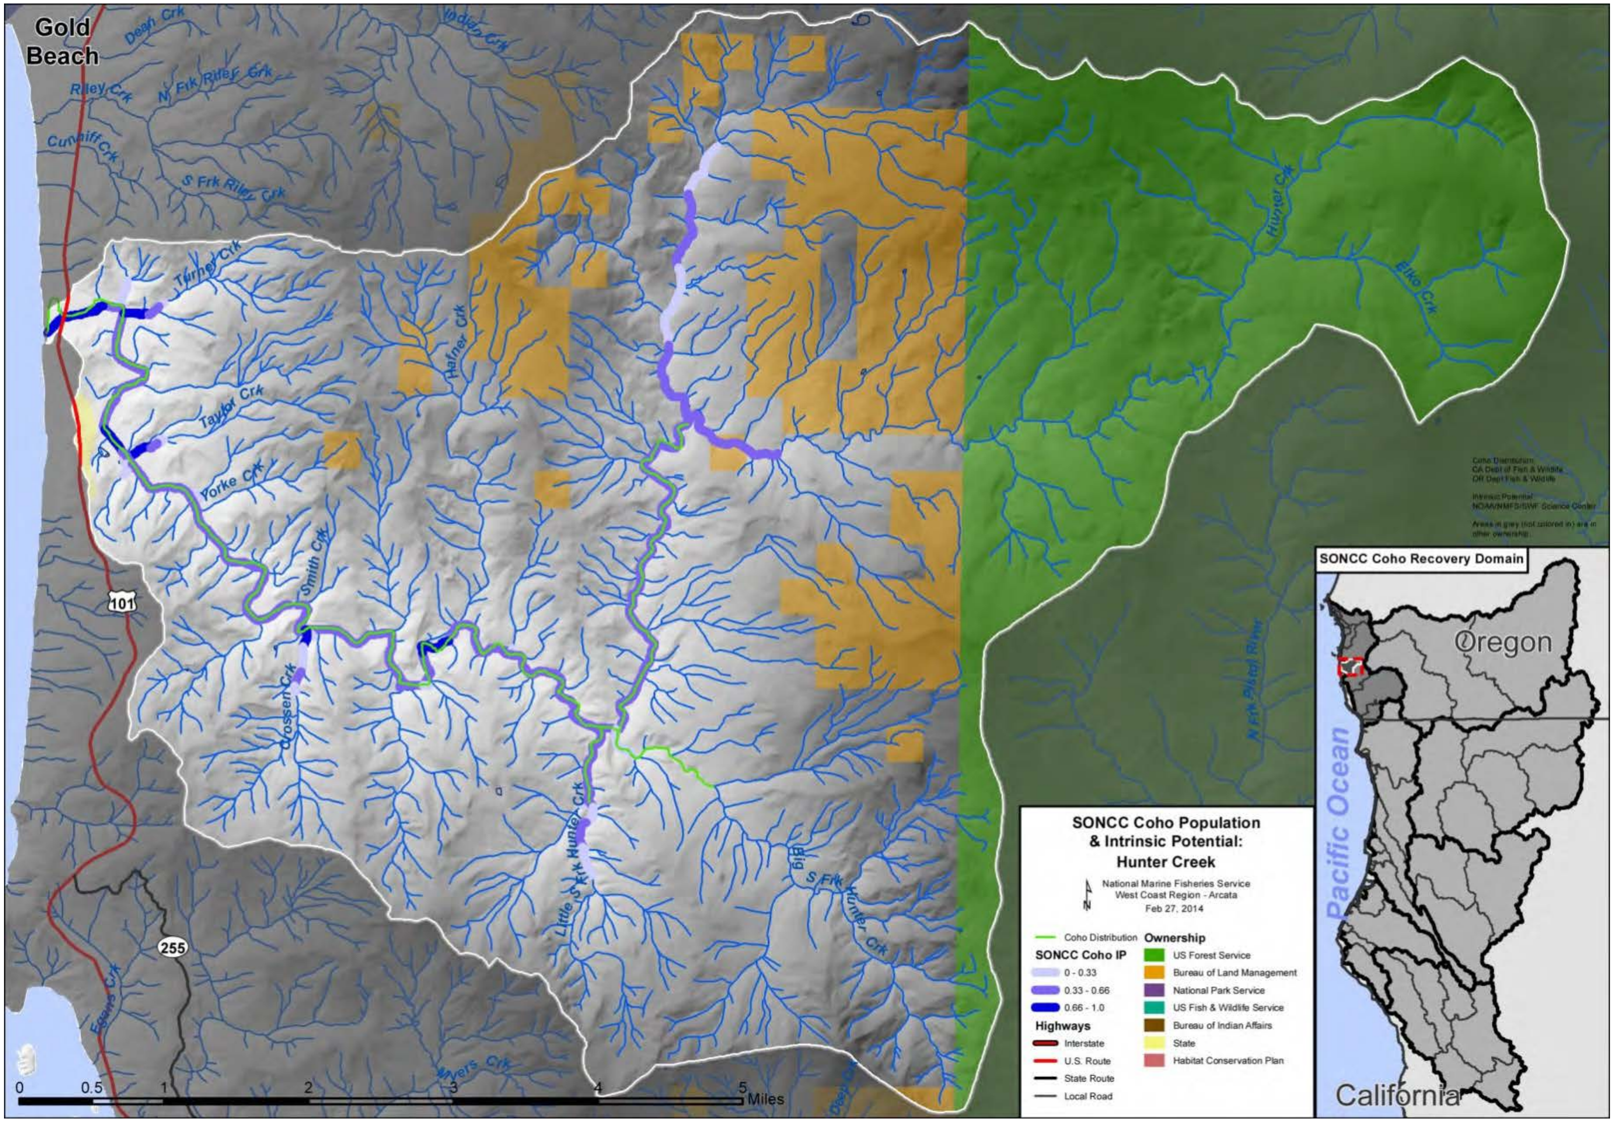

Figure 11-1. The geographic boundaries of the Hunter Creek coho salmon population. Figure shows modeled Intrinsic Potential of habitat (Williams et al. 2006), land ownership, coho salmon distribution (ODFW 2013a), and location within the Southern-Oregon/Northern California Coast Coho Salmon ESU and the Northern Coastal diversity stratum (Williams et al. 2006). Grey areas indicate private ownership.

11.2 Historic Fish Distribution and Abundance

Historic data on the distribution and abundance of coho salmon in Hunter Creek is limited. Annual estimates of coho salmon adults in Hunter Creek were 136 in 2001, 52 in 2002, 17 in 2004, 22 in 2005 and 35 in 2008 (ODFW 2009a). Williams et al. (2006) identified the estuary, lower mainstem, and tributaries below Conn Creek as having the highest coho salmon intrinsic potential habitat (IP > 0.66) in the basin. Hunter Creek has a total of 14.63 IP-km of coho salmon rearing habitat. Table 11-1 lists streams with high IP coho salmon habitat in the Hunter Creek population area.

Table 11-1 Tributaries with high IP reaches (IP > 0.66). (Williams et al. 2006).

Stream Name	Stream Name
Crossen Creek	Taylor Creek
Hunter Creek Estuary	Turner Creek
Lower Mainstem Hunter Creek	

11.3 Status of Hunter Creek Coho Salmon

Spatial Structure and Diversity

Coho salmon still inhabit their historic range in Hunter Creek from the Big South Fork Hunter Creek downstream, including the lowest extent of the Big South Fork Hunter Creek and Little South Fork Hunter Creek (Maguire 2001d). However, in dive surveys of three reaches of Hunter Creek (upstream of Yorke Creek, downstream of Little South Fork Hunter Creek, and upstream of North Fork Hunter Creek) in 2002-2004, coho salmon were only found at the reach downstream of Little South Fork Hunter Creek and were at very low densities (0.038 and 0.063/sq. meter) (ODFW 2005a). This indicates patchy distribution and likely a small population, which would generally have less genetic diversity than larger ones. Thus, spatial structure and diversity is likely low.

Population Size and Productivity

The Oregon Department of Fish and Wildlife (ODFW 2009a) estimated coho salmon populations for the period 1998 to 2008 for south coast Oregon, including Hunter Creek. Coho salmon adults were found in 5 of 11 years, with annual estimates of 136 in 2001, 52 in 2002, 17 in 2004, 22 in 2005 and 35 in 2008. One year class appears to be completely missing and the lack of consistent returns in other brood years indicates very low productivity in the Hunter Creek. There is no information regarding consistency of ODFW survey effort across years, so some qualification of these results is required. Also, in high flow years, surveys can be difficult or impossible. Consequently, the population may be somewhat larger than estimated and there may have been some coho salmon adults in years when the population estimate was zero. The productivity and size of this population is driven not only by the dynamics of the Hunter Creek population, but by those of nearby populations as well, which contribute spawners as strays. However, the supply of strays to Hunter Creek is not expected to be substantial or consistent in the near term because most adjacent populations in the SONCC coho salmon ESU are at low levels.

Extinction Risk

Not applicable because Hunter Creek is not an independent population.

Role in SONCC Coho Salmon ESU Viability

The Hunter Creek population is considered dependent because it does not have a high likelihood of sustaining itself over a 100-year time period in isolation and likely received sufficient immigration to alter its dynamics and extinction risk (Williams et al. 2006). Although such populations cannot be viable on their own, they increase connectivity by allowing dispersal among independent populations, acting as a source of colonists in some cases. Historically, the Hunter Creek population would have interacted with the Northern Coastal independent populations such as the lower Rogue River to the north, and with other dependent populations such as the Pistol River to the south. Any restored habitat in Hunter Creek provides potential connectivity that could assist with metapopulation function in the SONCC coho salmon ESU.

11.4 Plans and Assessments

State of Oregon

Expert Panel Limiting Factors Report for Southwest Oregon

ODFW (2008b) convened a panel of fisheries and watershed science experts as an initial step in their development of a recovery plan for Oregon's SONCC coho salmon populations. Deliberations of the expert panel provided ODFW with initial, strategic guidance on limiting factors and threats to recovery. Based on the input of panel members, ODFW (2008b) summarized the concerns for the Hunter Creek population as follows:

> Key concerns were a loss of over-winter tributary habitat complexity and floodplain connectivity for juveniles, especially in the lowlands which are naturally very limited in these systems and have been impacted by past and current urban, rural residential, and forestry development and practices. High water temperatures for summer parr due to a loss of riparian function and channel straightening is also a key concern in this stream. The secondary concern was related to a loss of over-winter, lowland habitat complexity due to past and current agricultural practices.

Oregon Plan for Salmon and Watersheds
http://www.oregon.gov/OPSW/about_us.shtml

The State of Oregon developed a conservation and recovery strategy for coho salmon in the SONCC and Oregon Coast ESUs (State of Oregon 1997). The Oregon Plan for coho salmon is a comprehensive plan that includes voluntary actions for all of the threats currently facing coho salmon in these ESUs and involves all relevant state agencies. Reforms to fishery harvest and hatchery programs were implemented by ODFW in the late 1990s. Many habitat restoration projects have occurred across the landscape in headwater habitat, lowlands, and the estuary. The action plans, implementation success, and annual reports can be found at http://www.oregon.gov/OPSW/.

South Coast Watersheds Council (SCWC)

Hunter Creek Watershed Assessment

The Hunter Creek Watershed Assessment (Maguire 2001d) was prepared for the Hunter Creek Watershed Council by the SCWC. The purpose of the assessment was to compile, summarize, and synthesize existing data and information pertaining to the Hunter Creek basin's condition. This information is the foundation for the prioritization of projects outlined in the Hunter Creek Watershed Action Plan.

Hunter Creek Watershed Action Plan

The Hunter Creek Watershed Action Plan (Massingill 2001d) lays out a restoration strategy with specific recommended actions for Hunter Creek. These actions include: increasing the size and complexity of the estuary, identifying and restoring wetlands, identifying current and potential sediment sources in the basin, protecting existing riparian vegetation and planting new riparian vegetation, converting alder-dominated stands to conifer, and assessing the risk of failure of road crossings in earthflow areas."

11.5 Stresses

Table 11-2. Severity of stresses affecting each life stage of coho salmon in Hunter Creek. Stress rank categories, assessment methods, and data used to assess stresses are described in Appendix B.

	Stresses [2]	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Stress Rank
1	Lack of Floodplain and Channel Structure[1]	Medium	Very High	Very High[1]	Very High	High	Very High
2	Degraded Riparian Forest Conditions[1]	-	Very High	Very High[1]	High	Medium	Very High
3	Altered Sediment Supply	High	Medium	High	High	Medium	High
4	Impaired Water Quality	Low	High	Very High	High	Low	High
5	Impaired Estuary/Mainstem Function	-	Low	Very High	High	Medium	High
6	Altered Hydrologic Function	Medium	Medium	Medium	Medium	Low	Medium
7	Barriers	-	Low	Low	Low	Low	Low
8	Adverse Hatchery-Related Effects	Low	Low	Low	Low	Low	Low
9	Adverse Fishery- and Collection-Related Effects	-	-	Low	Low	Low	Low

[1]Key limiting stresses and limited life stage.
[2]Increased Disease/Predation/Competition is not considered a stress for this population.

Key Limiting Stresses, Life Stages, and Habitat

The juvenile life stage is most limited and quality winter rearing habitat is lacking as vital habitat for the population. Degraded riparian conditions eliminated the source of large wood recruitment. The complexity of the channel has been significantly reduced by the combined effect of excess fine sediment that fills pools and the lack of structure to meter out sediment or provide scour mechanisms which create and maintain pools. These findings are consistent with those of the Oregon Expert Panel (Section 11.4).

Lack of Floodplain and Channel Structure

The lack of floodplain and channel structure is the most limiting stress to coho salmon. Channelization of lower Hunter Creek has disconnected the stream from its riparian zone and wetlands and has likely disrupted surface water-groundwater interactions. Large fallen conifers and root masses that formerly forced the scour of pools are now scarce or absent, depriving coho salmon of necessary cover in their summer and winter habitats (Appendix B). ODFW and USFS conducted large wood surveys and found poor levels of large wood (<1 key piece per 100m). Wood has been removed from stream channels (EA Engineering, Science, and Technology 1998).

ODFW and USFS habitat surveys of the Hunter Creek basin found that pool frequency varied from fair (10 to 20 percent) in lower Big South Fork and upper mainstem Hunter to good (20 to 35 percent) in the mainstem above the North Fork and the lower North Fork (Appendix B). Surveys of lower Hunter Creek found pool frequencies greater than 35 percent and pool depths greater than three feet, which ODFW rates as very good (Appendix B). However, pool frequencies and depths are probably substantially reduced from historic conditions. For example, nearby Quosatana Creek in the Lower Rogue River sub-basin has a watershed with similar size to Hunter Creek but has mainstem pool depths of 10 feet (USFS 1996a). Hunter Creek pools historically may have approached or exceeded this depth.

Degraded Riparian Forest Conditions

There are few large trees capable of providing large wood in the riparian zone of Hunter Creek. Specifically, ODFW found there were fewer than 75 conifers greater than 36” in diameter per 1000 ft. in all reaches of Hunter Creek (Appendix B). Large conifers stabilize bank structure, maintain shade, and improve both thermal and nutrient buffering. The riparian zone of Hunter Creek is significantly altered, and hardwood trees like alder and willow are now the most abundant species in alluvial valleys. These species do not provide long lasting large wood for channel forming processes (Cederholm et al. 1997). Serpentine soils naturally limit the presence of large-diameter conifer forests in much of the east side of the Hunter Creek basin. In serpentine areas, Port Orford cedar is an important riparian tree that has suffered high mortality due to the spread of introduced Port-Orford cedar root rot (EA Engineering, Science, and Technology 1998). Sediment deposition and shifting bedload may cause mortality of streamside hardwoods and conifers, inhibiting riparian recovery and succession.

Altered Sediment Supply

Sediment contribution from landslides and erosion occurs naturally in the Hunter Creek basin; however, roads, timber harvest, and bank erosion following removal of riparian vegetation have elevated fine sediment input. In lower Hunter Creek, where coho salmon are known to occur, sand and fine sediment has degraded (Appendix B). Excess fine sediment directly impacts coho salmon egg viability and can reduce food for fry, juveniles and smolts. Poor pool frequency and depth throughout the Hunter Creek basin (Maguire 2001d) is likely due to elevated levels of fine sediment partially filling pools, a lack of scour-forcing obstructions such as large wood, and in some reaches diminished scour due to channel widening.

Impaired Water Quality

Hunter Creek is recognized as temperature impaired from its mouth to 18.4 miles upstream (Oregon Department of Environmental Quality (ODEQ) 2002a). This is the area that contains some of the highest IP coho salmon habitat in the basin. North Fork Hunter Creek is also listed by ODEQ (2002a) as temperature impaired in the lower 4.8 miles. Upper mainstem temperatures are naturally warm (72 to 75 °F) because the headwaters have serpentine soils where vegetation is naturally sparse and stream shade low (Massingill 2001d). The Little South Fork is currently too warm during the summer, as is lower Hunter Creek which has temperatures as high as 74 to 75 °F. Only the lower Big South Fork is currently cool enough for rearing coho salmon. Aquatic insect samples on federal lands in the South Fork show that communities are diverse and very good in headwaters, but decline to fair or poor in lower reaches.

Lower Hunter Creek is pH-impaired during the summer. Septic systems could be a source of pollution (Massingill 2001d). Reduced flow levels combined with increased nutrients contribute to nuisance algae blooms that can elevate pH during the day and depress dissolved oxygen levels at night.

Impaired Estuary/Mainstem Function

The lack of estuary function is a high stress to juveniles and smolts. The Hunter Creek estuary has occasional nuisance algae blooms (Figure 11-2) and has lost both depth and complexity due to excess fine sediment deposition. Almost all former estuarine habitat has been altered. Highway 101 bisects the estuary just upstream of the mouth and acts as a dike along most of its length. There are also dikes along the south side of the estuary in front of a large commercial development. Further upstream, former estuarine habitat has been diked and filled for other commercial and agricultural use. One large side channel remains, but this channel, along with most of the estuary, shows signs of fine sediment accretion and lacks complex features such as large wood and deep pools. There appear to be no remaining tidal wetlands in the Hunter Creek estuary. Water quality is poor in the estuary during the low-flow season due to high water temperatures and the presence of algae blooms.

Figure 11-2. Algal bloom in the Hunter Creek estuary.

Altered Hydrologic Function

Altered hydrologic function is a low stress to Hunter Creek coho salmon. Maguire (2001d) notes that residential development and increased water demand have the potential to compromise flows. Timber harvest and roads have likely increased peak flows in the Hunter Creek basin (EA Engineering, Science, and Technology 1998). Such peak flows are known to cause channel scour, loss of large wood and pool filling. Disconnection of the channel and floodplain also may disrupt surface and groundwater connections that can provide a cooling influence that benefits coho salmon and other salmonids.

Barriers

Barriers to coho salmon migration exist in Hunter Creek, including several in the Lower Hunter Creek mainstem watershed (Maguire 2001d). Because coho salmon have access to most of the Hunter Creek basin, barriers represent a low stress.

Adverse Hatchery-Related Effects

There are no operating hatcheries in the Hunter Creek population area. Hatchery-origin coho salmon may stray into Hunter Creek; however, the proportion of adults that are of hatchery origin is likely less than five percent and there is no hatchery in the basin producing other species of salmonids. Therefore, adverse hatchery-related effects pose a low risk to all life stages. (Appendix B).

Adverse Fishery- and Collection-Related Effects

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low stress to juveniles, smolts, and adults.

11.6 Threats

Table 11-3. Severity of threats affecting each life stage of coho salmon in Hunter Creek. Threat rank categories, assessment methods, and data used to assess threats are described in Appendix B.

	Threats	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Threat Rank
1	Roads[1]	Medium	Very High	Very High[1]	Very High	Very High	Very High
2	Timber Harvest[1]	Very High	Very High	Very High[1]	Very High	Medium	Very High
3	Channelization/Diking	Low	Very High	Very High	Very High	Very High	Very High

13	Fishing and Collecting	-	-	Low	Low	Low	Low

[1]Key limiting threats and limited life stage.

Key Limiting Threats

The two key limiting threats, those which most affect recovery of the population by influencing stresses, are roads and timber harvest.

Roads

Roads have been identified as a major source of sediment in the Hunter Creek watershed (EA Engineering, Science, and Technology 1998). Lower Hunter Creek, the Little Fork Hunter Creek, and Big South Fork Hunter Creek all have densities of over 3 miles of road per square mile of basin (mi/mi^2). USFS and BLM lands in the headwaters of the North Fork and mainstem Hunter Creek have road densities of 1.6 to 2.5 mi/mi^2. Unpaved roads often concentrate surface runoff and deliver sediment to stream channels. They also can initiate slope failures and landslides. Paved roads increase runoff and peak flows.

Channelization/Diking

Almost all high IP (>0.66) habitat areas in Hunter Creek have been altered by channelization and diking. Constriction of the channel by dikes and levees increases current velocity, making it unsuitable for winter rearing, and increases bedload mobility that scours redds and causes mortality of eggs. Road berms that parallel streams confine the channel, cutting it off from its floodplain and adjacent wetlands (Figure 11-3). Filling of the Hunter Creek estuary to enable commercial development has isolated formerly productive wetlands and decreased coho salmon rearing habitat. Channel migration in the estuary is also constrained by the Highway 101 bridge.

Figure 11-3. Lower Hunter Creek flows adjacent to residential development. Creek is closely confined by a berm for Hunter Creek Road. Some houses encroach closely upon the creek and fully occupy the riparian floodplain.

Timber Harvest

Private industrial timber lands cover much of the middle and lower Hunter Creek basin, including tributaries occupied by coho salmon habitat in their lowest reaches. Harvest cycles are on 30 to 50 year rotations. A high percentage (over 50%) of Hunter Creek is industrial timberlands managed under the Oregon Forest Practices Act. The high harvest rates and associated roads negatively impact multiple aspects of coho salmon habitat. In addition, nearly all intrinsic potential streams are surrounded by private industrial forestlands. Active timber harvest on private lands within the Hunter Creek basin is widespread and occurring rapidly with the expectation it will continue. Use of herbicides for site preparation after clear cutting to prevent growth of hardwoods or shrubs may also pose a risk to salmonids (Ewing 1999).

Agricultural Practices

Most of the upper Hunter Creek basin is unsuitable for agriculture. Agricultural practices occur in much of the high IP area in the lower basin, and pose a high threat to coho salmon. River terraces were cleared for farming and channels moved to accommodate greater agricultural production. Although agriculture may have been responsible for original changes to aquatic habitat, much of what was formerly farm land has now been converted to residential or industrial use.

Urbanization/Residential Development

Development in the Hunter Creek basin poses an overall high threat to coho salmon. Most development has occurred on the floodplain of the lower and middle reaches of Hunter Creek and the estuary, where coho salmon habitat occurs. Rural residences use both surface water and groundwater, which can deplete streamflows. This diminishes habitat and contributes to stream warming. Rural residential septic systems may leach nutrients or pollutants into nearly streams, and pesticides and herbicides used on lawns can pollute nearby waterways. Commercial and industrial land use in lower Hunter Creek and the upper estuary may also contribute to non-point source pollution.

Dams/Diversions

There are no dams known to impede passage in Hunter Creek; however, diversions are a concern, particularly in lower Hunter Creek. Massingill (2001d) notes that Hunter Creek water rights are over-allocated from May through October, but approximately 25 percent of the water rights are junior to the in-stream rights held by ODFW which date from 1964.

High-Intensity Fire

The proximity of the Hunter Creek basin to the coast is a strong moderating factor on fire risk. However, serpentine terrain in the upper Hunter Creek basin has sparse vegetation and drier site conditions that make fires more frequent than in coastal rain forests. Early seral conditions with crowded trees elevate the risk of catastrophic fire regionally (Southwest Oregon Resource Conservation and Development Council 2003). If fire causes widespread loss of ground cover, substantial erosion may wash fine sediment into streams and degrade coho salmon habitat. Thus, fire poses an overall medium risk to coho salmon.

Road-stream Crossing Barriers

Road-stream crossings pose a low threat to coho salmon. The Big South Fork Hunter Creek has the highest density of stream crossings of any watershed in the basin, while the Lower and Middle Hunter Creek mainstem have moderate to high densities of road crossings (Maguire 2001d). Road crossing surveys were conducted to assess erosion potential; however, it is likely that some of these crossings impede fish migration.

Climate Change

There is low risk of change in average precipitation over the next 50 years (Appendix B). Modeled regional average temperature shows a moderate increase over the next 50 years (Appendix B). Average temperature could increase by up to 1^{o} C in the summer and by a similar amount in the winter. The risk of sea level rise is high (Thieler and Hammer-Klose 2000), which may impact the quality and extent of wetland juvenile and smolt habitat. Adults may be negatively impacted by climate-related ocean acidification, changes in ocean conditions, and prey availability (see Independent Science Advisory Board 2007, Feely et al. 2008, Portner and Knust 2007).

Mining/Gravel Extraction

Sand and gravel have been extracted from gravel bars along the lower 10 km of Hunter Creek since at least the 1960s (Jones et al. 2011). Gravel mining at two sites is covered under a NMFS biological opinion until September 2016 (NMFS 2011b). Gravel mining can reduce instream habitat complexity, but it is unknown whether this has occurred in Hunter Creek. Air photo analysis indicates a decline in bar area from 1940-2009, but the reasons are unknown (Jones et al. 2011).

Hatcheries

Hatcheries pose a low threat to all life stages of coho salmon in the Hunter Creek population area. The rationale for these ratings is described under the "Adverse Hatchery-Related Effects" stress.

Invasive and Non-Native/Alien Species

Given the extent of residential development in the lower floodplain of Hunter Creek, it is likely that invasive plant species will spread from residential landscaping into riparian areas, particularly if there are pre-existing gaps in the riparian vegetation. Some of these species could impede restoration of riparian forests and wetlands. The extent to which this has already occurred is unknown.

Fishing and Collecting

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low stress to juveniles, smolts, and adults.

11.7 Recovery Strategy

The most immediate need for habitat restoration and threat reduction in Hunter Creek is in those areas currently occupied by coho salmon in mainstem Hunter Creek, Little South Fork Hunter Creek, and Big South Fork Hunter Creek. Unoccupied areas must also be restored to provide enough habitat for coho salmon recovery.

The Hunter Creek population is dependent and therefore cannot be viable on its own; however, it is necessary to restore habitat within the basin so that it can support all life stages of coho salmon and provide connectivity between other populations in the ESU. The recovery criterion for this population is that 80% of available IP habitat must be occupied in years following spawning of brood years with high marine survival. The most important factor limiting recovery of coho salmon in Hunter Creek is a deficiency in the amount of suitable rearing habitat for juveniles. The processes that create and maintain such habitat must be restored by increasing habitat complexity within the channel, re-establishing off-channel rearing areas, restoring riparian forests, and reducing threats to instream habitat. The effects of fishing on this population's ability to meet its viability criteria should be evaluated.

Table 11-4 on the following page lists the recovery actions for the Hunter Creek population.

Table 11-4. Recovery action implementation schedule for the Hunter Creek population. Recovery actions for monitoring and research are listed in tables at the end of Chapter 5.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-HunC.2.4.15	Floodplain and Channel Structure	Yes	Improve estuarine habitat	Reconnect estuarine habitat	Highway 101 bridge	2b
SONCC-HunC.2.4.15.1	*Develop plan to replace Highway 101 bridge that will allow Hunter Creek to meander across estuarine floodplain*					
SONCC-HunC.2.4.15.2	*Install new bridge, guided by plan*					
SONCC-HunC.2.4.17	Floodplain and Channel Structure	Yes	Improve estuarine habitat	Restore estuarine habitat	Hunter Creek Estuary, immediately upstream of Highway 101	2b
SONCC-HunC.2.4.17.1	*Assess tidally influenced habitat and develop a plan to restore tidal channels*					
SONCC-HunC.2.4.17.2	*Restore tidal wetlands and tidal channels in historic estuary, guided by the plan*					
SONCC-HunC.19.1.4	Timber Harvest	Yes	Improve timber harvest practices	Improve regulatory mechanisms	Population wide	2b
SONCC-HunC.19.1.4.1	*Determine how to revise Oregon Forest Practice Rules so that they do not limit recovery of SONCC coho salmon and make appropriate revisions*					
SONCC-HunC.19.1.4.2	*Adopt rules for fish-bearing streams sufficient to protect both water quality and fish habitat*					
SONCC-HunC.19.1.4.3	*Adopt rules to increase protection of non-fish-bearing streams that address practices that adversely impact water quality and fish habitat*					
SONCC-HunC.19.1.4.4	*Ensure management measures for landslide prone areas include protection of water quality and fisheries habitat*					
SONCC-HunC.19.1.4.5	*Until more permanent regulatory mechanisms can be put in place, immediately adopt interim rules that increase protection for salmon habitat in forested areas, including increased natural recruitment of large wood on perennial and intermittent streams likely to deliver wood downstream, increased shade on all perennials, and protective buffers on small intermittent streams*					
SONCC-HunC.7.1.1	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve long-range planning	Private land	2b
SONCC-HunC.7.1.1.1	*Review General Plan or City/County Ordinances to ensure coho salmon habitat needs are accounted for. Revise if necessary*					
SONCC-HunC.7.1.1.2	*Develop watershed-specific guidance for managing riparian vegetation. Consider larger riparian buffers in coho occupied habitat*					
SONCC-HunC.2.1.13	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	All streams where coho salmon would benefit immediately	2b
SONCC-HunC.2.1.13.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-HunC.2.1.13.2	*Place instream structures, guided by assessment results*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-HunC.2.1.42	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	Population wide	2c
SONCC-HunC.2.1.42.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-HunC.2.1.42.2	*Place instream structures, guided by assessment results*					
SONCC-HunC.2.2.11	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Lower mainstem Hunter Creek, including estuary and tributaries within the floodplain, and all streams where coho salmon would benefit immediately	2b
SONCC-HunC.2.2.11.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-HunC.2.2.11.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-HunC.2.2.44	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Population wide	2c
SONCC-HunC.2.2.44.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-HunC.2.2.44.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-HunC.2.2.10	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	Lower mainstem Hunter Creek and tributaries within floodplain, and all streams where coho salmon would benefit immediately	2b
SONCC-HunC.2.2.10.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for land owners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-HunC.2.2.10.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-HunC.2.2.10.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					
SONCC-HunC.2.2.43	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	Population wide	2c
SONCC-HunC.2.2.43.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for land owners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-HunC.2.2.43.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-HunC.2.2.43.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-HunC.2.2.16	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Remove, set back, or reconfigure levees and dikes	Lower Hunter Creek	2b
SONCC-HunC.2.2.16.1	*Assess feasibility and develop a plan to remove or set back levees and dikes that includes restoring the natural channel form and floodplain connectivity once the levees and dikes have been removed or set back*					
SONCC-HunC.2.2.16.2	*Remove or set back levees and dikes and restore channel form and floodplain connectivity, guided by the plan*					
SONCC-HunC.28.2.27	Roads	Yes	Reduce pollutants and stormflow	Increase regulatory oversight	Population wide	2b
SONCC-HunC.28.2.27.1	*Strengthen city and county ordinances to minimize new impervious surfaces and require treatment to current standards*					
SONCC-HunC.28.2.27.2	*Strengthen city and county ordinances to require treatment to current standards when existing impervious surfaces are expanded, reconditioned, reconstructed or replaced*					
SONCC-HunC.28.2.27.3	*Develop local regulatory mechanisms that reduce amount of total impervious area through incentives*					
SONCC-HunC.28.1.12	Roads	Yes	Reduce sediment delivery to streams	Reduce road-stream hydrologic connection	Prioritize middle and lower reaches of basin, Big South Fork, and all streams where coho salmon would benefit immediately	2b
SONCC-HunC.28.1.12.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-HunC.28.1.12.2	*Decommission roads, guided by assessment*					
SONCC-HunC.28.1.12.3	*Upgrade roads, guided by assessment*					
SONCC-HunC.28.1.12.4	*Maintain roads, guided by assessment*					
SONCC-HunC.28.1.46	Roads	Yes	Reduce sediment delivery to streams	Reduce road-stream hydrologic connection	Population wide	2c
SONCC-HunC.28.1.46.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-HunC.28.1.46.2	*Decommission roads, guided by assessment*					
SONCC-HunC.28.1.46.3	*Upgrade roads, guided by assessment*					
SONCC-HunC.28.1.46.4	*Maintain roads, guided by assessment*					
SONCC-HunC.12.1.28	Agricultural Practices	No	Improve agricultural practices	Improve regulatory mechanisms	Population wide	2b
SONCC-HunC.12.1.28.1	*Determine the best way to revise the Agricultural Water Quality Management Act (AWQMAP) so that it does not limit recovery of SONCC coho salmon and recommend appropriate revisions*					
SONCC-HunC.12.1.28.2	*Ensure basin rules are specific and linked to implementing AWQMAP recommendations, including developing specific standards for riparian buffers*					
SONCC-HunC.12.1.28.3	*Ensure that AWQMA plans address both impaired areas and proactive prevention of water quality impairment*					
SONCC-HunC.12.1.28.4	*Adopt interim buffers equal to the buffer standards NMFS is recommending in Washington state until the state establishes its own buffers*					
SONCC-HunC.12.1.28.5	*Change the complaint-based compliance monitoring process to a focused compliance program*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-HunC.2.2.38	Floodplain and Channel Structure	No	Reconnect the channel to the floodplain	Improve regulatory mechanisms	Population wide	2c
SONCC-HunC.2.2.38.1	*Improve protective regulations for beaver and develop guidelines for relocation that are practical for restoration groups*					
SONCC-HunC.10.2.8	Water Quality	No	Reduce pollutants	Set standard	Population wide	2d
SONCC-HunC.10.2.8.1	*Develop TMDLs for water bodies listed under Clean Water Act Section 303(d)*					
SONCC-HunC.7.1.26	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Increase regulatory oversight	All coho salmon bearing streams	3b
SONCC-HunC.7.1.26.1	*Strengthen city and county ordinances to limit development within the 100 year channel migration zone*					
SONCC-HunC.7.1.26.2	*Strengthen city and county ordinances to limit development within the 50 year flood elevation*					
SONCC-HunC.22.2.25	Urban, Residential, Industrial Development	No	Improve flow timing or volume	Increase instream flows	All streams with ODFW water rights for fish, and all streams where coho salmon would benefit immediately	3b
SONCC-HunC.22.2.25.1	*Secure adequate instream flows to fulfill ODFW water rights for fish*					
SONCC-HunC.22.2.45	Urban, Residential, Industrial Development	No	Improve flow timing or volume	Increase instream flows	Population wide	3d
SONCC-HunC.22.2.45.1	*Secure adequate instream flows to fulfill ODFW water rights for fish*					
SONCC-HunC.7.1.2	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Increase conifer riparian vegetation	Forest federal lands	3c
SONCC-HunC.7.1.2.1	*Develop an appropriate timber harvest management plan for benefits to coho salmon habitat*					
SONCC-HunC.7.1.2.2	*Plant conifers, guided by the plan*					
SONCC-HunC.10.7.40	Water Quality	No	Restore nutrients	Add marine-derived nutrients to streams	All streams where coho salmon would benefit immediately	3c
SONCC-HunC.10.7.40.1	*Develop a plan to supply appropriate amounts of marine-derived nutrients to streams (e.g. carcass placement, pellet dispersal)*					
SONCC-HunC.10.7.40.2	*Supply marine-derived nutrients to streams guided by the plan*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID		*Step Description*				
SONCC-HunC.10.7.41	Water Quality	No	Restore nutrients	Add marine-derived nutrients to streams	Population wide	3d
SONCC-HunC.10.7.41.1		*Develop a plan to supply appropriate amounts of marine-derived nutrients to streams (e.g. carcass placement, pellet dispersal)*				
SONCC-HunC.10.7.41.2		*Supply marine-derived nutrients to streams guided by the plan*				
SONCC-HunC.7.1.3	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Remove invasive species	Lower mainstem	3d
SONCC-HunC.7.1.3.1		*Remove invasive species from lower river riparian zones and replace with conifers or native hardwood species, such as cottonwoods*				
SONCC-HunC.7.1.3.2		*Develop an educational program that teaches local landowners the methods and benefits of restoring riparian stand functions*				
SONCC-HunC.10.2.14	Water Quality	No	Reduce pollutants	Educate stakeholders	Population wide	3d
SONCC-HunC.10.2.14.1		*Develop an educational program that teaches landowners and businesses about avoiding pollution from septic systems, backyard pesticides, fuels, and nutrients*

12. Pistol River Population

Northern Coastal Stratum

Dependent Population

Recovery criteria: 80% of available IP habitat must be occupied in years following spawning of brood years with high marine survival

Habitat likely available to support all life stages

93 mi^2 watershed (57% Federal ownership)

30 IP-km (19 IP-mi) (23% High)

Dominant Land Uses are 'Timber Harvest' and 'Agriculture'

Key Limiting Stresses are 'Lack of Floodplain and Channel Structure' and 'Degraded Riparian Forest Conditions'

Key Limiting Threats are 'Roads', and 'Timber Harvest'

Highest Priority Recovery Actions

• Construct off-channel habitats, alcoves, backwater habitat, and old stream oxbows • Improve timber harvest practices by revising Oregon Forest Practices Act • Reduce sediment delivery to streams from roads	• Improve grazing practices • Decommission, upgrade, or maintain roads • Increase beaver abundance

12.1 History of Habitat and Land Use

The relevant history of the Pistol River is described in the Pistol River Watershed Analysis (U.S Forest Service [USFS] 1998b) and the Pistol River Watershed Assessment (Maguire 2001e), which are the basis of this summary. Early settlers likely diminished the habitat capacity of the two lower river tributaries, which no longer have recognizable channels. Two ranches in the grassy meadows near the lower river have been in continuous grazing since that time.

Long-time residents remember a river too cold to swim in most of the summer, before intensive timber harvest began in the 1950s (Maguire 2001e). The 1955 flood carried sediment that filled the lower river, which had previously been the site of major salmon spawning. Where the lower Pistol River had been a sequence of riffles and deep corner pools, it became a series of long riffles with small, shallow pools. Tributaries like Deep Creek were changed by repeated debris torrents after timber harvest, but local residents report prior use by 300 to 400 spawning salmon (Maguire 2001e). These same observers note that the river's flood flows rise and fall much more quickly than before timber harvest and that base flow conditions appear greatly reduced. The mouth of the river now opens later in the fall than it used to. Local residents used to breach the sand berm at the mouth of the Pistol River, but that is no longer allowed (Maguire 2001e).

Private industrial timber land ownership covers 30 percent of the basin and lies between the federally managed land in the upper basin and the ranchland in the lower valley.

Since the Northwest Forest Plan (US Department of Agriculture [USDA] and US Department of the Interior [USDI] 1994) was adopted, there has been a very low level of timber harvest in the Pistol River basin on USFS and BLM lands. Streams in these upper tributaries have started to recover. Private industrial timber harvest is active in the western portion of the Pistol River basin, including much of the South Fork, where harvest rotations are 30 to 50 years.

The intensity of grazing in the lower Pistol River has undoubtedly decreased since a cheese factory located in the lower basin ceased operation in the 1960s, but fields still constrain the lower river channel and occupy its floodplain. Residential development has occurred in the lower Pistol River, but not to the same degree as other southwest Oregon streams like Hunter Creek and the lower Chetco River. Widespread restoration efforts over the last decade have had mixed success (Swanson 2005).

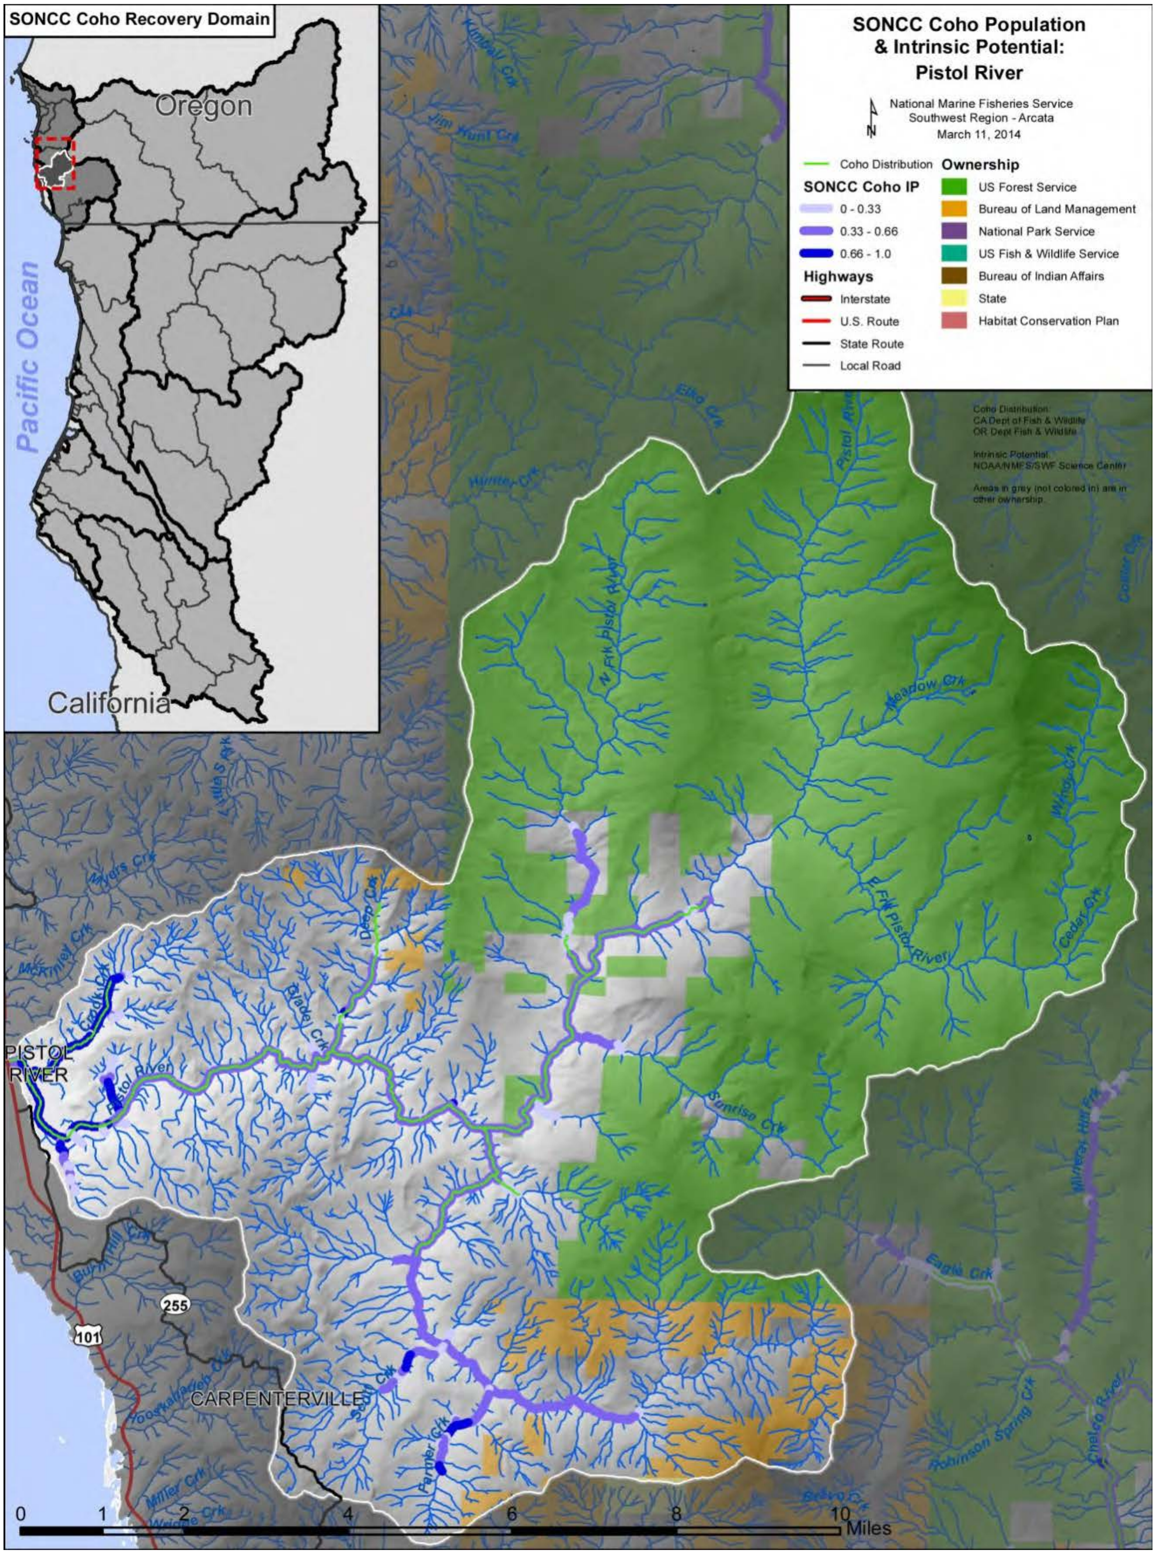

Figure 12-1. The geographic boundaries of the Pistol River coho salmon population. Figure shows modeled Intrinsic Potential of habitat (Williams et al. 2006), land ownership, coho salmon distribution (ODFW 2013a), and location within the Southern-Oregon/Northern California Coast Coho Salmon ESU and the Northern Coastal diversity stratum (Williams et al. 2006). Grey areas indicate private ownership.

12.2 Historic Fish Distribution and Abundance

The steep headwaters of the upper Pistol River prevent coho salmon access very far up major tributaries except in the South Fork (Maguire 2001e). Modeling by Williams et al. (2006) found high intrinsic potential (IP >0.66) habitat for coho salmon in the lower mainstem Pistol River, estuarine tributary Crook Creek and two unnamed tributaries of the lower river. Additionally, flat reaches in Deep Creek, and South Fork Pistol River tributaries, Farmer and Scott creeks, have patches of high IP (Table 12-1). The two unnamed tributaries of lower Pistol River are not found on U.S. Geological Survey (USGS) 1:24000 topographic map (USGS 1989) and no longer have recognizable stream channels when examined using aerial photos; therefore, they are not listed in Table 12-1. Pistol River had sufficient capacity before disturbance to provide possible refugia for smaller nearby populations and a modest source of colonists to adjacent smaller streams, such as Hunter Creek.

Table 12-1. Tributaries with high IP reaches (IP > 0.66) (Williams et al. 2006).

Stream Name	Stream Name	Stream Name
Crook Creek	Farmer Creek	Pistol River Estuary
Deep Creek	Lower Pistol River	Scott Creek

12.3 Status of Pistol River Coho Salmon

Spatial Structure and Diversity

Much of the high IP in the lower mainstem Pistol River and its tributaries is presently unsuitable for coho salmon spawning or rearing. Some low gradient tributaries of the lower river are only partially degraded, but others have been completely lost. Although coho salmon population levels are low, spawning still occurs in the mainstem Pistol River up to the East Fork Pistol, in Crook Creek and Deep Creek, in lower North Fork Pistol River, and in the lower South Fork Pistol River including its tributary Koontz and Davis Creek (Figure 12-1). The Oregon Department of Fish and Wildlife (ODFW; 2005a) conducted a total of 14 snorkel surveys at sites in the Pistol River basin from 2002 to 2004. They found juvenile coho salmon in 3 of 11 reaches (6 of 352 pools) sampled, all at very low levels of ≤0.001 coho/m^2, including in the lower South Fork and two mainstem Pistol River reaches upstream of the North Fork Pistol River. Pistol River coho salmon are still well distributed but persisting at low levels, which is likely diminishing genetic diversity.

Population Size and Productivity

Although ODFW (2005a) found coho salmon juveniles in each year of their surveys between 2002 and 2004, they were found only at extremely low levels. Coho salmon are only intermittently present in Crook Creek (Swanson 2005), a formerly productive tributary. Population estimates for 1998 to 2008 for south coast Oregon coho salmon were provided by ODFW (2009a). They estimated escapement in the Pistol River as 78 coho salmon in 1999, 155 in 2000, 118 in 2002, and zero in all the other years. The lack of consistent spawner returns within year classes and the absence of some year classes indicate very low productivity in the Pistol River. Because there is no information on ODFW survey effort, some qualification of these results is required. If surveys were only in lower river tributaries, then coho salmon that spawned in upper basin tributaries would not have been counted. Similarly, in high flow years, counts may be difficult or impossible. Consequently, the population may be somewhat larger than estimated and there may have been some coho salmon adults in years when the population estimate was zero. The productivity and size of this population is driven not only by the dynamics of the Pistol River population, but by those of nearby populations as well, which contribute spawners as strays. However, the supply of strays to Pistol River is not expected to be substantial or consistent in the near term because most adjacent populations in the SONCC coho salmon ESU are at low levels.

Extinction Risk

Not applicable because the Pistol River is not an independent population.

Role in SONCC Coho Salmon ESU Viability

Although dependent populations such as the Pistol River are not viable on their own, they do increase connectivity by allowing dispersal among independent populations and provide areas of refugia for other populations, acting as a source of colonists in some cases. The Pistol River may have been a source of colonists to nearby dependent populations, such as Hunter Creek. Any restored habitat in Pistol River provides potential connectivity that assists metapopulation function in the SONCC ESU.

12.4 Plans and Assessments

State of Oregon

Oregon Plan for Salmon and Watersheds
http://www.oregon.gov/OPSW/about_us.shtml

The State of Oregon developed a conservation and recovery strategy for coho salmon in the SONCC and Oregon Coast ESUs (State of Oregon 1997). The Oregon Plan for coho salmon is a comprehensive plan that includes voluntary actions to address all of the threats currently facing coho salmon in these ESUs and involves all relevant state agencies. Reforms to fishery harvest and hatchery programs described in the Oregon Plan were implemented by ODFW in the late 1990s. Many habitat restoration projects have occurred across the landscape in headwater habitat, lowlands, and the estuary.

Report of the Oregon Expert Panel on Limiting Factors

ODFW (2008b) convened a panel of fisheries and watershed science experts as an initial step in their development of a recovery plan for Oregon's SONCC coho salmon populations. Deliberations of the expert panel provided ODFW with initial, strategic guidance on limiting factors and threats to recovery. Based on the input of panel members, ODFW (2008b) summarized the concerns for the Pistol River population as follows:

> Key concerns in the Pistol River were a loss of over-winter tributary habitat complexity and floodplain connectivity for juveniles, especially in the lowlands

which are naturally very limited in these systems and have been impacted by past and current urban, rural residential, and forestry development and practices. High water temperatures for summer parr due to a loss of riparian function and channel straightening is also a key concern in these streams. The secondary concern was related to a loss of over-winter, lowland habitat complexity due to past and current agricultural practices.

Cumulative Effects of Southwest Oregon Coastal Land Use on Salmon Habitat

Oregon State University (OSU) Oak Creek Labs conducted a study funded by ODFW and the Oregon Department of Forestry (ODF) to determine relationships between forest harvest and Pacific salmon productivity (Frissell 1992). The study assessed basins along the Oregon coast extending from the Sixes River to the southern border during the period from 1986 to 1992.

Curry County Soil and Water Conservation District

Pistol River Package Monitoring Report

The Pistol River Package Monitoring Report (Swanson 2005) describes conditions in the Pistol River after numerous basin enhancements were carried out, including large wood placement, fish passage improvements, riparian fencing and planting, rock weirs, and bio-engineered bank stabilization structures.

South Coast Watershed Council (Pistol River Watershed Council)

Pistol River Watershed Assessment

This assessment (Maguire 2001e) summarizes conditions, historic changes and restoration needs in the Pistol River basin. Community concerns, salmonid habitat, limiting factors, and prospects for recovery of fisheries and watershed health are included.

Pistol River Action Plan

The Pistol River Action Plan (Massingill 2001e) is a companion to Maguire (2001e), and proposes specific targets for restoration.

United States Forest Service

Pistol River Watershed Analysis

The Pistol River Watershed Analysis was written by the USFS (1998b) in accordance with the Northwest Forest Plan (USDA and USDI 1994) and sets a course of restoration for their ownership in the Pistol River. Planned activities include road decommissioning, hardwood thinning and conifer planting in riparian zones and combating the spread of Port Orford root disease in the watershed.

12.5 Stresses

Table 12-2. Severity of stresses affecting each life stage of coho salmon in the Pistol River. Stress rank categories, assessment methods, and data used to assess stresses are described in Appendix B.

	Stresses[2]	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Stress Rank
1	Lack of Floodplain and Channel Structure[1]	High	Very High	Very High[1]	Very High	High	Very High
2	Degraded Riparian Forest Conditions[1]	-	Very High	Very High[1]	High	High	Very High
3	Altered Sediment Supply	Very High	Very High	Very High	High	High	Very High
4	Impaired Water Quality	Medium	High	Very High	High	Low	High
5	Altered Hydrologic Function	High	High	High	High	Low	High
6	Impaired Estuary/Mainstem Function	-	Low	Very High	High	Medium	High
7	Barriers	-	Low	Low	Low	Low	Low
8	Adverse Hatchery-Related Effects	Low	Low	Low	Low	Low	Low
9	Adverse Fishery- and Collection- Related Effects	-	-	Low	Low	Low	Low

[1]Key limiting stresses and limited life stage.
[2]Increased Disease/Predation/Competition is not considered a stress to this population.

Key Limiting Stresses, Life Stages, and Habitat

The upper South Fork Pistol River above Farmer Creek may provide coho salmon refugia because it has suitable gradient, cool water temperatures, and pools greater than 1 meter deep; however, there are no data documenting coho presence in that reach. Otherwise there are currently no functioning coho salmon refugia in the Pistol River or its tributaries. Crook Creek is too warm at its convergence with the mainstem to support coho salmon (Maguire 2001e) and Deep Creek has excessive amounts of fine sediment (Swanson 2005).

The juvenile life stage is most limited and quality winter rearing habitat, as well as summer rearing habitat, is lacking as vital habitat for the population. Juvenile summer rearing habitat is impaired by an excess of fine sediment, which has filled in the mainstem, tributary channels, and the estuary, and contributes to high water temperature. Lack of floodplain and channel structure due to channelization and filling of the floodplain has eliminated much of the coho salmon rearing habitat in the basin. Winter rearing habitat is often formed by instream large wood, but is also found in estuaries and floodplain wetlands. Degraded riparian conditions have eliminated the source of large wood recruitment and floodplain wetlands have been filled or disconnected from the river. Overall, these findings are consistent with those of the Oregon Expert Panel (Section 12.4), except that the expert panel did not consider excess sediment to be a concern.

Lack of Floodplain and Channel Structure

Long-time lower Pistol River residents described the transformation of the channel from one with well-developed deep pools joined by short riffles to one dominated by riffles with few pools of limited depth (Maguire 2001e). High fine sediment load and bedload movement inhibit channel recovery and also creates adverse conditions for eggs because redds are scoured out or deposits smother eggs and prevent fry emergence.

Before disturbance, the Pistol River riparian zone was comprised of large conifers that lived hundreds of years and then fell into streams, forming pools and complex habitats with which coho salmon co-evolved. Large wood was swept from many mainstem and tributary channels in the 1955 and 1964 floods, which lead to a loss of habitat complexity. Current large wood recruitment is also low. Large wood surveys by ODFW show that all Pistol River reaches have poor levels of large wood (<1 key piece per 100m). USFS large wood surveys found very good levels of large wood in the upper East Fork Pistol River, North Fork Pistol River, and Sunrise Creek on USFS lands, but these streams are largely inaccessible to coho salmon.

Disconnection of the lower Pistol River and estuary from its floodplain and confinement of its channel (Figure 12-2) are major impediments to lower river recovery. Lower Crook Creek has high IP, but its lower reaches are channelized also.

ODFW and USFS habitat data indicate that in the mainstem Pistol River, pool frequencies are greater than 35 percent, which they rate as good. An upper East Fork Pistol River reach, lower Meadow Creek, and the South Fork tributary Koontz and Davis Creek all had poor ratings (<10 percent pools). Pool frequency is only fair (10 to 25 percent) in the lower North Fork, lower Sunrise Creek, Deep Creek, and South Fork tributaries including Scott Creek.

Pool depth of greater than one meter (3.3 ft.) is rated as good by ODFW, and on that basis the South Fork and mainstem Pistol River below the East Fork have good pool depth. However, the Pistol River formerly had pools that were up to 20 feet deep (Maguire 2001e).

Figure 12-2. Aerial photo of Pistol River showing confinement by a levee. The levee separates the active channel from adjacent farm and industrial gravel operation to the west (left). The levees also cut off the river from oxbows and meanders on the east bank (right), which would have formerly created ideal coho salmon rearing areas. Yellow arrows highlight pockets of residential development.

Degraded Riparian Forest Conditions

ODFW surveys found fewer than 75 conifers greater than 36” in diameter per 1000 ft. on the South Fork Pistol River, mainstem Pistol River downstream of the East Fork, Sunrise Creek, and Deep Creek. This low density of large trees in the riparian zone has led to poor bank structure, reduced shade, and reduced thermal and nutrient buffering. The riparian zone of the mainstem Pistol River is predominantly hardwood trees (Figure 12-3), with very few large conifers. Willow and alder are the most abundant species in the alluvial valleys, although cottonwoods were once a significant part of the riparian community (Maguire 2001e). High bedload transport in the lower Pistol River is likely causing high mortality of both conifers and alders, because these species die if their root systems are buried.

Figure 12-3. Photo of the lower mainstem Pistol River. The river has a willow and alder riparian zone. Note also excess sediment and lack of channel structure.

Altered Sediment Supply

Sediment contribution from landslides and erosion occurs naturally in the Pistol River basin; however, roads, timber harvest, and bank erosion following removal of riparian vegetation have elevated fine sediment input. For example, debris torrents in 2003 covered large wood restoration projects with approximately 100,000 to 200,000 cubic yards of sediment in lower Deep Creek (Swanson 2005). Debris flows significant enough to alter channel structure occurred in the South Fork Pistol River and upper mainstem Pistol River in 1996 (Maguire 2001e). Excess fine sediment directly impacts coho salmon egg viability and can reduce food for fry, juveniles and smolts. Poor pool frequency and depth throughout the Pistol River basin (Maguire 2001e) is likely due to elevated levels of fine sediment partially filling pools, a lack of scour-forcing obstructions such as large wood, and in some reaches diminished scour due to channel widening.

Figure 12-4. Photo of Pistol River estuary. View is looking downstream from the Pistol River Road bridge. The large gravel bars occupy a formerly deep channel here, suggesting excess fine sediment.

Impaired Water Quality

The mainstem Pistol River is listed under the Clean Water Act Section 303(d) for impaired temperature and dissolved oxygen from the mouth upstream to RM 19.8, and the lower half mile of the South Fork is also listed as temperature impaired. Maguire (2001e) reported that the ODEQ maximum floating weekly maximum temperature (MWMT) threshold for impairment of 64 °F was exceeded at all stations measured, indicating lack of suitability for coho salmon rearing; however, there are a few additional stations/years in the ODEQ LASAR database (see Appendix B) with temperatures below the 64 °F threshold: Glade Creek at mouth, upper Farmer Creek, South Fork Pistol River at upper crossing, Deep Creek at mouth (2 of 8 years), and North Fork Pistol River near mouth (1 of 6 years). Figure 12-5 shows water temperatures for the Pistol River from 1995 to 2000 as reported by Maguire (2001e). The lower East Fork Pistol River and Deep Creek are almost cool enough to provide suitable coho salmon habitat. Lower reaches of the North Fork and the upper mainstem Pistol River are showing improvement (65 °F to 69 °F), but the South Fork is much too warm to support coho salmon (71.4 °F to 72.8 °F). Lower mainstem Pistol River temperatures are also too warm (71.8 °F -75 °F). The Pistol River warms 2 to 4 °F between the East Fork Pistol and South Fork Pistol (Maguire 2001e).

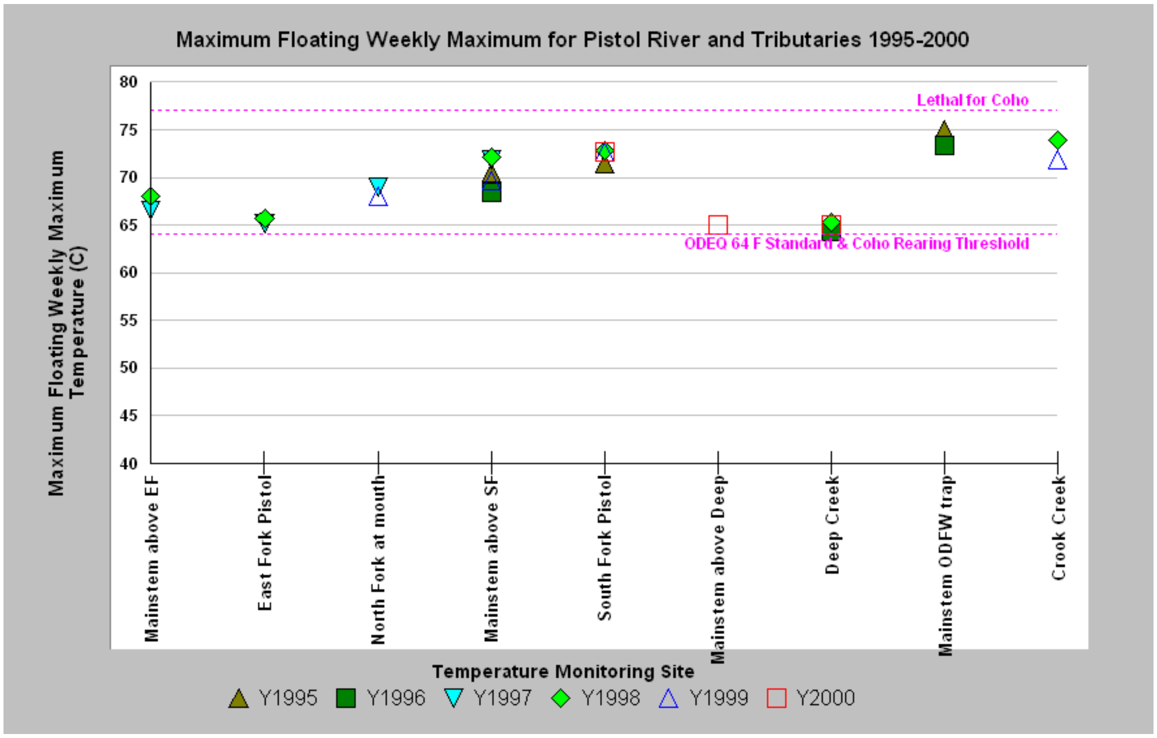

Figure 12-5. Maximum floating weekly maximum water temperatures for the Pistol River. Data includes tributaries and shows a pattern of exceeding coho salmon rearing requirements (McCullough 1999) and ODEQ standards (64 °F). The lethal temperature reference value of 77 °F is from Sullivan et al. (2000).

Water quality in the Pistol River is also compromised by low dissolved oxygen (DO) levels. The low DO levels are likely due to stagnation and to algal blooms, which are encouraged by excess nutrients and lack of shade. There are seasonal problems with elevated phosphorous, *E. coli* and biological oxygen demand (Maguire 2001e).

Altered Hydrologic Function

Changes in Pistol River basin hydrology have led to a substantial decrease in available habitat for coho salmon, resulting in a high level of stress for most life stages. Excess fine sediment blocks surface and groundwater interactions by clogging interstitial spaces of stream gravels that are known to help maintain cool temperatures. This type of connection likely created cold water strata at depth in the deeper pools that were formerly common, even when surface waters were warm. Some Pistol River Watershed Council members believe that the summer base flows have also diminished (Maguire 2001e). Studies elsewhere in the Pacific Northwest indicate that converting forest stands of fewer large trees to ones with many small trees can decrease base flows for several decades (Murphy 1995).

The hydrology of the lower basin has been substantially altered through disconnection of the floodplain and channelization. High road densities in some Pistol River watersheds are likely to lead to increased peak flows. These peak flows can scour eggs and flush fry, juveniles, and smolts from the river system.

Impaired Estuary/Mainstem Function

The Pistol River estuary retains little of its historic form or function and provides little opportunity for estuarine rearing. Studies elsewhere in Oregon found that estuarine tributaries and sloughs can be important habitat types for rearing coho salmon juveniles (Koehler and Miller 2003, Miller and Sadro 2003). The remnants of past estuarine habitat indicate the Pistol River estuary was formerly large with numerous tributaries, tidal channels, and likely tidal wetlands. The diking and filling for conversion to agricultural uses has completely eliminated these habitats. Lack of riparian vegetation in the estuary and the accretion of fine sediment have led to highly degraded water quality and habitat conditions. Long-time residents remember pools up to 20 feet deep, while ODFW 1991 habitat data indicated a mean pool depth of only 3.3 feet in the lowermost Pistol River reach (Maguire 2001e). Long-time residents noted a decrease in estuarine use by smelt, which is likely due to a change in seasonality of the opening of the mouth. Crook Creek, the largest estuary tributary, loses surface flow during the summer for its last 500 feet (Swanson 2005), seasonally preventing fish use of this important rearing stream. Highway 101 bisects the estuary near the mouth of the river, constraining the estuary and preventing full tidal inundation upstream. The estuary to the west of Highway 101 encompasses a fair amount of sand and mudflat habitat that could be used for rearing, but it lacks complex habitat features such as large wood or deep pools. Reduced estuarine function poses an overall high stress to Pistol River coho salmon.

Barriers

Although road densities in the Pistol River basin are high, which increases risk of passage problems, coho salmon still have access to most of the basin (Maguire 2001e). The dry reach at the mouth of Crook Creek (Swanson 2005) is a seasonal barrier to juveniles. A major passage problem into Deep Creek has been resolved by replacing a culvert with a bridge (Swanson 2005). Consequently, barriers represent a low stress.

Adverse Hatchery-Related Effects

Hatchery-origin coho salmon may stray into Pistol River; however, the proportion of adults that are of hatchery origin is likely less than five percent and there is no hatchery in the basin producing other species of salmonids. Therefore, adverse hatchery-related effects pose a low risk to all life stages.

Adverse Fishery- and Collection-Related Effects

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low stress to juveniles, smolts, and adults.

12.6 Threats

Table 12-3. Severity of threats affecting each life stage of coho salmon in the Pistol River. Threat rank categories, assessment methods, and data used to assess threats are described in Appendix B.

	Threats[2]	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Threat Rank
1	Roads[1]	High	Very High	Very High[1]	Very High	Very High	Very High
2	Timber Harvest[1]	Very High	Very High	Very High[1]	Very High	Medium	Very High
3	Channelization/Diking	Medium	Very High	Very High	Very High	Very High	Very High
4	Agricultural Practices	Low	Medium	High	High	High	High
5	Dams/Diversion	Low	Medium	Medium	Medium	Low	Medium
6	Urban/Residential/Industrial Dev.	Low	Medium	Medium	Medium	Medium	Medium
7	High Severity Fire	Low	Medium	Medium	Medium	Medium	Medium
8	Climate Change	Low	Low	Medium	Medium	Medium	Medium
9	Mining/Gravel Extraction	Low	Low	Low	Low	Low	Low
10	Road-Stream Crossing Barriers	-	Low	Low	Low	Low	Low
11	Hatcheries	Low	Low	Low	Low	Low	Low
12	Fishing and Collecting	-	-	Low	Low	Low	Low

[1]Key limiting threats and limited life stage.
[2]Invasive and Non-Native/Alien Species is not considered a threat to this population.

Key Limiting Threats

The two key limiting threats, those which most affect recovery of the population by influencing stresses, are roads and timber harvest.

Roads

Roads pose an overall very high threat to the Pistol River coho salmon population. There are high road densities (2.5 to 3.0 mi/mi^2) in the South Fork Pistol River and very high densities (>3.0 mi/mi^2) in the Upper and Lower Pistol River. Road densities are medium (1.6-2.5 mi/mi^2) in the East Fork Pistol River, North Fork Pistol River, and in mainstem watersheds between the East Fork and South Fork Pistol River. Additionally there is a high number of road stream crossings, streamside roads, and many road segments that cross steep unstable slopes or erodible soils. These conditions all pose a risk of elevated fine sediment yield. Road density estimates are conservative because they do not include skid roads, landings, or temporary roads. The main timber harvest haul road along the Pistol River has initiated large landslides (Maguire 2001e). A main haul road also follows the South Fork Pistol River.

Timber Harvest

Timber harvest poses an overall very high threat to the coho salmon population. Private industrial timber lands managed under the Oregon Forest Practices Act occupy 30 percent of the landscape, but they coincide with nearly all the low gradient intrinsic potential streams. Therefore, these lands have a disproportionate effect on coho salmon. The high harvest rates and associated roads negatively impact multiple aspects of coho salmon habitat. Deep Creek is an example of where short timber harvest rotations are likely inhibiting channel and coho salmon recovery.

Studies of adjacent southwest Oregon basins found that "downstream, cumulative impacts of human activity are pervasive in southwest Oregon, wherever logging has occurred over an extensive portion of a drainage basin or has involved operations on steep, unstable slopes. The downstream effects of channel sedimentation and aggradation can severely damage streams even where buffer zones of riparian vegetation have been retained, and such effects persist more than 20-30 years after logging activities have ceased" (Frissell 1992).

Channelization/Diking

Channelization and diking have occurred in high IP reaches in the lower tributaries, along the lower mainstem, and in the estuary. Crook Creek had ideal gradient and valley width for coho salmon, but the channel has been straightened and greatly reduced in complexity (Figure 12-6). The lower mainstem and estuary have been similarly channelized and disconnected from the floodplain and adjacent wetlands. Roads that follow the river or tributaries may cut them off from their floodplains as well.

Agricultural Practices

The same farms and ranches have operated in the lower river for well over 100 years and levels of grazing are likely not as high as they were in the past. Nonetheless, long term activities have led to the disconnection of the lower Pistol River and estuary from floodplains (Figure 12-2). Lower Pistol River tributaries have also been profoundly altered; two unnamed tributaries with high IP now have unrecognizable channels. Crook Creek has also been straightened and disconnected from its floodplain (Figure 12-6), but landowners have been trying to restore it (Swanson 2005). The negative effects of pesticides and herbicides on Pacific salmon species and aquatic ecosystem function are becoming more well documented regionally (National Marine Fisheries Service (NMFS) 2008, Laetz et al. 2009), but the extent of use of these chemicals by Pistol River farms and ranches is unknown.

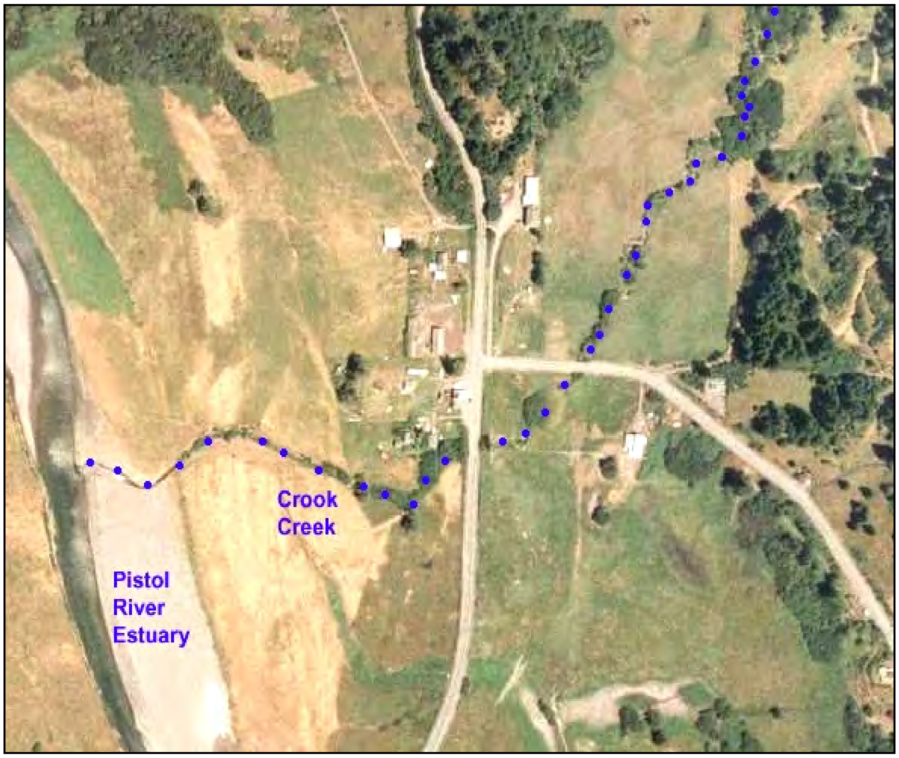

Figure 12-6. Photo of Crook Creek joining the Pistol River estuary. Convergence is at center left. The creek's channel is straightened and confined. It also lacks a functional riparian zone.

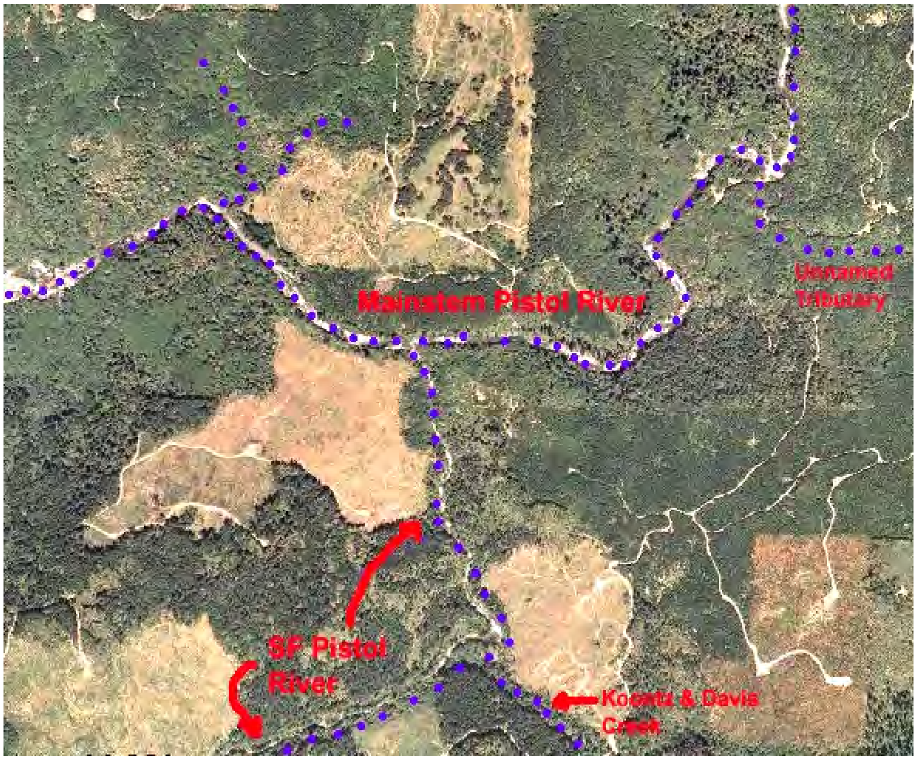

Figure 12-7. Photo of the mainstem Pistol River and the South Fork. Also shown is lower tributary Koontz and Davis Creek. Note extensive clear cuts and high road density.

Dams/Diversions

There are no known dams on the Pistol River. The Oregon Water Resources Department has a Pistol River instream water right of 15 cfs (Maguire 2001e). The sum of the diversion water rights in the Pistol River basin is 1.5 cfs, primarily for agricultural use, but only 0.1 cfs of this is senior to the instream right (Maguire 2001e). The effects of water diversions on coho salmon in the Pistol River basin are not well understood. Crook Creek, an important coho salmon tributary, loses surface flow at the downstream end of an agricultural area. However, the contribution of diversions to the dry creek condition is unknown A potentially significant contributor to the diminished flow in the Pistol River is the aggradation of the stream bed, with more flow now sub-surface.

Urbanization/Residential/Industrial Development

Both commercial and residential development is occurring in the sensitive lower river and estuary. This area once held some of the most productive coho salmon habitats.

High Severity Fire

High severity fires in this basin pose a medium threat to this coho salmon population. The Pistol River is very near the coast and has moderate air temperatures and high rainfall. Consequently, it should have naturally low fire risk; however, hot (100 °F) 35 mph east winds occur seasonally, which can cause extreme seasonal fire risk (Maguire 2001e). Large areas of the Pistol River basin are presently covered by even-aged plantations and hardwoods that elevate fire risk. Sudden oak death syndrome is known to occur in the adjacent North Fork Chetco basin (Oregon Department of Agriculture (ODA) 2008) and could become a significant contributor to increased fire risk if it causes mortality of tanoaks in the Pistol River basin.

Climate Change

There is low risk of average temperature increase over the next 50 years (Appendix B). Modeled regional average temperature shows a moderate increase over the next 50 years (Appendix B). Average temperature could increase by up to 1 °C in the summer and by a similar amount in the winter. The risk of sea level rise is also low (Appendix B, Thieler and Hammer-Klose 2000). Adults may be negatively impacted by climate-related ocean acidification, changes in ocean conditions, and prey availability (see Independent Science Advisory Board 2007, Feely et al. 2008, Portner and Knust 2007). Overall, climate change poses a medium threat to the population.

Mining/Gravel Extraction

Mining poses a low threat to the coho salmon population. Pistol River does not have geologic formations that bear gold and so was spared mining impacts that were experienced by interior basins of the Rogue River. Gravel mining can inhibit channel recovery by flattening the stream's profile upstream and downstream from the point of extraction. The Sixes River company gravel permit for operation in the Pistol River has expired and there is no prospect of gravel mining activity in the near future (Wheeler 2009).

Road-Stream Crossing Barriers

Road-stream crossing barriers pose a low threat to the coho salmon population. Although there are many road-stream crossings on private industrial timber lands in the western Pistol River basin, many are well above the range of coho salmon. Maguire (2001e) and the ODFW (2008e) fish passage database do not indicate that road-stream crossing barriers are a significant problem for coho salmon distribution in the Pistol River basin.

Hatcheries

Hatcheries pose a low threat to all life stages of coho salmon in the Pistol River population area. The rationale for these ratings is described under the “Adverse Hatchery-Related Effects” stress

Fishing and Collecting

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low threat to juveniles, smolts, and adults.

12.7 Recovery Strategy

The most immediate need for habitat restoration and threat reduction in the Pistol River is in those areas currently occupied by coho salmon in mainstem Pistol River, Crook Creek, Deep Creek, North Fork Pistol River, South Fork Pistol River, and Koontz and Davis Creek. Unoccupied areas must also be restored to provide enough habitat for coho salmon recovery, and the places with the greatest chance of success are those with high IP, such as the lower mainstem Pistol River, the estuary, Crook Creek, Deep Creek, Scott Creek, and Farmer Creek.

The Pistol River population is considered dependent and therefore cannot be viable on its own; however, it is necessary to restore habitat within the basin so that it can support all life stages of coho salmon and provide connectivity between other populations in the ESU. The recovery criterion for this population is that 80% of available IP habitat must be occupied in years following spawning of brood years with high marine survival.

The most important factor limiting recovery of coho salmon in the Pistol River is a deficiency in the amount of suitable rearing habitat for juveniles. The processes that create and maintain such habitat must be restored by increasing habitat complexity within the channel, re-establishing off-channel rearing areas, restoring riparian forests, and reducing threats to instream habitat. The effects of fishing on this population’s ability to meet its viability criteria should be evaluated.

Table 12-4 on the following page lists the recovery actions for the Pistol River population.

Table 12-4. Recovery action implementation schedule for the Pistol River population. Recovery actions for monitoring and research are listed in tables at the end of Chapter 5.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-PisR.19.3.3	Timber Harvest	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve timber harvest practices	All areas where coho salmon would benefit immediately	2b
SONCC-PisR.19.3.3.1	*Determine how to revise Oregon Forest Practice Rules so that they do not limit recovery of SONCC coho salmon and make appropriate revisions*					
SONCC-PisR.19.3.3.2	*Adopt rules for fish-bearing streams sufficient to protect both water quality and fish habitat*					
SONCC-PisR.19.3.3.3	*Adopt rules to increase protection of non-fish-bearing streams that address practices that adversely impact water quality and fish habitat*					
SONCC-PisR.19.3.3.4	*Ensure management measures for landslide prone areas include protection of water quality and fisheries habitat*					
SONCC-PisR.19.3.3.5	*Until more permanent regulatory mechanisms can be put in place, immediately adopt interim rules that increase protection for salmon habitat in forested areas, including increased natural recruitment of large wood on perennial and intermittent streams likely to deliver wood downstream, increased shade on all perennials, and protective buffers on small intermittent streams.*					
SONCC-PisR.19.3.40	Timber Harvest	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve timber harvest practices	Population wide	2c
SONCC-PisR.19.3.40.1	*Determine how to revise Oregon Forest Practice Rules so that they do not limit recovery of SONCC coho salmon and make appropriate revisions*					
SONCC-PisR.19.3.40.2	*Adopt rules for fish-bearing streams sufficient to protect both water quality and fish habitat*					
SONCC-PisR.19.3.40.3	*Adopt rules to increase protection of non-fish-bearing streams that address practices that adversely impact water quality and fish habitat*					
SONCC-PisR.19.3.40.4	*Ensure management measures for landslide prone areas include protection of water quality and fisheries habitat*					
SONCC-PisR.19.3.40.5	*Until more permanent regulatory mechanisms can be put in place, immediately adopt interim rules that increase protection for salmon habitat in forested areas, including increased natural recruitment of large wood on perennial and intermittent streams likely to deliver wood downstream, increased shade on all perennials, and protective buffers on small intermittent streams.*					
SONCC-PisR.2.2.6	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Lower mainstem, estuary, Crooks Creek, and all streams where coho salmon would benefit immediately	2b
SONCC-PisR.2.2.6.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-PisR.2.2.6.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-PisR.2.2.41	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Population wide	2c
SONCC-PisR.2.2.41.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-PisR.2.2.41.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-PisR.2.2.7	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	All streams where coho salmon would benefit immediately	2b
SONCC-PisR.2.2.7.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for land owners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-PisR.2.2.7.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-PisR.2.2.7.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					
SONCC-PisR.2.2.42	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	Population wide	2c
SONCC-PisR.2.2.42.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for land owners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-PisR.2.2.42.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-PisR.2.2.42.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					
SONCC-PisR.28.1.4	Roads	Yes	Reduce sediment delivery to streams	Reduce road-stream hydrologic connection	Population wide; prioritize upper South Fork Pistol River and Crook, Deep, Farmer, and Scott creeks	2b
SONCC-PisR.28.1.4.1	*Assess and prioritize road-stream connection, and identify appropriate treatments*					
SONCC-PisR.28.1.4.2	*Decommission roads, guided by assessment*					
SONCC-PisR.28.1.4.3	*Upgrade roads, guided by assessment*					
SONCC-PisR.28.1.4.4	*Maintain roads, guided by assessment*					
SONCC-PisR.12.1.26	Agricultural Practices	No	Improve agricultural practices	Improve regulatory mechanisms	Population wide	2b
SONCC-PisR.12.1.26.1	*Determine the best way to revise the Agricultural Water Quality Management Act (AWQMAP) so that it does not limit recovery of SONCC coho salmon and recommend appropriate revisions*					
SONCC-PisR.12.1.26.2	*Ensure basin rules are specific and linked to implementing AWQMAP recommendations, including developing specific standards for riparian buffers*					
SONCC-PisR.12.1.26.3	*Ensure that AWQMA plans address both impaired areas and proactive prevention of water quality impairment*					
SONCC-PisR.12.1.26.4	*Adopt interim buffers equal to the buffer standards NMFS is recommending in Washington state until the state establishes its own buffers*					
SONCC-PisR.12.1.26.5	*Develop a process in the AWQMA Program that tracks and evaluates implementation*					
SONCC-PisR.12.1.26.6	*Change the complaint-based compliance monitoring process to a focused compliance program*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-PisR.7.1.22	Riparian	No	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	Private lands and all areas where coho salmon would benefit immediately	2b
SONCC-PisR.7.1.22.1	*Assess grazing contribution to sediment delivery, pollutants, and impaired riparian conditions*					
SONCC-PisR.7.1.22.2	*If problems are identified, develop and implement grazing management strategy that decreases delivery of sediment and pollutants to streams and improves riparian condition*					
SONCC-PisR.7.1.22.3	*Monitor effectiveness of grazing management to ensure grazing does not limit recovery of SONCC coho salmon*					
SONCC-PisR.7.1.45	Riparian	No	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	Population wide	2c
SONCC-PisR.7.1.45.1	*Assess grazing contribution to sediment delivery, pollutants, and impaired riparian conditions*					
SONCC-PisR.7.1.45.2	*If problems are identified, develop and implement grazing management strategy that decreases delivery of sediment and pollutants to streams and improves riparian condition*					
SONCC-PisR.7.1.45.3	*Monitor effectiveness of grazing management to ensure grazing does not limit recovery of SONCC coho salmon*					
SONCC-PisR.28.2.25	Roads	No	Reduce pollutants and stormflow	Increase regulatory oversight	Population wide	2b
SONCC-PisR.28.2.25.1	*Strengthen city and county ordinances to minimize new impervious surfaces and require treatment to current standards*					
SONCC-PisR.28.2.25.2	*Strengthen city and county ordinances to require treatment to current standards when existing impervious surfaces are expanded, reconditioned, reconstructed or replaced*					
SONCC-PisR.28.2.25.3	*Develop local regulatory mechanisms that limits development and reduces amount of total impervious area through incentives*					
SONCC-PisR.7.1.2	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve long-range planning	Private land	2c
SONCC-PisR.7.1.2.1	*Review General Plan or County Ordinances to ensure coho salmon habitat needs are accounted for. Revise if necessary*					
SONCC-PisR.7.1.2.2	*Develop watershed-specific guidance for managing riparian vegetation. Consider larger riparian buffers in coho occupied habitat*					
SONCC-PisR.2.2.35	Floodplain and Channel Structure	No	Reconnect the channel to the floodplain	Improve regulatory mechanisms	Population wide	2c
SONCC-PisR.2.2.35.1	*Improve protective regulations for beaver and develop guidelines for relocation that are practical for restoration groups*					
SONCC-PisR.10.2.9	Water Quality	No	Reduce pollutants	Set standard	Population wide	2d
SONCC-PisR.10.2.9.1	*Develop TMDLs for water bodies listed under Clean Water Act Section 303(d)*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority

13. Chetco River Population

Northern Coastal Stratum

Core, Functionally Independent Population

High Extinction Risk

Population likely below depensation threshold

4,500 Spawners Required for ESU Viability

356 mi^2 watershed (82% Federal ownership)

135 IP-km (84 IP-mi) (8% High)

Dominant Land Uses are ‘Recreation’ and ‘Timber Harvest’

Key Limiting Stresses are ‘Lack of Floodplain and Channel Structure’ and ‘Degraded Riparian Forest Conditions’

Key Limiting Threats are ‘Channelization/Diking’ and ‘Urban/Residential/Industrial Development’

Highest Priority Recovery Actions

• Increase instream flows • Improve timber harvest practices by revising Oregon Forest Practices Act • Increase large woody debris (LWD), boulders, or other instream structure	• Restore tidally-influenced habitats • Increase riparian vegetation • Construct off-channel habitats, alcoves, backwater habitat, and old stream oxbows

13.1 History of Habitat and Land Use

Historically, the mouth of the Chetco River and the surrounding low lying bottom lands were dominated by salt water and fresh water marshes. The population area was forested with a diversity of habitat types which supported abundant life (U.S. Forest Service (USFS) 1996a). The lower Chetco River was the center of coho salmon productivity in this population (Maguire 2001f), coinciding with areas that have the highest intrinsic potential (IP >0.66) coho salmon habitat. Large floating wood jams changed location on lower Chetco River gravel bars, scouring holes as they moved. Beaver were also abundant in the lower portions of the river and estuary and likely contributed to habitat complexity (Maguire 2001f).

The discovery of gold in the interior Chetco River basin in the 1850s precipitated the first major alteration to fish habitat. Miners excavated river terraces, leaving a lasting footprint on some stream channels. Although some of this activity occurred upstream of the range of coho salmon, it released fine sediment that affected downstream reaches. Near the coast, timber harvest intensity increased. In the early 1900s, a railroad was constructed and timber was exported from the lower tributary, Jack Creek.

After World War II, timber harvest and road building on public and private lands increased and resulted in widespread disturbance. The 1964 flood delivered massive amounts of fine sediment that filled in deep pools, changed channel configuration, and eliminated much of the coho salmon habitat (Maguire 2001f). This loss was likely greatest in the mainstem, South Fork, Eagle Creek, and Panther Creek. Long-time fishermen of the Chetco River recounted that formerly deep pools were filled and the river bar was so aggraded that you could drive on it after the flood (Maguire 2001f). Timber harvest on U.S. Forest Service lands and private land continued through the 1970s and 1980s. Land management practices have resulted in the replacement of large streamside conifers with hardwoods in most of the population area (USFS 1996b; Maguire 2001f).

The estuary was altered by the construction of levees at the mouth in 1962 to improve navigation to the ocean (Figure 13-1). Long-time residents remember that before the levees were constructed, a sand bar formed in late summer which created a lagoon with connections to tributaries and wetlands (Maguire 2001f). Levee construction disconnected wetlands and streams that were vital coho salmon habitat, and also changed the salinity and other water quality parameters by altering the tidal exchange. The Corps of Engineers dredges the navigation channel routinely to keep the entrance open to the boat basin.

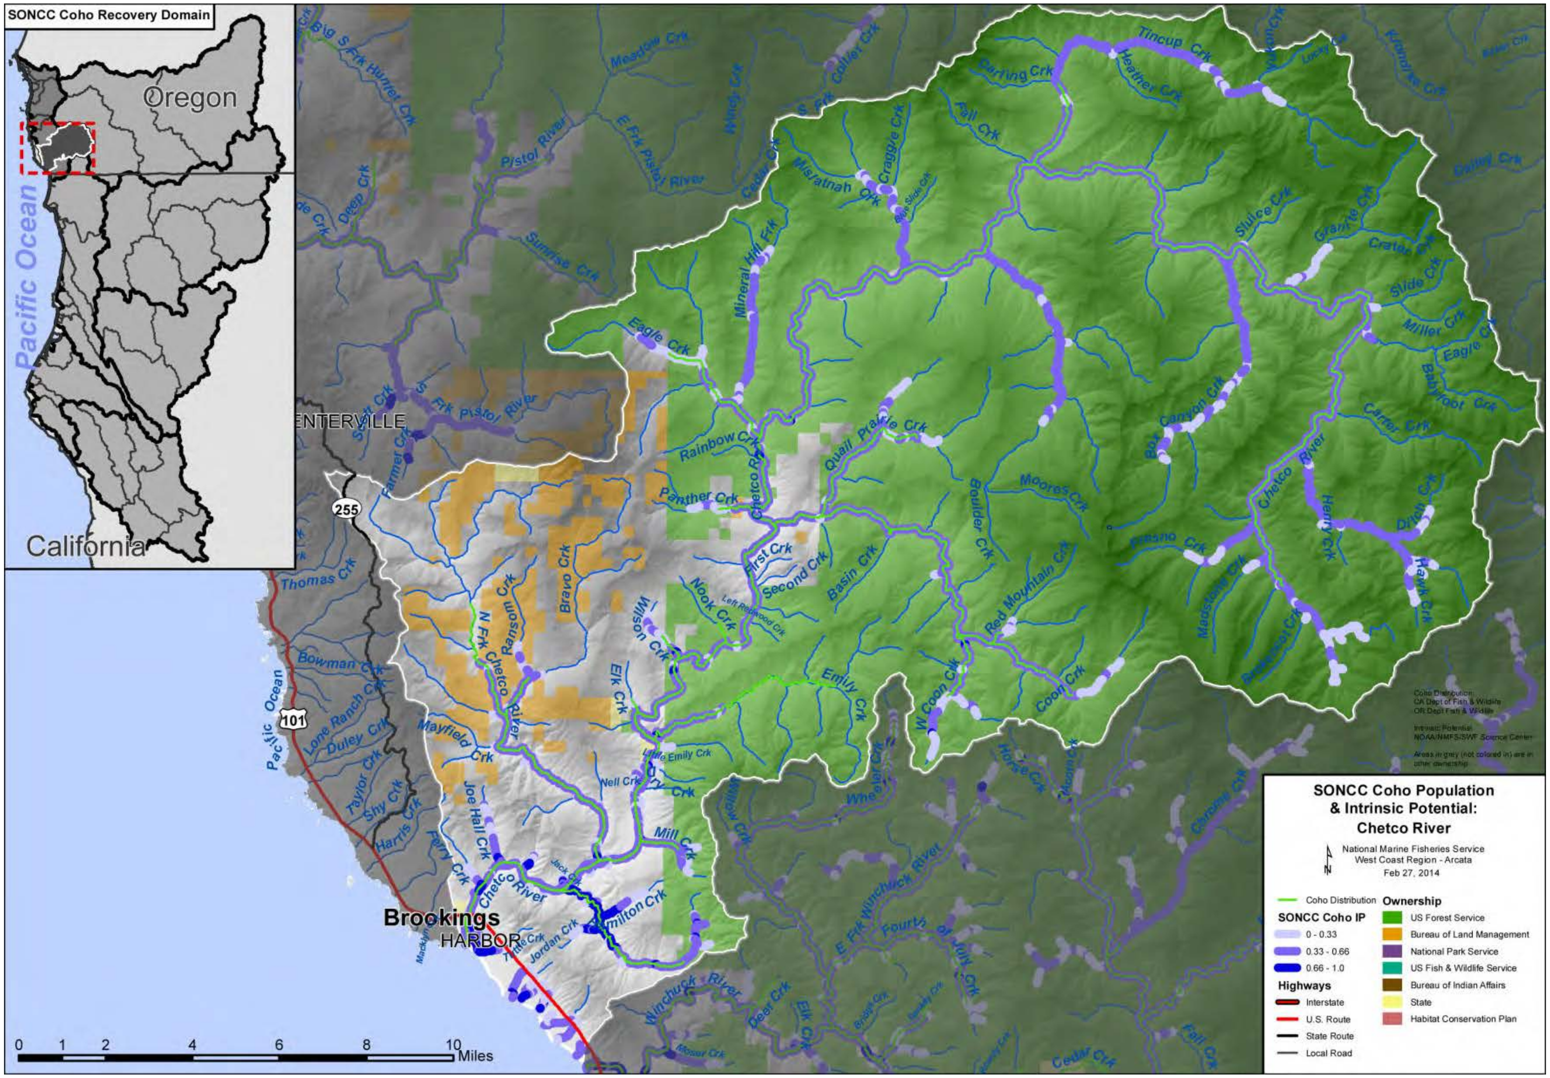

Figure 13-1. The geographic boundaries of the Chetco River coho salmon population. Figure shows modeled Intrinsic Potential of habitat (Williams et al. 2006), land ownership, coho salmon distribution (ODFW 2013a), and location within the Southern-Oregon/Northern California Coast Coho Salmon ESU and the Northern Coastal diversity stratum (Williams et al. 2006). Grey areas indicate private ownership.

13.2 Historic Fish Distribution and Abundance

The Chetco River coho salmon population is not well studied and there is little trend data, but local residents described coho salmon in the Chetco River estuary as formerly abundant and the target of a "net fishery" (Maguire 2001f). The lower tributaries were subject to extensive fishing pressure, with Tuttle Creek noted as having particularly large runs of coho salmon (Maguire 2001f).

The Oregon Department of Fish and Wildlife (ODFW) believe that the "abundance of coho salmon has been reduced due to modification of low gradient streams" (Maguire 2001f). The lower mainstem Chetco, North Fork Chetco, and Jack Creek are modeled as the most potentially suitable reaches for juvenile rearing (IP > 0.66) in the entire basin (Williams et al. 2006). Small patches of high IP also occur at the mouths of lower and middle Chetco River tributaries and in upstream areas of the South Fork and its tributary, Coon Creek. Moderate IP reaches occur in many upper tributaries. Table 13-1 lists tributaries with high IP (>0.66) reaches.

Table 13-1. Tributaries with high IP reaches (IP > 0.66). (Williams et al. 2006).

Stream Name	Stream Name	Stream Name
Chetco Estuary	Jack Creek	North Fork Chetco
Emily Creek	Joe Hill Creek	SF Chetco/Coon Creek
Hamilton Creek (tributary of Jack Creek)	Lower Chetco River	Tuttle Creek
Jordan Creek (tributary of Jack Creek)	Mill Creek	Wilson Creek

13.3 Status of Chetco River Coho Salmon

Spatial Structure and Diversity

Coho salmon occur in many parts of the Chetco River population area and juvenile coho salmon have been found in the upper mainstem reaches in the Kalmiopsis Wilderness (ODFW 2005a). Coho salmon are present in several tributaries throughout the population area including tributaries in the upper-most portions of the watershed (USFS 1996b). Coho salmon are present in the majority of the IP habitat identified by Williams et al. 2006.

Although the genetic structure of the population has not been studied, it is likely that diversity has been diminished as the population has declined, consistent with the known dynamics of small populations (Chapter 2). The ODFW Expert Panel expressed concern that out-of-basin hatchery-produced coho salmon may stray into the Chetco River and affect the genetic integrity of the wild population (ODFW 2008b). However, hatchery effects were not considered a stress or threat to this population given the small number of strays thought to affect the Chetco River.

Population Size and Productivity

The USFS (1996b) characterized the Chetco River coho salmon population as historically "a fair sized run," but currently relatively scarce. The population has diminished greatly from the historic levels described in Maguire (2001f). The Expert Panel stated that the Chetco River coho population has a very low abundance and is verging on extirpation (ODFW 2008b). Population estimates for 1998 to 2012 for the Chetco River are shown in Figure 13-2.

The range of estimates is from zero to 665 adults. Years with no observed returns are 1998, 1999, 2002, 2003, 2005, 2009, and 2012 (ODFW 2009a, Confer 2013). It is problematic to draw definitive conclusions from these data because the locations of sampling and water conditions at time of sampling are unknown. Some of these data come from Chinook salmon spawning surveys were coho salmon were also observed, but they did not target coho salmon. Their utility is lowered by the fact that coho salmon spawning may not occur in the same places or at the same times as Chinook salmon.

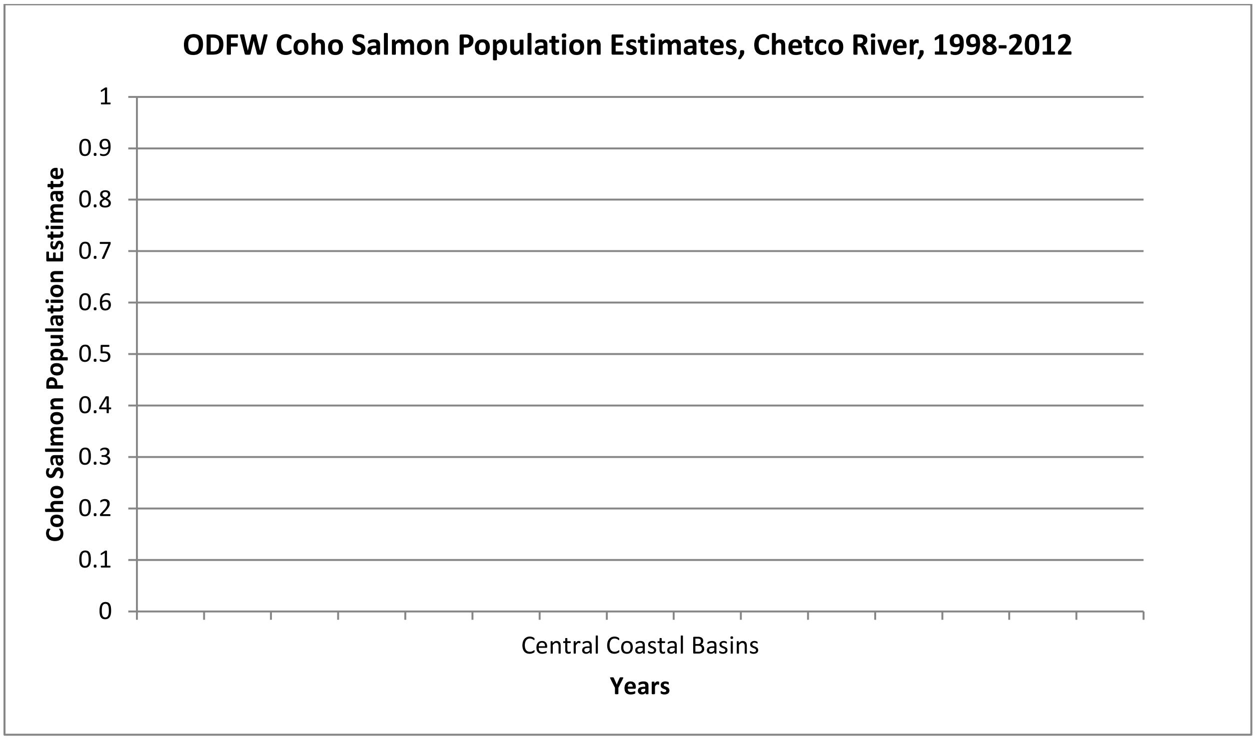

Figure 13-2. Chetco River basin-wide adult coho salmon return estimates. The data are for the years 1998 to 2012 (Confer 2013).

The more robust returns in 2001, 2004 and 2007 suggest that one year class is stronger than the other two. Unfortunately it collapsed in 2010. The lack of returns in 2003, after 307 coho spawned in the Chetco River in 2000, suggests that successful recruitment of juveniles to the adult life stage was problematic. The overall population productivity for Chetco River coho salmon appears to be very low.

Little information is available for juvenile SONCC coho salmon in the Chetco River, as well. Juveniles were found at only two locations and at very low densities within the basin during snorkeling surveys conducted in 2003 and 2004 (Jepsen and Rodgers 2004, Jepsen 2006). In a trapping operation on Jack Creek between March 9 and May 10, 2007, ODFW captured 69 out-migrant coho salmon smolts (Confer, 2007). Operation of this trap between March 13 and May 16, 2008 caught 163 coho salmon smolts (Mazur 2010). The trap did not provide enough data for ODFW to make estimates of the total outmigration for either year, but it is likely four to five times the number caught. In addition, low water levels stopped the trap in mid-May while the coho salmon smolt outmigration likely lasts to mid-June.

Extinction Risk

The Chetco River population is at high risk of extinction because the estimated average spawner abundance has been less than the depensation threshold in the three consecutive years of lowest abundance within the last twelve years (Williams et al. 2008). NMFS' determination of population extinction risk is based on the viability criteria provided by Williams et al. 2008 (Table 3, pg. 17). These viability criteria are related to population size and rate of decline. As Williams et al. (2008) provided no viability criteria for assessing moderate and high risk based on spatial structure and diversity, spatial structure and diversity were not considered in NMFS' determination of population extinction risk.

Role in SONCC Coho Salmon ESU Viability

The Chetco River population is a core, Functionally Independent population within the Northern Coastal diversity stratum; historically having had a high likelihood of persisting in isolation over 100-year time scales, and with population dynamics or extinction risk over a 100—year time period that are not substantially altered by exchanges of individuals with other populations (Williams et al. 2006). To contribute to stratum and ESU viability, the Elk River core population should have at least 2,400 spawners. Sufficient spawner densities are needed to maintain connectivity and diversity within the stratum and continue to represent critical components of the evolutionary legacy of the ESU. Besides its role in achieving demographic goals and objectives for recovery, as a core population the Chetco River may serve as a source of spawner strays for nearby coastal populations. At present, the capacity of the Chetco River coho salmon population to provide recruits to adjacent independent populations is limited due to its low spawner abundance. Conversely, recruits straying from nearby rivers may enhance recovery of the Chetco River population.

13.4 Plans and Assessments

State of Oregon

http://www.Oregon.gov

Expert Panel on Limiting Factors for Oregon's SONCC coho salmon populations

ODFW (2008b) convened a panel of fisheries and watershed scientists as an initial step in their development of a recovery plan for Oregon's SONCC coho salmon populations. Deliberations of the expert panel provided ODFW with initial, strategic guidance on limiting factors and threats to recovery. Based on the input of panel members, ODFW (2008b) summarized the concerns for the Chetco River population as follows:

Key concerns in the Chetco River were primarily loss of over-winter tributary and freshwater estuarine habitat complexity and floodplain connectivity for juveniles, especially in the lowlands which are naturally very limited in this system and have been impacted by past and current urban, rural residential, and forestry development and practices. Secondary concerns were related to a loss of large wood and habitat complexity, high water temperatures in tributaries for summer parr (excluding the mainstem, where rearing is not expected), reduced estuarine habitat for smolts, and a very low spawner abundance susceptible to genetic impacts by out-of-basin hatchery fish.

Oregon Plan for Salmon and Watersheds

The State of Oregon developed a conservation and recovery strategy for coho salmon in the SONCC and Oregon Coast ESUs (State of Oregon 1997). The Oregon Plan for coho salmon is a comprehensive plan that includes voluntary actions for all of the threats currently facing coho in these ESUs and involves all relevant state agencies. Reforms to fishery harvest and hatchery programs were implemented by ODFW in the late 1990s. Many habitat restoration projects have occurred across the landscape in headwater habitat, lowlands, and the estuary. The action plans, implementation, and annual reports can be found at http://www.oregon.gov/OPSW/.

Southwest Oregon Salmon Restoration Initiative

The Southwest Oregon Salmon Restoration Initiative (Prevost et al. 1997) was created to help fulfill a memorandum of understanding between ODFW and the National Marine Fisheries Service (NMFS) to recover coho salmon. The initiative provides the framework for recovery in southwest Oregon and helped foster formation of watershed councils. Although the Chetco River has 72.8 miles of "high value" coho salmon habitat, there are no reaches or tributaries designated as "core areas" that are the highest priority for restoration in the SONCC coho salmon ESU.

Oregon Coastal Management Program (OCMP)

The OCMP has identified several areas of the Chetco River (mainstem Chetco River from Box Canyon Creek to estuary, North Fork Chetco River, and Bravo Creek) as impaired water bodies under Clean Water Act Section 303(d) as a result of excessively high river temperatures. Due to this listing, a total maximum daily load (TMDL) must be prepared for these areas, in accordance with 40 CFR 130.6. The Oregon Department of Water Quality has initiated a TMDL for the Chetco River basin. The TMDL is in the initial scoping and data collection phase.

Cumulative Effects of Southwest Oregon Coastal Land Use on Salmon Habitat

Oregon State University (OSU) Oak Creek Labs conducted a study funded by ODFW and the Oregon Department of Forestry (ODF) to determine relationships between forest harvest and Pacific salmon productivity (Frissell 1992). The study assessed basins along the Oregon coast extending from the Sixes River to the southern border during the period from 1986 to 1992 with the most extensive research conducted in Euchre Creek to the south of the Elk River.

South Coast Watersheds Council
http://oregonwatersheds.org/

Chetco River Watershed Assessment

The Chetco River Watershed Assessment (CRWA) (Maguire 2001f) identified reduced juvenile summer and over-wintering habitat as the greatest limiting factor for coho salmon, and linked degraded habitat conditions to sedimentation of channels, reduction of large wood jams, diking and draining of wetlands, and riparian removal on the lower mainstem Chetco River and its tributaries. The report offered solutions such as the potential for reducing increased peak flows, reducing estuary eutrophication, and increasing water supply.

Chetco River Action Plan

The Chetco River Action Plan was written to address issues raised in the CRWA. Its intent is to define specific priority actions for restoration. Recommendations include educating residents regarding the need for riparian and water quality protection and water conservation. Recommended actions include increasing conifers in riparian zones, reconnecting wetlands in the lower Chetco River and estuary, and decreasing erosion potential related to roads. The document concludes Jack Creek and the North Fork Chetco have the greatest coho salmon restoration potential.

13.5 Stresses

Table 13-2. Severity of stresses affecting each life stage of coho salmon in the Chetco River. Stress rank categories, assessment methods, and data used to assess stresses are described in Appendix B.

	Stresses[2]	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Stress Rank
1	Degraded Riparian Forest Conditions[1]	-	Very High	Very High[1]	Very High	Very High	Very High
2	Lack of Floodplain and Channel Structure[1]	High	High	Very High[1]	Very High	High	Very High
3	Impaired Estuary/Mainstem Function	-	Low	Very High	High	High	High
4	Impaired Water Quality	Low	High	Very High	High	Medium	High
5	Altered Hydrologic Function	Medium	High	High	Medium	Low	High
6	Altered Sediment Supply	Low	Medium	Medium	Medium	Low	Medium
7	Barriers	-	Low	Low	Low	Low	Low
8	Adverse Hatchery-Related Effects	Low	Low	Medium	Low	Low	Low
9	Adverse Fishery- and Collection- Related Effects	-	-	Low	Low	Low	Low

[1]Key limiting stresses and limited life stage.
[2]Increased Disease/Predation/Competition is not considered a threat to this population.

Key Limiting Stresses, Life Stages, and Habitat

The juvenile life stage is most limited and quality winter rearing habitat, as well as summer rearing habitat, is lacking for the population. Juvenile summer rearing habitat is impaired by high water temperatures resulting from degraded riparian conditions and water withdrawals. Winter rearing habitat is severely lacking because of channel simplification, disconnection from the floodplain, degraded riparian conditions, poor large wood availability, and an estuary which has been altered and reduced in size due to development, channelization, and diking. Large wood has been removed and is not naturally replacing at the rates required to maintain key components of habitat complexity. Overall, these findings are consistent with those of the Oregon Expert Panel (ODFW 2008b) (Section 13.4).

Degraded Riparian Forest Conditions

Degraded riparian forest condition is the most significant stress affecting coho viability in the Chetco River basin. Old growth conifers historically lined the banks of the lower mainstem Chetco River and tributaries in most of the population area. These trees helped create high quality coho salmon rearing habitat by maintaining stable banks, creating undercuts beneath roots, contributing large wood to the channel, and providing shade to maintain cool stream temperature. Canopy within the North Fork watershed is currently dominated by hardwood species. ODFW riparian surveys indicate poor riparian conditions on the North Fork Chetco with fewer than 75 conifers larger than 36 inches in diameter per thousand feet of stream length. The CRWA (USFS 1996b) used remote sensing to gauge the size of trees within 200 feet of streams and found few large conifers along reaches on USFS lands. The Oregon Department of Agriculture (2008) documented sudden oak death syndrome in the riparian zones of the North Fork Chetco River and Joe Hall Creek.

Lack of Floodplain and Channel Structure

The lower Chetco River channel has been disconnected from its estuary, floodplain, wetlands, and smaller tributaries. Tributary channels and floodplains have been simplified. Higher peak flows have increased bank erosion, caused loss of large woody structure, and scoured channels in many upper tributaries in the Chetco population area (USFS 1996b). Large wood surveys from ODFW and the USFS confirm very low levels in the North Fork, upper South Fork, Boulder Creek, and Mislatnah Creek. Historically, large floating wood jams changed location on lower Chetco River gravel bars, scouring holes as they moved (Maguire 2001f). Beaver were also abundant in the lower-river and estuary and likely contributed to habitat complexity and overwintering habitat (Maguire 2001f). Today, the Chetco River is very responsive to rain events and contributes to the displacement of juvenile coho salmon. During winter storms, discharge of the Chetco River routinely increases from less than 1,000 cfs to over 20,000 cfs within 24 hours.

Stream channels in the Chetco River tend to be wide and shallow, and pools lack both depth and complexity (Massingill 2001f). Good quality spawning gravel is present, but quantity is limited. Only large mainstem reaches have pools deeper than 3 feet. An insufficient abundance of deep pools in most lower and middle Chetco River channels limits juvenile rearing potential. For example, the South Fork Chetco River, including Coons Creek, have coho salmon present and are showing a cooling trend, but lack deep pools and large wood.

Impaired Estuary/Mainstem Function

The Chetco River estuary was historically small, and much of what once was estuarine rearing habitat no longer serves this function for coho salmon (Massingill 2001f). There is little to no remaining estuarine rearing habitat or refugia for smolts or adults. Upstream of the mouth, steep terrain adjacent to the mainstem limits the availability of tidal estuarine habitat. Formerly productive Tuttle Creek is disconnected as it now flows through several hundred feet of culverts underneath an RV Park. Reduced freshwater flows into the estuary contribute to and exacerbate stagnation and water quality problems. Lack of juvenile rearing habitat and impaired water quality in the estuary constitute an overall high stress for coho salmon.

Impaired Water Quality

Temperature is the most widespread water quality impairment in Chetco River. The river temperature exceeds ODEQ (2002a) standards coming out of the Kalmiopsis Wilderness because of sparse vegetation and riparian conditions resulting from granitic soil (Maguire 2001f). Historically, it was cooled by tributaries flowing from forested watersheds in the middle and lower basin. Most tributaries and the lower mainstem Chetco River have warmed considerably in modern times and do not meet the ODEQ (2002a) temperature criterion of MWMT 64 °F. Tributaries no longer provide a significant buffer to mainstem temperatures and their function as cold water refugia for downstream migrating coho salmon juveniles and other salmonids is now impaired. Although tributaries still provide cool water refugia, the quantity and quality of the cold water refugia has decreased over time while temperatures gradually warm. Temperature data confirm that reaches of the mainstem are acutely stressful or lethal to salmonids (Figure 13-3), indicating that cooler water inputs from tributaries has become even more important over time. The water temperature in stream channels on U.S. Forest Service (USFS) lands has been improving. Emily Creek and the South Fork Chetco River have been gradually approaching suitable water temperatures for coho salmon (USFS 1996b). The middle North Fork Chetco River and its tributary Bosley Creek, on BLM lands, are currently suitable for coho salmon, but Bravo Creek and the lower North Fork reaches on private timberlands are too warm. There are also problems with high total phosphates, and occasional high pH, in the lower Chetco River (Maguire 2001f). Water quality in the estuary is poor due to low dissolved oxygen in the summer (Maguire 2001f).

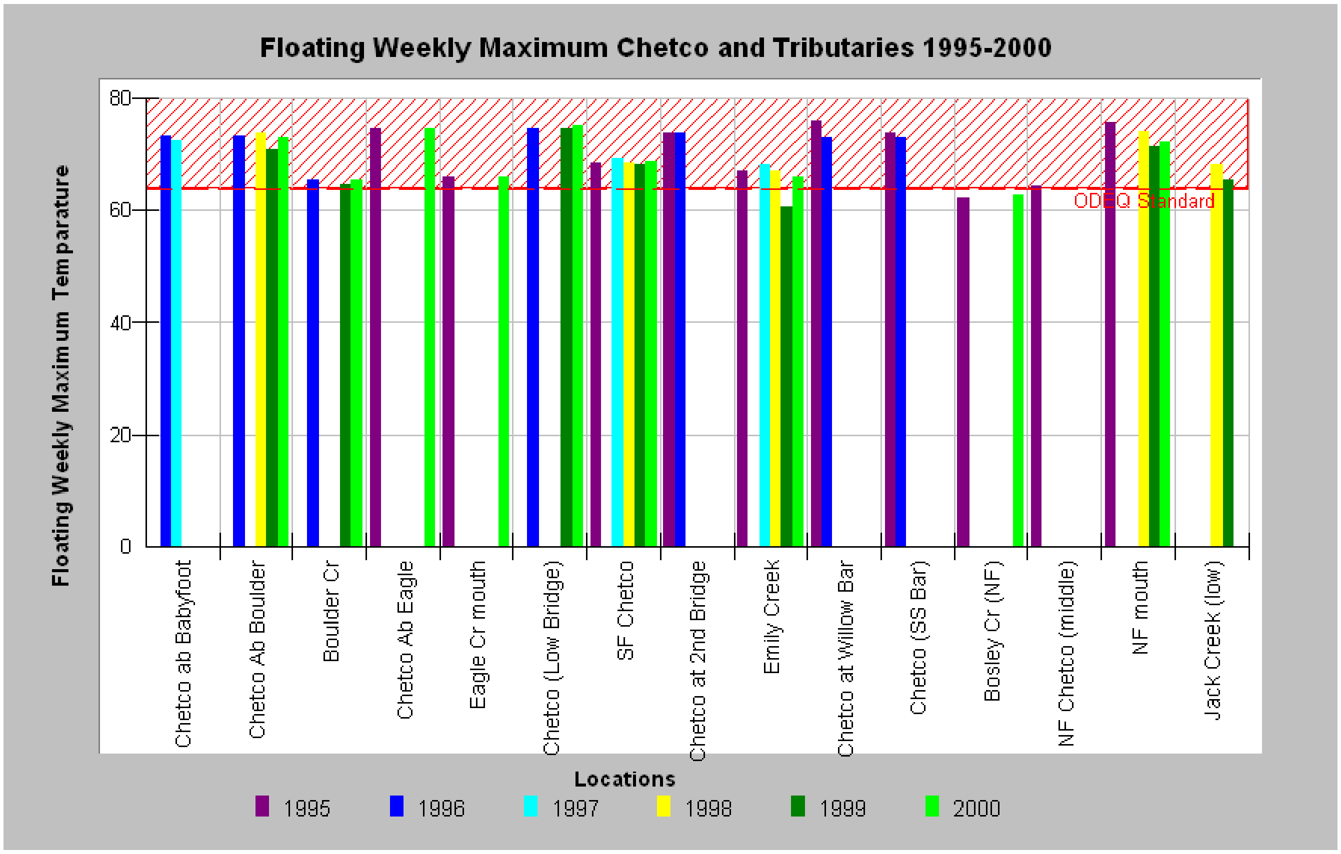

Figure 13-3. Maximum floating weekly maximum temperatures (MWMT). These data show that from 1995 to 2000, water temperature exceeded the 64 °F standard at most locations (Maguire 2001f).

Altered Hydrologic Function

In late summer and early fall, water withdrawals that reduce flow in the lower Chetco River and tributaries are of concern. The lower Chetco River, North Fork Chetco, middle mainstem Chetco, and Jack Creek are over-allocated during low flow months (Massingill 2001f). In 1964, the State of Oregon Water Rights Division established a minimum flow requirement of 80 cfs for the Chetco River. Total allocated water rights for out of stream use are 59 cfs (Maguire 2001f). Minimum flow levels were not met in 11 of the 25 years from 1970 to 1994, and the number of days per year below this level ranged from two to 77 days (USFS 1996b). These reduced flows disrupt juvenile rearing habitat as well as migration of smolts. Base flows may also decrease in the first ten years following clear cutting because of the increase in water use by young trees growing in dense stands (Murphy 1995) and the lack of water holding capability of the soil. Disconnection of the floodplain and channel disrupts exchange of surface water and groundwater that helps maintain cool water temperatures needed for juvenile rearing of coho salmon (Chapter 3).

Two areas have been identified by ODFW as Streamflow Restoration Priority Areas: Jack Creek and the Chetco River mainstem above the North Fork. These areas were determined to have both “need” (due to their fish resources) and “optimism” (availability of water resources) (Maguire 2001f).

Altered Sediment Supply

Altered sediment supply poses an overall medium stress to coho salmon in the Chetco River. Sediment contribution from landslides and erosion occurs naturally in the Chetco River basin; however, roads, timber harvest, and bank erosion following removal of riparian vegetation have elevated fine sediment input. Excess fine sediment directly impacts coho salmon egg viability and can reduce food for fry, juveniles and smolts. Poor pool frequency and depth throughout the Chetco River basin (Massingill 2001f) are likely due to elevated levels of fine sediment partially filling pools, a lack of scour-forcing obstructions such as large wood, and in some reaches diminished scour due to channel widening. Overall, coarse sediment supply in the Chetco River basin has declined since the 1970s (Wallick et al. 2009) due to improved management practices on public lands in the upper basin.

Barriers

One tributary, Ferry Creek, lies in a culvert for several hundred feet just upstream of its confluence which is likely a complete barrier. Road-stream crossings in the Lower, Middle and North Fork watersheds and their tributaries that could be barriers to coho salmon or other adult and juvenile salmonids have been inventoried and necessary restoration actions are planned (Maguire 2001f), although progress is unknown. Tuttle Creek, once a highly productive coho salmon tributary to the estuary has been redirected underground through culverts with an RV park directly over. The partial barrier at the mouth of Joe Hall Creek has recently been removed by the Oregon Department of Transportation.

Adverse Hatchery-Related Effects

There are no operating hatcheries in the Chetco River population area. The ODFW Expert Panel expressed concern that out-of-basin hatchery-produced coho salmon may stray into the Chetco River and affect the genetic integrity of the wild population (ODFW 2008b). Juvenile coho salmon are likely exposed to increased competition from the stocking of significant numbers of Chinook salmon. Hatchery-origin coho salmon may stray into the Chetco River; however, the proportion of adults that are of hatchery origin is likely less than five percent and there is no hatchery in the basin producing other species of salmonids. Therefore, adverse hatchery-related effects pose a low risk to all life stages (Appendix B).

Adverse Fishery- and Collection-Related Effects

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low stress to juveniles, smolts, and adults.

13.6 Threats

Table 13-3. Severity of threats affecting each life stage of coho salmon in the Chetco River. Threat rank categories, assessment methods, and data used to assess threats are described in Appendix B.

	Threats	Egg	Fry	Juvenile[1]	Smolt	Adult	Overall Threat Rank
1	Urban/Residential/Industrial Dev.[1]	Low	High	Very High[1]	Very High	High	Very High
2	Channelization/Diking[1]	Medium	High	High[1]	High	High	High
3	Roads	Medium	High	High	High	High	High
4	Timber Harvest	High	High	High	High	Medium	High
5	Mining/Gravel Extraction	Medium	High	High	Medium	Medium	High

7	Agricultural Practices	Low	Medium	Medium	Medium	Medium	Medium
8	Dams/Diversion	Low	Medium	Medium	Medium	Medium	Medium
9	High Severity Fire	Low	Medium	Medium	Medium	Medium	Medium
10	Climate Change	Low	Low	Medium	Medium	Medium	Medium
11	Road-Stream Crossing Barriers	-	Medium	Medium	Low	Medium	Medium
12	Hatcheries	Low	Low	Medium	Low	Low	Low
13	Fishing and Collecting	-	-	Low	Low	Low	Low

[1]Key limiting threats and limited life stage

Key Limiting Threats

The two key limiting threats, those which most affect recovery of the population by influencing stresses, are urban/residential/industrial development and channelization/diking.

Urban/Residential/Industrial Development

The number of rural landowners in the Chetco River basin has increased considerably since 1950. For example, in 1950 there were less than ten adjoining property owners near the mouth of the North Fork, and in 2001 there were 92 (Massingill 2001f). The highest intrinsic potential coho habitat is centered in the lower basin where most land is privately owned and land management is often intensive. Human population growth is concentrated around Brookings Harbor at the mouth of the Chetco River and upstream to USFS ownership at the mouth of the South Fork Chetco River. As rural populations grow, so does the demand for water, the risks of increases in peak flow, increases in sediment inputs, riparian vegetation removal, increased bank protection and water contamination. Currently, municipal uses account for most of the water withdrawals from the Chetco River and its tributaries (Massingill 2001f).

Development continues to occur adjacent to the estuary, and fill material has reduced the size and function of the estuary. Marina development and other commercial activities in and near the estuary combine with urbanization to create a high amount of impervious area that can contribute to non-point source pollution. Paved roads, parking lots, rooftops, or other surfaces that do not absorb rainfall tend to send much more water to streams, elevating peak flows and contributing pollution to streams (Booth and Jackson 1997). Leakage or percolation from rural residential septic systems is a potential source of nutrient pollution and increases the severity of summer algal blooms in the estuary.

Channelization/Diking

Nearly all of the tidal wetlands in the Chetco River have been channelized or diked and are no longer available to coho salmon. Development along the south side of the river likely eliminated limited tidal wetlands that provided off-channel habitat for coho salmon rearing and holding. Two marinas and a large jetty have been built in the estuary and most of the floodplain is developed. Many reaches of the lower Chetco River mainstem, its tributaries, and the estuary have high intrinsic potential coho salmon habitat (Williams et al. 2006); however, this portion of the river has been disconnected from the floodplain. The estuary was partially filled when levees were constructed to improve navigability into the ocean. The mouth of the river and the mainstem upstream are now channelized and diked. Tuttle Creek, which was formerly productive for coho salmon (Maguire 2001f) has been straightened, confined, and buried inside several hundred feet of culverts. The Chetco River channel above the North Fork has been confined in order to expand pastures for grazing. Streams are also forced into narrow channels due to confinement by roads throughout the population area (USFS 1996b). This leads to reduced floodplain connectivity and function, increased current velocity, and makes reaches less suitable for coho rearing.

Roads

The highest road densities in the middle, lower, and North Fork Chetco River are on private lands. Maguire (2001f) used road crossing density to evaluate the risk of sediment impacts and found the highest density of road crossings in the Chetco coastal area and middle Chetco mainstem. There was a moderately high risk due to density of road crossings in Jack Creek, and the lower and upper Chetco mainstem. The North Fork and Eagle Creek both received moderate risk ratings. On USFS land, streams with the highest road densities are Mill, Emily, Eagle, Panther, West Coon and Quail Prairie creeks, South Fork Chetco River, and the south side of the Chetco River below Long Ridge (USFS 1996b). The Chetco River is naturally very responsive to rain events and roads contribute to even greater peak flows by quickly routing water through roadside ditches. The lower Chetco River near the coast and middle mainstem is at the highest risk of damaging peak flows due to roads (Massingill 2001f). There is a moderate risk for elevated peak flows in Jack Creek, the lower mainstem Chetco, and the North Fork Chetco.

Timber Harvest

Timber harvest in the Chetco River basin poses a high threat to coho salmon due to the overlap with high IP coho salmon habitat. Only about 12% of the population area is private industrial forest, but it is focused in the most valuable coho habitat. The effects of short rotation, high intensity forestry is disproportionate to the small percentage of the land base it occupies. Landscape-scale imagery available from Google Earth shows widespread timber harvest and extensive road networks on private timber land in the western portion of the population area. More than 50 percent of the area in many small drainages along the Chetco River from Eagle Creek to the mouth has been harvested (USFS 1996b). Other parts of the population area have also experienced intense timber harvest, such as Basin Creek which has had 60 percent of its area harvested recently. These levels of timber harvest have been found to disrupt channels and diminish Pacific salmon species diversity in other Oregon coastal basins (Reeves et al. 1993).

Mining/Gravel Extraction

In July 2013, the US Department of Interior approved a 5-year administrative withdrawal of mineral rights in 17 miles of Chetco River mainstem. The near term threat of mining has been reduced, but will return after 2018. Furthermore, most of the suction dredge activity within the Chetco watershed is occurring on tributaries such as Quail Prairie Creek, Nook Creek, and Mislatnah Creek. Gold mining claims remain in the upper Chetco River basin (Zaitz 2010), which cover several miles of stream. Mining activity could potentially increase, including use of larger dredges and heavy equipment (Zaitz 2010).

The largest active gravel mining site is in the lower Chetco River near the mouth of Jack Creek, where the river is low gradient and the valley is unconfined. In the future, this operation may work outside of Corps jurisdiction, in which case would not receive Corps or NMFS review. In-stream gravel mining is expected to continue into the future with permit applications for at least two sites.

Agricultural Practices

Grazing is the principal agricultural activity in the Chetco River basin. The conversion of land to agricultural production has led to the confinement of the lower Chetco River channel and lower portions of the North Fork Chetco River and Jack Creek creating a disconnection from the historic floodplain. The levees, dikes, and general encroachment of pasture and agricultural lands onto the floodplain have greatly reduced off channel rearing habitat availability.

Dams/Diversions

One major tributary to the estuary, Ferry Creek, is dammed just upstream of its confluence. There are no other known diversions that block fish passage. Dams and diversions lead to an overall loss of water from the stream by diverting water for agricultural or municipal use. The lower Chetco River, North Fork Chetco, middle mainstem Chetco, and Jack Creek are over-allocated during low flow months (Massingill 2001f). In 1964, the State of Oregon Water Rights Division established a minimum flow requirement of 80 cfs for the Chetco River. Minimum flow levels were not met in 11 of the 25 years from 1970 to 1994, and the number of days per year below this level ranged from two to 77 days (USFS 1996). Currently, municipal uses account for most of the water withdrawals from the Chetco River and its tributaries (Massingill 2001f).

High Severity Fire

Extensive portions of the Chetco River population area burned in the 23,500 acre Silver Fire of 1987. The Biscuit Fire of 2002 burned most of the upper Chetco River, including most of the Kalmiopsis Wilderness area (Azuma et al. 2004). However, 63 percent of the area burned in the Biscuit Fire was at low to very low intensity. In the North Fork Chetco, sudden oak death syndrome is killing tan oak and bay laurel trees (ODA 2008), which can elevate fire risk because dead trees are more flammable.

Climate Change

Climate change in this region will have the greatest impact on juveniles, smolts, and adults. Although the current climate is generally cool, modeled regional average temperature predicts a moderate increase over the next 50 years. Average temperature could increase by up to 1.5^{o} C in the summer and by 1^{o} C in the winter. Annual precipitation in this area is predicted to stay within the natural range of current variability; however seasonal patterns in precipitation will likely occur (Mote and Salathe 2010). Overall, the range and degree of variability in temperature and precipitation are likely to increase. The vulnerability of the estuary and coast to sea level rise is moderate to high in this coastal population. Rising sea level may impact the quality and extent of wetland rearing habitat.

Road-Stream Crossing Barriers

There are nine remaining barriers which have been identified as problematic for fish passage. High road densities, especially on private lands, indicate the likelihood of other barriers yet to be identified. These private lands overlap most of the high IP coho salmon habitat.

Hatcheries

Hatcheries pose a low threat to all life stages of coho salmon in the Chetco River population area. The rationale for these ratings is described under the “Adverse Hatchery-Related Effects” stress.

Invasive Non-Native/Alien Species

Sudden oak death (SOD) is a non-native pathogen which affects almost all native plants, trees, and shrubs. SOD infections often result in mortalities to some species of oaks and bay laurels. There are known outbreaks of SOD in Curry County and the Chetco River. SOD infestation in Oregon is focused in the North Fork Chetco River and is quickly spreading. The quarantine area is now 264 square miles. SOD infections, and the control efforts to limit outbreaks, result in effects to riparian function by removing trees from riparian areas. SOD poses a medium threat to SONCC coho salmon due to the current infestation and rate of spreading.

Japanese knotweed (*Polygonum cuspidatum*) has spread into the Chetco River (ODA 2010) and efforts are underway to control its spread and distribution. This is a concern because Japanese knotweed is aggressive, fast growing, and out-competes native vegetation in riparian areas. Scotch broom and gorse are also locally common and similarly invasive. If these plants replace conifers or hardwoods in riparian zones, it substantially impacts coho salmon habitat.

Fishing and Collecting

Based on estimates of the fishing exploitation rate, as well as the status of the population relative to depensation and the status of NMFS approval for any scientific collection (Appendix B), these activities pose a low threat to juveniles, smolts, and adults.

13.7 Recovery Strategy

The most important factor limiting recovery of coho salmon in the Chetco River is a deficiency in the amount of suitable rearing habitat for juveniles. The processes that create and maintain such habitat must be restored by increasing channel complexity, restoring flow, and reducing stream temperatures. Channel complexity should be improved by restoring large wood in streams, restoring those processes that provide large wood to streams, constructing off-channel ponds or backwater habitat, restoring wetlands, moving levees, or limiting development and fill. Areas adjacent to the stream should be replanted with conifers to re-establish mature streamside forest as a source for large wood recruitment. Restoration of sufficient water may require changes in water use and allocation.

Habitat restoration and threat reduction in the Chetco River should be focused on those areas currently occupied by coho salmon, which would allow for immediate benefits to the population. Unoccupied areas must also be restored to provide enough habitat to achieve population viability and provide for conditions suitable to allow for re-colonization. The effects of fishing on this population’s ability to meet its viability criteria should be evaluated.

Table 13-4 on the following page lists the recovery actions for the Chetco River population.

Table 13-4. Recovery action implementation schedule for the Chetco River population. Recovery actions for monitoring and research are listed in tables at the end of Chapter 5.

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-CheR.2.8.4	Floodplain and Channel Structure	Yes	Improve timber harvest practices	Improve regulatory mechanisms	Population wide	1
SONCC-CheR.2.8.4.1	*Determine how to revise Oregon Forest Practice Rules so that they do not limit recovery of SONCC coho salmon and make appropriate revisions*					
SONCC-CheR.2.8.4.2	*Adopt rules for fish-bearing streams sufficient to protect both water quality and fish habitat*					
SONCC-CheR.2.8.4.3	*Adopt rules to increase protection of non-fish-bearing streams that address practices that adversely impact water quality and fish habitat*					
SONCC-CheR.2.8.4.4	*Ensure management measures for landslide prone areas include protection of water quality and fisheries habitat*					
SONCC-CheR.2.8.4.5	*Until more permanent regulatory mechanisms can be put in place, immediately adopt interim rules that increase protection for salmon habitat in forested areas, including increased natural recruitment of large wood on perennial and intermittent streams likely to deliver wood downstream, increased shade on all perennials, and protective buffers on small intermittent streams*					
SONCC-CheR.2.4.9	Floodplain and Channel Structure	Yes	Improve estuarine habitat	Restore tidally influenced habitats	Areas of estuary where coho salmon would benefit immediately	2a
SONCC-CheR.2.4.9.1	*Assess coho use of different estuarine habitats and develop a plan to enhance those habitats (i.e. brackish wetlands, tidal sloughs, salt marshes, and tidally influenced freshwater)*					
SONCC-CheR.2.4.9.2	*Restore tidally influenced habitats, guided by the plan*					
SONCC-CheR.2.4.69	Floodplain and Channel Structure	Yes	Improve estuarine habitat	Restore tidally influenced habitats	Population wide	2b
SONCC-CheR.2.4.69.1	*Assess coho use of different estuarine habitats and develop a plan to enhance those habitats (i.e. brackish wetlands, tidal sloughs, salt marshes, and tidally influenced freshwater)*					
SONCC-CheR.2.4.69.2	*Restore tidally influenced habitats, guided by the plan*					
SONCC-CheR.22.2.43	Urban, Residential, Industrial Development	Yes	Improve flow timing or volume	Increase instream flows	Mainstem and tributaries downstream of the Kalmiopsis Wilderness	2a
SONCC-CheR.22.2.43.1	*Identify, map, and quantify all surface water diversions*					
SONCC-CheR.22.2.43.2	*Assess water diversions, prioritize, and adjust management to benefit life history requirements of coho*					
SONCC-CheR.22.2.43.3	*Secure dedicated unused water diversion rights*					
SONCC-CheR.22.2.43.4	*Verify permitted water diversions*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-CheR.2.5.8	Floodplain and Channel Structure	Yes	Improve tidal exchange of water	Set back or remove dikes or levees	Areas of estuary where coho salmon would benefit immediately	2a
SONCC-CheR.2.5.8.1	*Assess and prioritize levees for setback or removal*					
SONCC-CheR.2.5.8.2	*Remove or setback levees, guided by assessment results*					
SONCC-CheR.2.5.70	Floodplain and Channel Structure	Yes	Improve tidal exchange of water	Set back or remove dikes or levees	Population wide	2b
SONCC-CheR.2.5.70.1	*Assess and prioritize levees for setback or removal*					
SONCC-CheR.2.5.70.2	*Remove or setback levees, guided by assessment results*					
SONCC-CheR.7.1.46	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	Private lands where coho salmon would benefit immediately	2a
SONCC-CheR.7.1.46.1	*Assess grazing contribution to sediment delivery, pollutants, and impaired riparian conditions*					
SONCC-CheR.7.1.46.2	*If problems are identified, develop and implement grazing management strategy that decreases delivery of sediment and pollutants to streams and improves riparian condition*					
SONCC-CheR.7.1.46.3	*Monitor effectiveness of grazing management to ensure grazing does not limit recovery of SONCC coho salmon*					
SONCC-CheR.7.1.75	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve grazing practices	Population wide	2b
SONCC-CheR.7.1.75.1	*Assess grazing contribution to sediment delivery, pollutants, and impaired riparian conditions*					
SONCC-CheR.7.1.75.2	*If problems are identified, develop and implement grazing management strategy that decreases delivery of sediment and pollutants to streams and improves riparian condition*					
SONCC-CheR.7.1.75.3	*Monitor effectiveness of grazing management to ensure grazing does not limit recovery of SONCC coho salmon*					
SONCC-CheR.7.1.3	Riparian	Yes	Improve wood recruitment, bank stability, shading, and food subsidies	Improve long-range planning	Population wide	2a
SONCC-CheR.7.1.3.1	*Review General Plan or City Ordinances to ensure coho salmon habitat needs are accounted for. Revise if necessary*					
SONCC-CheR.7.1.3.2	*Develop watershed-specific guidance for managing riparian vegetation. Consider larger riparian buffers in coho occupied habitat and discourage development adjacent to the estuary*					
SONCC-CheR.2.1.44	Floodplain and Channel Structure	Yes	Increase channel complexity	Improve and protect habitat	Jack Creek upstream of South Bank Road and Hamilton Creeks	2a
SONCC-CheR.2.1.44.1	*Acquire conservation easement from willing sellers/landowners*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
Step ID	*Step Description*					
SONCC-CheR.2.1.6	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	North Fork Chetco basin, alluvial terraces along the Lower Chetco, and Jacks Creek, and all streams where coho salmon would benefit immediately	2a
SONCC-CheR.2.1.6.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-CheR.2.1.6.2	*Place instream structures, guided by assessment results*					
SONCC-CheR.2.1.66	Floodplain and Channel Structure	Yes	Increase channel complexity	Increase LWD, boulders, or other instream structure	Population wide	2b
SONCC-CheR.2.1.66.1	*Assess habitat to determine beneficial location and amount of instream structure needed*					
SONCC-CheR.2.1.66.2	*Place instream structures, guided by assessment results*					
SONCC-CheR.2.2.5	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	North Fork Chetco basin, South Fork Chetco basin, alluvial terraces along the Lower Chetco, Jacks Creek, estuary, and all streams where coho salmon would benefit immediately	2a
SONCC-CheR.2.2.5.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-CheR.2.2.5.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-CheR.2.2.68	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Construct off channel habitats, alcoves, backwater habitat, and old stream oxbows	Population wide	2b
SONCC-CheR.2.2.68.1	*Identify potential sites to create refugia habitats. Prioritize sites and determine best means to create rearing habitat*					
SONCC-CheR.2.2.68.2	*Implement restoration projects that improve off channel habitats to create refugia habitat, as guided by assessment results*					
SONCC-CheR.2.2.32	Floodplain and Channel Structure	Yes	Reconnect the channel to the floodplain	Increase beaver abundance	All streams where coho salmon would benefit immediately	2a
SONCC-CheR.2.2.32.1	*Develop a beaver conservation plan that includes education and outreach, technical assistance for landowners, and methods for reintroduction and/or relocation of beaver as a last resort*					
SONCC-CheR.2.2.32.2	*Implement education and technical assistance programs for landowners, guided by the plan*					
SONCC-CheR.2.2.32.3	*Reintroduce or relocate beaver if appropriate, guided by the plan*					

Action ID	Target	KLS/T	Strategy	Action Description	Area	Priority
