Mission Statements

U.S. Department of the Interior

The U.S. Department of the Interior protects America's natural resources and heritage, honors our cultures and tribal communities, and supplies the energy to power our future.

California Department of Fish and Game

The mission of the Department of Fish and Game is to manage California's diverse fish, wildlife, and plant resources, and the habitats upon which they depend, for their ecological values and for their use and enjoyment by the public.

**Klamath Facilities Removal
Final Environmental Impact Statement/Environmental Impact Report**

**Siskiyou County, California
Klamath County, Oregon**

Lead Agencies: U.S. Department of the Interior, through the Bureau of Reclamation (Reclamation), and California Department of Fish and Game (CDFG), Sacramento, California.

State Clearinghouse # 2010062060

ABSTRACT

This Klamath Facilities Removal Environmental Impact Statement/Environmental Impact Report (EIS/EIR) evaluates the potential impacts of the removal of the four PacifiCorp¹ dams on the Klamath River as contemplated in the Klamath Hydroelectric Settlement Agreement (KHSA). The Klamath Basin Restoration Agreement (KBRA), as well as the transfer of Keno Dam, will be treated and analyzed as a connected action. Together, these two agreements attempt to resolve long-standing conflicts in the Klamath River Basin, located in southern Oregon and northern California. The KHSA and KBRA provide for the restoration of native fisheries and sustainable water supplies throughout the Klamath River Basin. Specifically, the KHSA established a process for a Secretarial Determination. This process includes studies, environmental review, and a decision by the Secretary of the Interior regarding whether removal of J.C. Boyle, Copco 1, Copco 2, and Iron Gate Dams (1) will advance restoration of salmonid (salmon, steelhead, and trout) fisheries of the Klamath Basin, and (2) is in the public interest, which includes but is not limited to, consideration of potential impacts on affected local communities and Tribes.

This EIS/EIR has been prepared according to requirements of the National Environmental Policy Act (NEPA) and the California Environmental Quality Act (CEQA). Direct, indirect, and cumulative impacts resulting from the project alternatives on the physical, natural, and socioeconomic environment of the region are addressed.

Executive Summary	ES-1
Chapter 1 – Introduction	1-1
1.1 Purpose and Approach of this Document	1-3
1.2 Physical and Biological Setting	1-4
1.2.1 Geography and Topography	1-4
1.2.2 Climate and Hydrology.....	1-6
1.2.3 Biology.....	1-6
1.2.3.1 Vegetation.....	1-6
1.2.3.2 Wildlife	1-7
1.2.3.3 National Wildlife Refuges	1-7
1.2.3.4 Fish.....	1-7
1.3 People and Historic Setting.....	1-10
1.3.1 Tribes	1-10
1.3.1.1 The Klamath Tribes	1-10
1.3.1.2 Quartz Valley Indian Community.....	1-10
1.3.1.3 Karuk Tribe.....	1-10
1.3.1.4 Hoopa Valley Tribe.....	1-10
1.3.1.5 Yurok Tribe.....	1-11
1.3.1.6 Resighini Rancheria	1-11
1.3.2 Early Euroamerican Settlement and Hydroelectric History.....	1-11
1.3.3 Water Use and Management.....	1-12
1.3.3.1 Water Management.....	1-12
1.3.4 Reclamation’s Klamath Project	1-12
1.3.5 Oregon Water Rights Adjudication	1-17
1.3.6 Klamath Hydroelectric Project and Relicensing.....	1-18
1.3.6.1 Klamath Hydroelectric Project	1-18
1.3.6.2 Federal Energy Regulatory Commission Relicensing.....	1-19
1.4 KHSA and KBRA.....	1-20
1.4.1 KHSA.....	1-21
1.4.1.1 Detailed Plan and Other Studies	1-22
1.4.1.2 State Cost Cap.....	1-22
1.4.1.3 Secretarial Determination	1-23
1.4.1.4 KHSA Implementation	1-24
1.4.2 KBRA	1-26
1.5 NEPA/CEQA	1-30
1.5.1 NEPA/CEQA Requirements.....	1-30
1.5.2 Purpose and Need/Project Objectives.....	1-31

Contents (continued)

Chapter 2 – Proposed Action and Description of the Alternatives	2-1
2.1 NEPA Requirements	2-1
2.2 CEQA Requirements	2-2
2.3 Alternatives Development	2-3
2.4 Proposed Action and Alternatives	2-8
2.4.1 Facilities Common to All Alternatives	2-8
2.4.1.1 J.C. Boyle Dam and Powerhouse.....	2-9
2.4.1.2 Copco 1 Dam and Powerhouse	2-11
2.4.1.3 Copco 2 Dam and Powerhouse	2-12
2.4.1.4 Iron Gate Dam and Powerhouse	2-13
2.4.2 Alternative 1: No Action/No Project Alternative	2-14
2.4.3 Alternative 2: Full Facilities Removal of Four Dams (Proposed Action)	2-21
2.4.3.1 Deconstruction Actions.....	2-25
2.4.3.2 Schedule	2-33
2.4.3.3 Workforce	2-35
2.4.3.4 Environmental Measures	2-35
2.4.3.5 Reservoir Restoration.....	2-37
2.4.3.6 Recreation Facilities.....	2-38
2.4.3.7 Keno Transfer	2-38
2.4.3.8 East and Westside Facilities – Programmatic Measure	2-40
2.4.3.9 City of Yreka Water Supply Pipeline Relocation – Programmatic Measure	2-40
2.4.3.10 KBRA – Programmatic Measures	2-41
2.4.4 Alternative 3: Partial Facilities Removal of Four Dams	2-67
2.4.4.1 Deconstruction Actions.....	2-68
2.4.4.2 Schedule	2-74
2.4.4.3 Workforce	2-74
2.4.4.4 Environmental Measures	2-75
2.4.4.5 Reservoir Restoration.....	2-75
2.4.4.6 Recreation Facilities.....	2-76
2.4.4.7 Keno Transfer	2-76
2.4.4.8 East and Westside Facilities – Programmatic Measure	2-76
2.4.4.9 City of Yreka Water Supply Pipeline Relocation – Programmatic Measure.....	2-76

2-21	KBRA Environmental Water Management Projects	2-65
2-22	Summary of Features to be Removed or Retained with Alternative 3.....	2-69
2-23	Estimated Construction Workforce for Partial Removal at each Facility.....	2-75
2-24	Minimum Structure Footprint and Dimensions for Fish Ladders at Each Dam	2-78
2-25	Fish Passage Improvements under the Fish Passage at Four Dams Alternative.....	2-79
2-26	Estimated Minimum Amount of Reinforced Concrete Necessary for Fish Ladder at Each Dam.....	2-80
2-27	Timetable for Implementation of Fish Passage Improvements at each Dam from Date of FERC License Renewal	2-89
2-28	Estimated Average Construction Workforce for Fish Passage at Four Dams	2-90
2-29	Estimated Construction Workforce for Full Removal of Iron Gate and Copco 1 Dams with Fish Passage at Copco 2 and J.C. Boyle Dams	2-92
2-30	Recreation Facilities under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative.....	2-93
3.1-1	KBRA Plans and Programs Analyzed	3.1-4
3.2-1	Location of Klamath Basin Features Relevant to the Water Quality Area of Analysis	3.2-2

Tables (continued)

<i>Table</i>	<i>Page</i>
3.2-2 Designated Beneficial Uses of Water in the Area of Analysis.....	3.2-4
3.2-3 Oregon Surface-Water Quality Objectives Relevant to the Proposed Action and Alternatives	3.2-7
3.2-4 California Surface-Water Quality Objectives.....	3.2-9
3.2-5 Minimum DO Concentrations Based on Percent Saturation Criteria	3.2-11
3.2-6 Hoopa Valley Tribe Surface-Water Quality Objectives	3.2-12
3.2-7 California Marine Water Quality Objectives Relevant to the Proposed Action and Alternatives.....	3.2-13
3.2-8 Water Quality Impaired Water Bodies within the Area of Analysis	3.2-14
3.2-9 Status of TMDLs in the Klamath Basin as of February 2012.....	3.2-15
3.2-10 Summary of Water Quality Guidance, Criteria, or Targets for Toxigenic Blue-Green Algae and Algal Toxins in the Area of Analysis.....	3.2-49
3.2-11 Summary of Model Predictions for SSCs in the Klamath River Downstream from Iron Gate Dam for the Proposed Action.....	3.2-98
3.2-12 Estimated Short-term Immediate Oxygen Demand (IOD) and Biochemical Oxygen Demand (BOD) by Month for Modeled Flow and SSCs Immediately Downstream from Iron Gate Dam Under the Proposed Action	3.2-115
3.2-13 Estimated Location of Minimum Dissolved Oxygen and Location at which Dissolved Oxygen Would Return to 5 mg/L Downstream from Iron Gate Dam Due to High Short-term SSCs Under the Proposed Action.....	3.2-116
3.2-14 Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts	3.2-162
3.3-1 Declines in Klamath River Anadromous Fish	3.3-5
3.3-2 Estimated Volume of Sediment Currently Stored within Hydroelectric Reach Reservoirs	3.3-35
3.3-3 Ceratomyxa shasta genotypes in the Klamath Basin.	3.3-42
3.3-4 Biological Opinion Flows and Lake Elevations.	3.3-58
3.3-A Summary of the Iron Gate Dam long-term flow targets expected to be achieved by water year 2010 unless modified by study results	3.3-58
3.3-B Instream flow recommendations by annual exceedence levels for net inflows to Upper Klamath Lake on a monthly basis below Iron Gate Dam	3.3-59

Tables (continued)

<i>Table</i>	<i>Page</i>
3.3-5 Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Fall-run Chinook Salmon	3.3-135
3.3-6 Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario SSCs Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Spring-run Chinook Salmon.....	3.3-142
3.3-7 Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario SSCs Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Coho Salmon.....	3.3-147
3.3-8 Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario SSCs Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Summer and Winter Steelhead	3.3-154
3.3-9 Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Pacific Lamprey	3.3-162
3.3-10 Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Green Sturgeon	3.3-165
3.3-11 Comparison of Short-term SSC Effects from the Proposed Action with and without Mitigation Measures; Most-likely Scenario (i.e., 50% Exceedance Probabilities) for Fall- and Spring-Chinook and Coho Salmon	3.3-250
3.3-12 Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Most-likely scenario (i.e., 50% Exceedance Probabilities) for Steelhead and Pacific Lamprey	3.3-253

Tables (continued)

<i>Table</i>	<i>Page</i>
3.3-13 Comparison of Short-term SSC Effects from the Proposed Action with and without Mitigation Measures; Most-Likely Scenario (i.e., 50% Exceedance Probabilities) for Green Sturgeon and Suckers.....	3.3-256
3.3-14 Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measure AR-8 for Freshwater Mussels.....	3.3-257
3.3-15 Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-Case Scenario (10% Exceedance Probabilities) for Fall- and Spring-run Chinook Salmon	3.3-258
3.3-16 Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-Case Scenario (10% Exceedance Probabilities) for Coho Salmon and Steelhead	3.3-260
3.3-17 Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-case Scenario (10% Exceedance Probabilities) for Pacific Lamprey, Green Sturgeon, and Suckers	3.3-262
3.3-18 Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-Case Scenario (i.e., 10% Exceedance Probabilities) for Freshwater Mussels	3.3-265
3.4-1 Summary of Algae Impacts	3.4-32
3.5-1 River Reaches in the PacifiCorp Study (2004a)	3.5-4
3.5-2 Distribution of Vegetation Cover Types Mapped in 2002 in the PacifiCorp Study Area (2004a).....	3.5-8
3.5-3 Sub-Classification of Vegetation Cover Types Mapped in 2002 in the PacifiCorp Study Area (2004a).....	3.5-9
3.5-4 Special-Status Species Known to Occur in the Project Area.....	3.5-31
3.5-5 Estimates of Historic, Existing and Future Wetlands at the Reservoirs	3.5-70
3.5-6 No Surface-Disturbing Activity Spatial Buffers and Seasonal Timing Restriction Stipulations for Raptor Nests.....	3.5-96
3.6-1 Biological Opinion Requirements for Iron Gate Dam Releases (cfs)	3.6-10
3.6-2 USGS Gages on the Klamath River.....	3.6-15
3.6-3 Historic Monthly Average Flows (cfs) in Wetter Years (10% Exceedance Level) during Water Years 1961-2009 on the Klamath River	3.6-16
3.6-4 Annual and Seasonal Daily Flows	3.6-17

Tables (continued)

<i>Table</i>	<i>Page</i>
3.6-5 Flood Frequency Analysis on Klamath River for 10-yr to 100-yr Floods based upon Full Period of Record of Each Gage	3.6-18
3.6-6 Modeled Average Monthly Flows (cfs) in Wetter Years (10% Exceedance Level) on the Klamath River under the No Action/No Project Alternative	3.6-22
3.6-7 No Action/No Project Alternative Resource Management Actions Affecting Flood Hydrology on the Klamath River.....	3.6-24
3.6-8 Flood Flow Exceedance: Modeled Wet Conditions on the Klamath River under the Proposed Action	3.6-29
3.6-9 Flood Attenuation of Iron Gate and Copco 1 Reservoirs	3.6-32
3.7-1 Well Construction Information for Wells within 2.5 Miles of J.C. Boyle Reservoir.....	3.7-10
3.8-1 Upper Klamath Basin Hydrologic Sub-Basins	3.8-6
3.8-2 Summary of Water Rights Listings From California’s Electronic Water Rights Information Management System	3.8-11
3.8-3 Common Benefits to all Indian Tribes with Dam Removal and Implementation of the KBRA	3.8-29
3.9-1 Federal Attainment Status of the Study Area	3.9-4
3.9-2 California Air Quality Attainment Status for the Study Area.....	3.9-7
3.9-3 Uncontrolled Emissions Inventories for the Proposed Action.....	3.9-13
3.9-4 Uncontrolled Emissions from Reservoir Restoration (Reseeding)	3.9-15
3.9-5 Uncontrolled Emissions from Relocation and Demolition of Recreation Facilities	3.9-16
3.9-6 Uncontrolled Emissions from Construction of Yreka Water Supply Pipeline	3.9-18
3.9-7 Uncontrolled Emissions Inventories for the Partial Facilities Removal Alternative	3.9-21
3.9-8 Uncontrolled Emissions Inventories for the Fish Passage at Four Dams Alternative.....	3.9-24
3.9-9 Uncontrolled Emissions Inventories for the Fish Passage at Two Dams, Remove Copco 1 and Iron Gate Alternative	3.9-25
3.9-10 Uncontrolled Emissions from Reservoir Restoration (Reseeding)	3.9-26
3.9-11 Uncontrolled Emissions from Relocation and Demolition of Recreation Facilities	3.9-27
3.9-12 Summary of Mitigated Emissions by Alternative.....	3.9-29
3.10-1 Projected Changes in Air Temperature under Existing Conditions.....	3.10-4
3.10-2 Projected Seasonal Changes in Precipitation.....	3.10-7

Tables (continued)

<i>Table</i>	<i>Page</i>
3.10-3 Representative Carbon Sequestration Rates and Saturation Periods for Key Agricultural and Forestry Practices	3.10-19
3.10-4 Uncontrolled Direct GHG Emissions Inventories for Proposed Action – Full Facilities Removal	3.10-24
3.10-5 Uncontrolled Direct GHG Emissions Inventories for Reservoir Restoration (Reseeding)	3.10-26
3.10-6 Electricity Generation GHG Emissions from Replacement Sources after Removal of Four Dams (Existing Resource Mix).....	3.10-30
3.10-7 Electricity Generation GHG Emissions from Replacement Sources after Removal of Four Dams (33 Percent RPS)	3.10-31
3.10-8 Adjusted Power Replacement Emissions Without Methane Emissions from Reservoirs	3.10-32
3.10-9 Uncontrolled Direct GHG Emissions Inventories for Partial Facilities Removal	3.10-37
3.10-10 Uncontrolled Direct GHG Emissions Inventories for Fish Passage at Four Dams	3.10-40
3.10-11 Electricity Generation GHG Emissions from Replacement Sources after Fish Passage Construction (Current Resource Mix).....	3.10-41
3.10-12 Electricity Generation GHG Emissions from Replacement Sources after Fish Passage Construction (33 Percent RPS).....	3.10-42
3.10-13 Adjusted Power Replacement Emissions With Methane Emissions from Reservoirs	3.10-42
3.10-14 Uncontrolled Direct GHG Emissions Inventories for Fish Passage at Two Dams, Remove Copco 1 and Iron Gate.....	3.10-44
3.10-15 Uncontrolled Direct GHG Emissions Inventories for Reservoir Restoration (Reseeding)	3.10-45
3.10-16 Electricity Generation GHG Emissions from Replacement Sources after Removal of Two Dams (Current Resource Mix).....	3.10-46
3.10-17 Electricity Generation GHG Emissions from Replacement Sources after Removal of Two Dams (33 Percent RPS)	3.10-47
3.10-18 Adjusted Power Replacement Emissions With Methane Emissions from Reservoirs	3.10-48
3.10-19 Impact Summary Table (Without Methane Generation from Reservoirs)	3.10-50
3.10-20 Impact Summary Table (With Methane Generation from Reservoirs)	3.10-50
3.11-1 Cumulative Annual Sediment Delivery to the Klamath River.....	3.11-10
3.11-2 Physical Properties of Reservoir Sediment.....	3.11-11

Tables (continued)

<i>Table</i>	<i>Page</i>
3.11-3 Estimated Future Sediment Volume in Reservoirs under the No Action/No Project Alternative.....	3.11-18
3.11-4 Estimated Particle Sizes that would be Suspended at Average and Maximum Daily Discharge Rates.....	3.11-21
3.11-5 Comparison of Wet and Dry Reservoir Samples	3.11-24
3.12-1 Effects of Current Dam Operations on Klamath Tribes Trust Resources and Rights	3.12-10
3.12-2 Effects of Current Dam Operations on Resources Traditionally Used by the Quartz Valley Tribe	3.12-18
3.12-3 Effects of Current Dam Operations on Resources Traditionally Used by the Karuk Tribe	3.12-24
13.12-4 Effects of Current Dam Operations on Hoopa Valley Indian Tribe Trust Resources and Rights.....	3.12-34
13.12-5 Effects of Current Dam Operations on Yurok Tribe Trust Resources and Rights.....	3.12-44
3.12-6 Effects of Current Dam Operations on Trust Resources and Rights and Resources Traditionally Used by the Resighini Rancheria	3.12-50
3.13-1 Klamath Hydroelectric Facilities Historic District National Register Eligibility Recommendation.....	3.13-28
3.14-1 Kuchel Act Lands in Reclamation’s Klamath Project, 2009	3.14-5
3.14-2 2009 Irrigable Lands in Reclamation’s Klamath Project by State.....	3.14-14
3.15-1 Summary of the 2009 Regional Economy for Klamath and Siskiyou Counties	3-15.4
3.15-2 Summary of the Regional Economy for the San Francisco Management Area (San Mateo, San Francisco, Marin, and Sonoma Counties, CA).....	3-15.7
3.15-3 Summary of the Regional Economy for the Fort Bragg Management Area (Mendocino County, CA).....	3.15-7
3.15-4 Summary of the 2009 Regional Economy for the KMZ-CA (Humboldt and Del Norte Counties, CA)	3.15-8
3.15-5 Summary of the 2009 Regional Economy for the KMZ-OR (Curry County, OR)	3.15-8
3.15-6 Summary of the Regional Economy for the Central Oregon Management Area (Coos, Douglas, and Lane Counties, OR)	3.15-9
3.15-7 Landings of Troll-Caught Chinook Salmon and Coho Salmon (# fish), 1981-2010, by Management Area.....	3.15-9
3.15-8 Landings of Troll-Caught Chinook Salmon and Coho Salmon (1000s of pounds dressed weight), 1981-2010, by Management Area.....	3.15-10

Tables (continued)

<i>Table</i>	<i>Page</i>
3.15-9 Ex-vessel Value of Troll-Caught Chinook Salmon and Coho Salmon (\$1000s, Base Year=2012), 1981-2010, by Management Area.....	3.15-10
3.15-10 Ocean Sport Salmon Effort (# angler days) during 1981-2010, by Management Area.....	3-15.13
3.15-11 Ocean Sport Chinook Salmon and Coho Salmon Landings (# fish) during 1981-2010, by Management Area	3-15.13
3.15-12 Summary of the Regional Economy for Del Norte, Humboldt and Siskiyou Counties in California and Klamath County, OR	3.15-14
3.15-13 Summary of the 2009 Regional Economy for Klamath, Jackson, Humboldt, and Siskiyou Counties.....	3.15-15
3.15-14 Commercially Guided Whitewater Boating Trips on Upper Klamath River from 2001 to 2009.....	3.15-16
3.15-15 Commercially Guided Whitewater Boating Trips on Lower Klamath River from 2000 to 2009.....	3.15-16
3.15-16 Whitewater Boating User Days on the Klamath River from 1994 to 2009	3.15-17
3.15-17 Income, Poverty, and Unemployment for Affected Federally Recognized Tribes	3-15.18
3.15-18 Yurok and Hoopa Valley Reservation Indian Tribes Gillnet Chinook Salmon Spring and Fall Run Harvest (# fish) from 1981 to 2010.....	3.15-19
3.15-19 Siskiyou County Average Tax Revenues from 2000 to 2010.....	3.15-22
3.15-20 Siskiyou County Annual Tax Amount Received from PacifiCorp from 2000 to 2011	3.15-22
3.15-21 Summary of the 2009 Regional Economy for Klamath, Modoc, and Siskiyou Counties	3.15-24
3.15-22 Crop Acreage Summary for Irrigated Agriculture in Reclamation’s Klamath Project Lands (acres).....	3.15-24
3.15-23 Representative Crop Prices from 2005 to 2009	3.15-25
3.15-24 Average Gross Farm Revenue Generated on Reclamation’s Klamath Project Lands from 2005 to 2009.....	3.15-25
3.15-25 Expenditures per User Day for Whitewater Boating on the Klamath River (2012 dollars)	3.15-36
3.15-26 Daily Expenditures per Person for Hunting and Wildlife Viewing (2012 dollars)	3.15-40
3.15-27 Regional Economic Effects from Annual O&M Expenditures for the No Action/No Project Alternative	3-15-40
3.15-28 Annual Ex-Vessel Revenue for Management Areas for the No Action/No Project Alternative	3.15-41

Tables (continued)

<i>Table</i>	<i>Page</i>
3.15-29 Regional Economic Total Effects from Ocean Commercial Fishing under No Action/No Project Alternative	3-15.41
3.15-30 Regional Economic Effects from Reservoir Recreation for the No Action/No Project Alternative.....	3.15-42
3.15-31 Regional Economic Effects from In-river Salmon Fishing for the No Action/No Project Alternative.....	3.15-43
3.15-32 Regional Economic Effects from In-river Steelhead Fishing for the No Action/No Project Alternative.....	3.15-43
3.15-33 Total Annual Recreational Salmon Effort, Nonresident Effort and Nonresident Expenditures for the No Action/No Project Alternative	3.15-44
3.15-34 Regional Economic Effects from Ocean Sport Salmon Fishing for the No Action/No Project Alternative.....	3.15-45
3.15-35 Regional Economic Effects from Whitewater Recreation for the No Action/No Project Alternative.....	3.15-45
3.15-36 Total Economic Effects over a 15 year period of In-Region Spending for Ongoing Restoration Actions under the No Action/No Project Alternative	3.15-50
3.15-37 Gross Farm Revenue for the No Action/No Project Alternative during Drought Years	3.15-51
3.15-38 Regional Economic Effects from Irrigated Agriculture for the No Action/No Project Alternative during Drought Years	3.15-51
3.15-39 Regional Economic Effects from Refuge Hunting for the No Action/No Project Alternative	3.15-52
3.15-40 Total Economic Effects over a 15-year Period of In-Region Spending for Tribal Program Under the No Action/No Project Alternative	3.15-53
3.15-41 Regional Economic Effects from Dam Decommissioning for Alternative 2, the Proposed Action	3.15-54
3.15-42 Change in Regional Economic Effects from O&M Expenditures between the No Action/No Project Alternative and Alternative 2, the Proposed Action.....	3.15-55
3.15-43 Mitigation Costs by Facility and Year (2012 \$) for Alternative 2, the Proposed Action.....	3.15-55
3.15-44 Regional Economic Effects from Mitigation Expenditures for Alternative 2, the Proposed Action	3.15-56
3.15-45 Annual Ex-vessel Revenue by Management Area (2012 dollars).....	3.15-57
3.15-46 Change in Regional Economic Effects from Ocean Commercial Fishing between the No Action/No Project Alternative and Alternative 2, the Proposed Action	3.15-57

Tables (continued)

<i>Table</i>	<i>Page</i>
3.15-47 Change in Regional Economic Effects from Reservoir Recreation between the No Action/No Project Alternative and Alternative 2, the Proposed Action	3-15-58
3.15-48 Total Annual Recreational Salmon Effort, Nonresident Effort and Nonresident Expenditures by Fishing Mode and Management Area for Alternative 2, the Proposed Action.....	3.15-59
3.15-49 Change in Regional Economic Effects from Ocean Sport Salmon Fishing between the No Action/No Project Alternative and Alternative 2, the Proposed Action	3.15-59
3.15-50 Change in Regional Economic Effects from In-river Salmon Fishing between the No Action/No Project Alternative and Alternative 2, the Proposed Action	3.15-60
3.15-51 Change in Regional Economic Effects from Whitewater Recreation between the No Action/No Project Alternative and Alternative 2, the Proposed Action	3.15-62
3.15-52 Evaluated Parcels by Land Use in Siskiyou County.....	3.15-66
3.15-53 Regional Economic Effects of KBRA Fishery Program Actions Relative to No Action/No Project Alternative over a 15-year period (2012 dollars).....	3.15-71
3.15-54 Regional Economic Effects of KBRA Water Resources Program Actions Relative to No Action/No Project Alternative over a 15-year period (2012 dollars).....	3.15-73
3.15-55 Gross Farm Revenue by IMPLAN crop sectors between the No Action/No Project Alternative and Alternative 2, the Proposed Action for Drought Years (1,000 \$).....	3.15-75
3.15-56 Change in Regional Economic Effects from Gross Farm Revenue between the No Action/No Project Alternative and Alternative 2, the Proposed Action	3.15-75
3.15-57 Change in Regional Economic Effects from Increased Pumping Costs between the No Action/No Project Alternative and Alternative 2, the Proposed Action	3.15-76
3.15-58 Regional Economic Effects from Lost Agricultural Production for the WURP	3.15-77
3.15-59 Change in Regional Economic Effects from Refuge Recreation between the No Action/No Project Alternative and Alternative 2, the Proposed Action	3.15-78
3.15-60 Regional Economic Effects of KBRA Regulatory Assurance Actions Relative to No Action/No Project Alternative over a 15-year period (2012 dollars).....	3.15-79
3.15-61 Regional Economic Effects of KBRA Tribal Program Actions Relative to No Action/No Project Alternative over a 15-year period (2012 dollars).....	3.15-82

Tables (continued)

<i>Table</i>	<i>Page</i>
3.15-62 Regional Economic Effects from Dam Decommissioning for Alternative 3	15-83
3.15-63 Change in Regional Economic Effects from O&M Expenditures between the No Action/No Project Alternative and Alternative 3	3.15-84
3.15-64 Mitigation Costs by Facility Year (2012 \$) for Alternative 3	3.15-84
3.15-65 Summary of Regional Economic Effects for Each Alternative	3.15-92
3.15-66 Summary of Regional Economic Effects over 15 Years of Ongoing Restoration Activities and KBRA Implementation	3.15-99
3.16-1 Population, Race, and Ethnicity, 2005-2009 American Community Survey	3.16-3
3.16-2 Tribal Enrollment within the Area of Analysis, 2005.....	3.16-4
3.16-3 Income and Poverty, 1999	3.16-5
3.16-4 Poverty in Siskiyou County	3.16-5
3.16-5 Income and Poverty in Tribes, 1999	3.16-6
3.16-6 Housing and Employment.....	3.16-6
3.16-7 Housing, Labor, and Employment, 2005	3.16-7
3.16-8 Employment and Labor Force, 2005-2009, American Community Survey	3.16-7
3.16-9 Federal Funds Distribution for Social Programs, 2010	3.16-8
3.16-10 Local Funds Distributed for Government Services, 2010	3.16-9
3.16-11 Beneficial Effects of the Proposed Action and Alternatives	3.16-40
3.17-1 Cities Included for Analysis.....	3.17-2
3.17-2 Klamath Falls and Housing Estimates, 2010	3.17-4
3.17-3 Medford and Jackson County Housing Estimates, 2010	3.17-5
3.17-4 Siskiyou County Housing Estimates, 2010.....	3.17-6
3.17-5 Unincorporated Areas Housing Estimates, 2010	3.17-8
3.17-6 Approximate Commute Distances (miles).....	3.17-9
3.18-1 Example Communities in the Area of Analysis with Utilities and Public Services Potentially Affected by Alternatives	3.18-3
3.18-2 Fire Protection Agencies in the Project Area.....	3.18-8
3.18-3 Utilities and Public Services in the Study Area	3.18-9
3.18-4 Regional Landfills and Recycling Centers and Type of Waste Accepted	3.18-16
3.18-5 Klamath Hydroelectric Project Facilities.....	3.18-18
3.18-6 Summary of Solid Waste Generation for Each Action Alternative.....	3.18-27
3.19-1 Visual Resource Inventory Matrix.....	3.19-6
3.19-2 Summary of Features that Would Be Removed under the Proposed Action Alternative and that would be Retained under the Partial Facilities Removal Alternative	3.19-27

Tables (continued)

<i>Table</i>	<i>Page</i>
3.19-3 Minimum Structure Footprint for Fish Ladders under the Fishway Alternatives	3.19-32
3.20-1 Public Lands Offering Recreational Opportunities in the Vicinity of the Klamath River.....	3.20-4
3.20-2 Rivers Providing Recreational Fishing Opportunities in the Region	3.20-6
3.20-3 Rivers with Whitewater Boating Opportunities in the Region	3.20-7
3.20-4 Comparison of Subject Reservoirs with Lakes and Reservoirs in the Region.....	3.20-8
3.20-5 Keno Impoundment/Lake Ewauna Developed Recreation Facilities	3.20-11
3.20-6 Acceptable Flow Ranges for Various River-Based Activities for Reaches of the Klamath River.....	3.20-13
3.20-7 J.C. Boyle Reservoir Developed Recreation Facilities.....	3.20-17
3.20-8 Hell’s Corner Reach Developed Recreation Facilities	3.20-18
3.20-9 Copco 1 Reservoir Developed Recreation Facilities	3.20-19
3.20-10 Iron Gate Reservoir Developed Recreation Facilities	3.20-20
3.20-11 River-Based Recreation Opportunities below Iron Gate Dam.....	3.20-23
3.20-12 Estimated Number of Recreational Salmon Angler Days and Chinook Salmon Harvest on the Klamath River (excluding the Trinity River), 2001-2010.....	3.20-26
3.20-13 Estimated Number of Recreational Steelhead Angler Days on the Klamath River (excluding the Trinity River), 2003-2008	3.20-26
3.20-14 Comparison of 1981 Flows to the Acceptable Range for Whitewater Boating and Fishing	3.20-31
3.20-15 Estimated Abundance of Fish Species at the 1981 WSR Designation	3.20-33
3.20-16 Estimated Number of Days Meeting the Range of Acceptable Flows for Recreational Activities on the Klamath River.....	3.20-42
3.22-1 Local and Regional Access Roads Relative to KHSA.....	3.22-2
3.22-2 Traffic Flow Projections	3.22-12
3.23-1 Maximum Allowable Noise Levels from Construction Equipment in Siskiyou County, CA.....	3.23-2
3.23-2 Existing Noise Levels at Residential Receptors near Construction Sites	3.23-7
3.23-3 Existing Peak Hour L _{eq} Along Proposed Haul and Commute Routes	3.23-8
3.23-4 Construction Operations, Equipment Types, and Their Noise Levels.....	3.23-9

Tables (continued)

<i>Table</i>	<i>Page</i>
3.23-5	Vibration Levels for Construction Equipment..... 3.23-10
3.23-6	Summary of Noise Levels from Deconstruction Activities for the Proposed Action 3.23-13
3.23-7	Summary of Vibration from Construction Activities for the Proposed Action..... 3.23-15
3.23-8	Summary of Construction-Related Traffic Noise from Off-site Hauling and Construction Worker Commute for the Proposed Action..... 3.23-15
3.23-9	Summary of Noise Levels from Construction Activities for the Fish Passage at Four Dams Alternative 3.23-18
3.23-10	Summary of Vibration Levels at Receptors from Construction Activities for the Fish Passage at Four Dams Alternative 3.23-19
3.23-11	Summary of Construction-Related Traffic Noise from Off-site Hauling for the Fish Passage at Four Dams Alternative..... 3.23-20
3.23-12	Summary of Construction-Related Traffic Noise from Off-site Hauling for the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative..... 3.23-22
4-1	Method for Developing the Cumulative Condition 4-4
4-2	Cumulative Effects Area of Analysis by Resource for Removal of the Four Facilities (KHSA) 4-6
4-3	Plans, Programs, and Other Documents Considered in Cumulative Effects Analysis..... 4-10
4-4	Projects Considered in Cumulative Effects Analysis 4-24
4-5	Summary of Water Quality Impacts from Chapter 3..... 4-30
4-6	Summary of Aquatic Resources Impacts from Chapter 3 4-59
4-7	Summary of Algae Impacts from Chapter 3 4-95
4-8	Summary of Terrestrial Resources Impacts from Chapter 3 4-104
4-9	Summary of Flood Hydrology Impacts from Chapter 3 4-116
4-10	Population Projections for the Eight Klamath Basin Counties 4-120
4-11	Summary of Ground Water Impacts from Chapter 3..... 4-123
4-12	Summary of Water Rights/Water Supply Impacts from Chapter 3 4-128
4-13	Summary of Air Quality Impacts from Chapter 3 4-137
4-14	Summary of Greenhouse Gases/Global Climate Change Impacts from Chapter 3 4-144
4-15	Summary of Geology, Soils and Geologic Hazards Impacts from Chapter 3 4-150
4-16	Summary of Cultural and Historic Resources Impacts from Chapter 3 4-159
4-17	Summary of Land Use, Agricultural and Forest Resources Impacts from Chapter 3 4-166

Tables (continued)

<i>Table</i>	<i>Page</i>
4-18 Summary of Population and Housing Impacts from Chapter 3	4-182
4-19 Summary of Public Health and Safety, Utilities and Public Services, Solid Waste, and Power Impacts from Chapter 3	4-185
4-20 Summary of Scenic Quality Impacts from Chapter 3	4-194
4-21 Summary of Recreation Impacts from Chapter 3	4-202
4-22 Summary of Toxic/Hazardous Materials Impacts from Chapter 3	4-211
4-23 Summary of Traffic and Transportation Impacts from Chapter 3	4-215
4-24 Summary of Noise and Vibration Impacts from Chapter 3	4-222
5-1 Summary of Environmental Impacts Relative to NEPA and CEQA	5-8
5-2 Summary of Environmental Effects Relative to NEPA	5-85
5-3 Summary of Significant Environmental Effects that Cannot be Avoided Relative to CEQA and NEPA	5-103
5-4 Summary of Adverse Environmental Effects Relative to NEPA	5-113
5-5 Summary of Major Long-term Benefits for Salmonid Restoration and Water Quality	5-123
5-6 Detailed Comparison of Alternative 2 and Alternative 3	5-127
5-7 Summary of Controversies and Issues Raised by Agencies and the Public	5-133
6-1 Related Federal Laws, Rules, Regulations, Executive Orders, and Other Authorities	6-1
6-2 California State Statutes and Regulations	6-7

2-25	Copco 2 Fish Ladder and Fish Screen, along the left side of the river, for power water diversion..... 2-85
2-26	Modifications at the tailrace of the Copco 2 Powerplant would extend the bank and install a tailrace barrier screen (red dots)..... 2-87
2-27	Conceptual fish passage facilities layout for Iron Gate Dam showing fish ladder, water intake screen, and spillway transition modifications 2-88
2-28	Anticipated schedule for Fish Passage at J.C. Boyle and Copco 2 Dams with Removal of Copco 1 and Iron Gate Dams 2-92
3.2-1	Water Quality Area of Analysis..... 3.2-3
3.2-2	Summary of Anticipated Effects of Inorganic and Organic Contaminants in Klamath Reservoir and Estuary Sediments Under the No Action/No Project Alternative and the Proposed Action, for Five Exposure Pathways..... 3.2-80
3.2-3	Predicted Water Temperature at the California-Oregon State line (RM 208.5) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario)..... 3.2-84
3.2-4	Estimated Changes in Daily Maximum Klamath River Water Temperatures at ≈RM 198 due to the Presence of Copco 1 and 2 Reservoirs for the 2000 Calendar Year. 3.2-85
3.2-5	Simulated Hourly Water Temperature Downstream from Iron Gate Dam (RM 190.1) Based on Year 2004 for Existing Conditions Compared to Hypothetical Conditions without J.C. Boyle (JCB), Copco 1, Copco 2, and Iron Gate (IG) Dams..... 3.2-87
3.2-6	Simulated Hourly Water Temperature Immediately Upstream of the Scott River Confluence (RM 143.9) Based on Year 2004 for Existing Conditions Compared to Hypothetical Conditions without J.C. Boyle (JCB), Copco 1, Copco 2, and Iron Gate (IG) Dams. 3.2-88

Figures (continued)

<i>Figure</i>	<i>Page</i>
3.2-7 Simulated Hourly Water Temperature Downstream from the Salmon River Confluence (≈RM 66) Based on Year 2004 for Existing Conditions Compared to Hypothetical Conditions without J.C. Boyle (JCB), Copco 1, Copco 2, and Iron Gate (IG) Dams	3.2-88
3.2-8 Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Action Assuming Typical Dry Hydrology (WY2001).....	3.2-91
3.2-9 Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Action Assuming Median Hydrology (WY1976).....	3.2-92
3.2-10 Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Action Assuming Typical Wet Hydrology (WY1984).	3.2-92
3.2-11 SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Action Assuming Typical Dry Hydrology (WY2001).	3.2-97
3.2-12 SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Action Assuming Median Hydrology (WY1976).	3.2-97
3.2-13 SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Action Assuming Typical Wet Hydrology (WY1984).	3.2-98
3.2-14 Annual predicted sediment delivery to the Pacific Ocean under the Proposed Action and the No Action (background conditions) by Water Year.....	3.2-101
3.2-15 Comparison of TP and TN Concentrations from Iron Gate Dam to Turwar (RM 5.8) for June–October and July–September 2007–2008: (a) Measured Current Conditions (Red Circle), (b) Dams-Out Estimate using Calculated Percent Retention Rates by Reach (Blue Cross), and (c) Dams-Out Estimate using Percent Retention Rates Predicted by the Empirical Relationship between Reach Inflow Concentration and Retention (Green Cross).	3.2-109
3.2-16 Predicted Dissolved Oxygen Downstream from J.C. Boyle Dam (RM 224.7 to 228.3) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).....	3.2-113
3.2-17 Predicted Dissolved Oxygen at the Oregon-California State line (RM 208.5) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).....	3.2-113

Figures (continued)

<i>Figure</i>	<i>Page</i>
3.2-18 Predicted Dissolved Oxygen Downstream from Iron Gate Dam (RM 190.1) for the Klamath TMDL Scenarios Similar to the Proposed Action (TCD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario)	3.2-119
3.2-19 Predicted Dissolved Oxygen Downstream from the Mainstem Confluence with the Shasta River (RM 176.7) for the Klamath TMDL Scenarios Similar to the Proposed Action (TCD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).....	3.2-119
3.2-20 Predicted Dissolved Oxygen at Seiad Valley (RM 129.4) for the Klamath TMDL Scenarios Similar to the Proposed Action (TCD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).....	3.2-120
3.2-21 Predicted Dissolved Oxygen Just Upstream of the Confluence with the Trinity River (RM 42.5) for the Klamath TMDL Scenarios Similar to the Proposed Action (TCD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).....	3.2-120
3.2-22 Predicted pH Downstream from J.C. Boyle Reservoir (RM 224.7) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).....	3.2-122
3.2-23 Predicted pH at the Oregon-California State line (RM 208.5) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).....	3.2-122
3.2-24 Predicted Klamath River pH Immediately Downstream from Iron Gate Dam for the Klamath TMDL Scenarios Similar to the Proposed Action (TCD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario)	3.2-125
3.2.25 Predicted Klamath River pH upstream of the Scott River (RM 143.0) for the Klamath TMDL Scenarios Similar to the Proposed Action (TCD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).....	3.2-125
3.2-26 Simulated Hourly Water Temperature Downstream from Iron Gate Dam (RM 190.1) Based on Year 2004 for Current Conditions Compared to Hypothetical Conditions: (a) without Iron Gate (IG), Copco 1 and 2, and J.C. Boyle (JCB) Dams and (b) without Iron Gate (IG) and Copco 1 and 2 Dams	3.2-153

Figures (continued)

<i>Figure</i>	<i>Page</i>	
3.3-1	Five Study Reaches within the Area of Analysis for the Aquatic Resources Analysis.	3.3-2
3.3-2	Normal conditions (50 Percent Exceedance Probability) SSCs for Three Locations Downstream from Iron Gate Dam under Existing Conditions, as Predicted Using the SRH-1D Model.	3.3-32
3.3-3	Extreme conditions (10 Percent Exceedance Probability) SSCs for Three Locations Downstream from Iron Gate Dam under Existing Conditions, as Predicted Using the SRH-1D Model.	3.3-33
3.3-4	Mobilization Flow and Return Period at which Sediment Mobilization Occurs.....	3.3-36
3.3-5	Mean daily flows (cubic feet per second) for the Klamath River at the USGS Gage at Keno for three different water years, generally representing drier (1908), more normal (1911) and wetter (1907) conditions.....	3.3-51
3.3-6	Timeline Depicting the Timing of Salmon Lifecycles in the Mainstem of the Klamath River Coinciding with Dam Removal Plans.....	3.3-53
3.3-7	Mean daily flows (cubic feet per second) for the Klamath River at the USGS Gage near Fall Creek (Gage #11512500) for three different water years, generally representing drier (1937), normal (1936) and wetter (1943) conditions.	3.3-55
3.3-8	Comparison of mean daily flows recorded at Keno (USGS Gage #11509500) historically (1905-1912) with more recent conditions (1961-2000).....	3.3-56
3.3-9	Comparison of SSCs under Proposed Action and Existing Conditions at Iron Gate Dam, as Predicted Using SRH-1D Model.	3.3-102
3.3-10	Comparison of SSCs under Proposed Action and Existing Conditions at Orleans, as Predicted Using SRH-1D Model.	3.3-103
3.3-11	Comparison of SSCs under Proposed Action and Existing Conditions at Klamath Station, as Predicted Using SRH-1D Model.	3.3-104
3.3-12	Sediment Erosion from Dams in the Hydroelectric Reach During 2020 Drawdown Beginning in January	3.3-106
3.3-13	Reach-Averaged Erosion in the Hydroelectric Reach during Wet Year.....	3.3-107

Figures (continued)

<i>Figure</i>	<i>Page</i>
3.3-14 Simulated Bed Composition from Copco 2 to Iron Gate Reservoirs during Two Successive Dry Water Years during and after Drawdown (Based on simulation results provided by Reclamation, March 2012).	3.3-107
3.3-15 Reach Averaged Bed Elevation Change for Two Successive Wet, Median, or Dry Water Years Following Reservoir Drawdown (Based on simulation results provided by Reclamation, March 2012).	3.3-109
3.3-16 Simulated Bed Composition from Iron Gate Dam to Bogus Creek during Two Successive Dry Water Years Following Reservoir Drawdown (Based on simulation results provided by Reclamation, March 2012).....	3.3-110
3.3-17 Simulated D50 (mm) from Iron Gate Dam to Bogus Creek during Successive Wet, Median, and Dry Water Years Following Reservoir Drawdown (Based on simulation results provided by Reclamation, March 2012).....	3.3-111
3.3-18 Time series of average daily mean water temperature (lower panel) forecasted at Iron Gate Dam (RM 190) for the Index Sequential climate scenario spanning years 2020 to 2061, for Proposed Action and Existing Conditions	3.3-115
3.3-19 PacifiCorp (2005) Simulated hourly water temperatures below Iron Gate Dam based on a dry water year (WY 2002) for existing conditions compared to the Proposed Action (without Project dams), and USEPA (2003) water temperature criteria for salmonid growth and migration.	3.3-116
3.4-1 Biovolume (in red) and percent biovolume (in blue) of <i>Microcystis aeruginosa</i> above, within, and downstream from Copco 1 and Iron Gate Reservoirs during 2005.....	3.4-9
3.5-1 PacifiCorp Terrestrial Resources Study Area.	3.5-2
3.5-2 PacifiCorp Terrestrial Resources Study Area.	3.5-5
3.5-3 J.C. Boyle Reservoir Historic Vegetation Types.	3.5-11
3.5-4 Copco Reservoir Historic Vegetation Types.	3.5-13
3.5-5 Iron Gate Reservoir Historic Vegetation Types.....	3.5-15
3.5-6 J.C. Boyle Reservoir Revegetation	3.5-71
3.5-7 Copco Reservoir Revegetation.	3.5-72
3.5-8 Iron Gate Reservoir Revegetation.....	3.5-73
3.6-1 Flood Hydrology Affected Area.	3.6-2
3.6-2 Historical Upper Klamath Basin Hydrology Before Dams, National Wildlife Refuges, and Reclamation’s Klamath Project.	3.6-6
3.6-3 USGS Stream Gage Locations.....	3.6-15

Figures (continued)

<i>Figure</i>	<i>Page</i>
3.6-4 Daily Average Flows at Five USGS Stream Gages on Klamath River.....	3.6-16
3.6-5 Stream Flows Downstream from Iron Gate Dam in Wet, Average, and Dry Conditions	3.6-17
3.6-6 Stream Flows Downstream from J.C. Boyle Dam in Wet, Average, and Dry Conditions	3.6-18
3.6-7 Modeled Flow Exceedances under the No Action/No Project Alternative and Proposed Action Near Keno Dam.	3.6-29
3.6-8 Modeled Flow Exceedances under the No Action/No Project Alternative and Proposed Action Below J.C. Boyle Dam.....	3.6-30
3.6-9 Modeled Flow Exceedances under the No Action/No Project Alternative and Proposed Action Below Iron Gate Dam.	3.6-30
3.6-10 Modeled Flow Exceedances under the No Action/No Project Alternative and Proposed Action Near Seiad Valley.....	3.6-31
3.6-11 Modeled Flow Exceedances under the No Action/No Project Alternative and Proposed Action at Orleans.	3.6-31
3.7-1 Generalized Ground Water Potentiometric Surface Contour Map and Ground Water Flow Directions in the Upper Klamath Basin.....	3.7-3
3.7-2 Enlarged Portion of the Generalized Ground Water Potentiometric Surface Contour Map and Flow Directions for the Areas around J.C. Boyle, Copco, and Iron Gate Reservoirs.	3.7-4
3.7-3 Locatable Wells within 2.5 Miles of J.C. Boyle Reservoir and Cross-Section Locations.....	3.7-9
3.7-4 J.C. Boyle Reservoir Cross-Sections J and K.....	3.7-11
3.7-5 J.C. Boyle Reservoir Cross-Section L.	3.7-12
3.8-1 Area of Analysis.	3.8-5
3.8-2 Schematic of Reclamation’s Klamath Project.	3.8-9
3.8-3 Flows for different year types under the Proposed Action and No Action Alternatives just downstream from Iron Gate Dam.....	3.8-16
3.8-4 90% Exceedance Flows Near Seiad Valley, Orleans, and Klamath for Dam Removal and No Action Alternatives.....	3.8-16
3.8-5 Annual flows under the No Action/No Project Alternative and Proposed Action	3.8-21
3.9-1 Area of Analysis for both the Klamath Hydroelectric Settlement Agreement (KHSAs) and the Klamath Basin Restoration Agreement (KBRA).....	3.9-2

Figures (continued)

<i>Figure</i>	<i>Page</i>
3.9-2 Particulate Matter (PM ₁₀ and PM _{2.5}) NAAQS and California Ambient Air Quality Standards (CAAQS) Designations.....	3.9-5
3.9-3 Particulate Matter (PM ₁₀ and PM _{2.5}) and Carbon Monoxide (CO) NAAQS Designations in Oregon.....	3.9-6
3.9-4 Ozone (O ₃) NAAQS and CAAQS Designations.....	3.9-7
3.9-5 Federal Class I Areas.	3.9-10
3.10-1 California GHG Emission Sources (as of 2008).....	3.10-11
3.10-2 Oregon GHG Emission Sources (as of 2007).....	3.10-12
3.10-3 Greenhouse Gas Emissions Comparison.	3.10-12
3.10-4 PacifiCorp Power Control Area Generation Resource Mix (as of 2007).	3.10-27
3.11-1 Klamath Basin Physiographic Provinces.	3.11-3
3.11-2 Existing Potential Landslide Areas.	3.11-14
3.14-1 Reclamation’s Klamath Project and National Wildlife Refuges in the Vicinity.	3.14-3
3.14-2 Land Ownership Around the Klamath River in the Vicinity of the Hydroelectric Reach.	3.14-6
3.14-3 Land Use at Keno and J.C. Boyle Dams.....	3.14-12
3.14-4 Land Use – Iron Gate and Copco Dams.	3.14-13
3.14-5 Upper Klamath Basin Agricultural Resources.....	3.14-16
3.15-1 Socioeconomic Area of Analysis.....	3.15-2
3.15-2 Klamath Management Zone Boundary and Ports.....	3.15-6
3.16-1 Tribal Lands near Haul Routes.	3.16-30
3.17-1 Population and Housing Area of Analysis.....	3.17-2
3.17-2 Census Block Groups.....	3.17-7
3.18-1 Klamath Basin.....	3.18-2
3.18-2 Hospitals and Fire Stations near the Project Area.	3.18-5
3.18-3 Fire Hazard in the Area of Analysis.	3.18-7
3.18-4 PacifiCorp Service Area.	3.18-17
3.19-1 Project Area Land Ownership for BLM and USFS.....	3.19-4
3.19-2 Key Observation Points from PacifiCorp (2004) Report.....	3.19-7
3.19-3 Historic River Channel for J.C. Boyle Reservoir	3.19-15
3.19-4 Historic River Channel at Copco I Reservoir	3.19-15
3.19-5 Historic River Channel at Iron Gate Reservoir.....	3.19-16
3.19-6 Iron Gate Dam before removal (top) and a simulation of what the facility could look like after full removal (bottom) except for Landform/Vegetation restoration details which cannot be fully depicted until completion of the Definite Plan.	3.19-17

Figures (continued)

<i>Figure</i>	<i>Page</i>
3.19-7 Copco 1 Dam before removal (top) and a simulation of what The facility could look like after full removal (bottom) except for Landform/Vegetation restoration details which cannot be fully depicted until completion of the Definite Plan	3.19-18
3.19-8 View of Copco 2 Powerhouse and Historic Structure	3.19-19
3.19-9 View of J.C. Boyle Powerhouse.	3.19-28
3.19-10 Example of cast in place pool and weir fish ladder used for fish passage, similar to that proposed for upstream fish passage for all four dams under this alternative.....	3.19-33
3.19-11 Example of fish ladder built into steep bedrock similar to Copco 1 option.....	3.19-33
3.20-1 Regional Recreation Areas.	3.20-3
3.20-2a Iron Gate Recreation Areas.....	3.20-14
3.20-2b Copco Recreation Areas.	3.20-15
3.20-2c J.C. Boyle Recreation Areas.	3.20-16
3.20-3 Klamath Wild and Scenic River Corridor.....	3.20-28
3.20-4 Comparison of Available Recreation Flows - Keno Reach.....	3.20-43
3.20-5 Comparison of Available Recreation Flows - JC Boyle Bypass Reach.....	3.20-43
3.20-6 Comparison of Available Recreation Flows - Hell's Corner Reach.....	3.20-44
3.20-7 Comparison of Available Recreation Flows - Copco 2 Bypass Reach.....	3.20-44
3.20-8 Comparison of Available Recreation Flows - Iron Gate to Scott River Reach	3.20-45
3.20-9 Comparison of Available Recreation Flows - Scott River to Salmon River Reach	3.20-45
3.20-10 Comparison of Available Recreation Flows – Salmon River to Trinity River Reach.....	3.20-46
3.20-11 Comparison of Available Recreation Flows - Trinity River to Ocean Reach	3.20-46
3.21-1 School Sites in the Project Area.....	3.21-6
3.21-2 HTRW Sites, Keno Dam and Keno Impoundment/ Lake Ewauna.....	3.21-8
3.21-3 HTRW Sites, Iron Gate and Copco Dams and Reservoirs	3.21-9
3.21-4 HTRW Sites, J.C. Boyle Dam and Reservoir	3.21-10
3.22-1 Regional Access Routes Relative to the KHSR.	3.22-2
3.22-2 Copco Road (north of river, facing west)	3.22-5
3.22-3 Access Bridge at J.C. Boyle Dam.....	3.22-6
3.22-4 Bridge Accessing Lakeview Road (looking south)	3.22-6
3.23-1 Primary Haul Routes from Dam Sites	3.23-2

Figures (continued)

<i>Figure</i>		<i>Page</i>
3.23-2	J.C. Boyle Noise Receptors (Closest Receptors to J.C. Boyle Dam)	3.23-4
3.23-3	Copco 1 and 2 Noise Receptor (Closest Receptor to Copco 1 and Copco 2 Dams).....	3.23-5
3.23-4	Iron Gate Noise Receptors (Closest Receptor to Iron Gate Dam)	3.23-6
3.23-5	Parcel Lots within One-Mile of Copco 1 and 2 Dam	3.23-24
3.23-6	Parcel Lots within One-Mile of Iron Gate Dam	3.23-25

Abbreviations and Acronyms

AADT	Annual Average Daily Traffic
AB	Assembly Bill
ACHP	Advisory Council on Historic Preservation
ACS	American Community Survey
AET	Apparent Effects Threshold
AF	Acre feet
AFA	Aphanizomenon flos-aquae
AGR	Agricultural Supply
AIP	Agreement in Principle
AIRFA	American Indian Religious Freedom Act
Alternative 1	No Action/No Project
Alternative 2	Full Facilities Removal of Four Dams Alternative (Proposed Action)
Alternative 3	Partial Facilities Removal of Four Dams Alternative
Alternative 4	Fish Passage at Four Dams Alternative
Alternative 5	Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative
APE	Area of Potential Effects
AQUA	Aquaculture, Mariculture
AQMA	Air Quality Maintenance Area
ARPA	Archaeological Resource Protection
ASDSO	Association of State Dam Safety Officials
ASR	Aquatic Scientific Resources
AUM	Annual Unit Month
AWS	Auxiliary Water Supply
B	Beneficial
BA	Biological Assessment
BB	Black Bullhead
BCoCs	bioaccumulative chemicals of concern
BEP	Business Emergency Plan
BGEPA	Bald and Golden Eagle Protection Act
BIA	Bureau of Indian Affairs
BIOL	Preservation and Enhancement of Designated Areas of Special Biological Significance
BLM	Bureau of Land Management

BLS	Bureau of Labor Statistics
BMI	Benthic Macroinvertebrates
BMP	Best Management Practice
BO	Biological Opinion
BOD	Biological Oxygen Demand
BOE	Board of Equalization
BP	Before Present
BSLVs	Bioaccumulation screening level values
BTs	Bioaccumulation Triggers
CAA	Federal Clean Air Act
CAAQS	California Ambient Air Quality Standards
Caltrans	California Department of Transportation
CAPCOA	California Air Pollution Control Officers Association
CARB	California Air Resources Board
CAS	California Climate Adaption Strategy
CASGEM	California Statewide Groundwater Elevation Monitoring
CBOD	Carbonaceous biochemical oxygen demand
CCA	California Coastal Act
CCR	California Code of Regulations
CEC	California Energy Commission
CDC	California Department of Conservation
CDC	Centers for Disease Control
CDFG	California Department of Fish and Game
CDM	Camp Dresser & McKee
CEQ	Council on Environmental Quality
CEQA	California Environmental Quality Act
CESA	California Endangered Species Act
CFR	Code of Federal Regulations
cfs	Cubic feet per second
CH ₄	methane
CHHSLs	California Human Health Screening Levels
CNDDB	California Natural Diversity Database
CO	Carbon Monoxide
CO ₂	Carbon Dioxide
CO ₂ e	Carbon Dioxide equivalent
COLD	Cold Freshwater Habitat
COMM	Commercial and Sport Fishing

COPCs	Chemicals of Potential Concern
COPCO	California Oregon Power Company
CPUC	California Public Utilities Commission
CRFD	Colestin Rural Fire Protection District
CRHR	California Register of Historical Resources
CRS	Congressional Research Service
CSSC	California Department of Fish and Game Species of Special Concern
CTR	California Toxics Rule
CUL	Native American Culture, Ceremonial and Cultural Water Use
CUPAs	Certified Unified Program Agencies
CWA	Clean Water Act
CWC	California Water Code
CWT	Coded Wire Tags
CZMA	Coastal Zone Management Act
dB	decibels
dBA	A-weighted decibels
DC	direct current
DDE	1,1-bis-(4-chlorophenyl)-2,2-dichloroethene
DDT	dichlorodiphenyltrichloroethane
DEA	David Evans and Associates
DEET	N,N-Diethyl-meta-Toluamide (insect repellent)

Glossary

abeyance	A state of temporary suspension.
abutment	Structural element that ties a dam into the existing ground.
acclimation (of fish)	The process of a fish adjusting to change in its environment, allowing it to survive changes in temperature, water and food availability, and other stresses.
acre-foot	The amount of water required to cover 1 acre to a depth of 1 foot. One acre-foot equals 326,851 gallons or 43,560 cubic feet. This volume measurement is used to describe a quantity of storage in a reservoir.
adfluvial	Fish who live in lakes and migrate into rivers or stream to spawn.
adjudication	The final judgment in a legal proceeding; the act of pronouncing judgment based on the evidence presented.
Affirmative Determination	A determination by the Secretary of the Interior under Section 3 of the Klamath Hydroelectric Settlement Agreement that facilities removal should proceed.
alluvial	Deposition of sediment over a long period of time by a river; an alluvial layer; pertaining to the soil deposited by a stream.
ammocoete	Juvenile lamprey.
anadromous	A type of fish that hatch in freshwater, migrate to the ocean, mature there, and return to freshwater to spawn. Salmon and steelhead are examples.
anoxic conditions	Conditions with a deficiency of oxygen.
anthropogenic	Made by people or resulting from human activities.

antidegradation policy	A policy designed to prevent deterioration of existing levels of good water quality.
appropriations	Funds set aside (as by a legislature) for a specific purpose.
attraction flows	Drawing fish to dam fishways or spillways through the use of water flows.
bedload sediment	Particles carried along the bottom of a river or stream, rather than in the current.
beneficial use	The uses of a water resource that are protected by state water quality standards. Beneficial uses include human consumption, aquatic life, recreation, and fish and wildlife habitat.
benthic	The ecological region at the lowest level of a body of water, including the sediment surface and some sub-surface layers. Organisms living in this zone are called benthos or benthic organisms.
berm	A mound or linear embankment of fill material, typically earth fill.
best management practices (BMPs)	Physical, structural or managerial practices that control soil loss and reduce water quality pollution caused by nutrients, animal wastes, toxics, and sediment.
bioaccumulation	The process by which substances accumulate in the tissues of living organisms.
biochemical oxygen demand (BOD)	The amount of oxygen needed by aerobic microorganisms to decompose all the organic matter in a sample of water; it is used as a measure of pollution.
biological opinion	The product of Endangered Species Act consultation, a document stating the opinion of the United State Fish and Wildlife Service or National Marine Fisheries Service on whether or not a federal action is likely to jeopardize the continued existence of listed species or result in the destruction or adverse modification of critical habitat.

blue-green algae	Algae that can cause problems in aquatic environments because some produce chemicals that are toxic to animals, including humans.
bulk bag	A container made from abrasion resistant fabric designed to contain loose material such as seeds, or in this case sand and gravel, and used for work area isolation.
camas	A type of lily used as a food source by Native Americans.
cession (of property)	The assignment of property to another entity.
chlorophyll-a	A photosynthetic pigment that serves as a surrogate measure for abundance of algae.
cofferdam	A temporary enclosure designed to be watertight or minimize water infiltration to isolate work areas for construction.
cohort	A group of fish spawned during a given period, usually within a year.
confluence	The meeting of two or more bodies of water, such as the point where a tributary joins the mainstem.
connected action	The National Environmental Policy Act defines a <u>connected action</u> as an action that (i) automatically triggers other actions that may require environmental impact statements (ii) cannot or will not proceed unless other actions are taken previously or simultaneously (iii) is an interdependent part of a larger action and depends on the larger action for its justification. Connected actions are closely related and therefore should be discussed in the same impact statement (40 CFR Part 1508.25 (a)1).
consolidation (of sediments)	The process by which sediments are compacted together.
contour line	A line connecting points of equal elevation.

Cooperating Agencies	Under the National Environmental Protection Act (NEPA), the agencies having responsibility to assist the Lead Agency by participating in the NEPA process. The role of the cooperating agencies may include conducting environmental analyses of resources which the cooperating agency has jurisdiction by law or special expertise.
critical habitat	Areas that are essential to the conservation of a species listed under the federal Endangered Species Act.
cyanobacteria	Photosynthetic bacteria, also known as blue-green algae. Cyanobacteria form extensive and highly visible blooms in the freshwater and marine environment.
Dam Removal Entity	The party with primary responsibility for carrying out the dam removal and other components of the Klamath Hydroelectric Settlement Agreement.
decommissioning	Taking out of use, such as dismantling a dam or destroying an unneeded road.
desiccation	Drying out.
diel	Pertaining to a 24-hour period; daily.
direct effects	Related to socioeconomics, they are one or a series of production changes or expenditures made by producers/consumers as a result of an activity or policy. These initial changes are determined by an analyst to be a result of this activity or policy. Applying these initial changes to the multipliers in an IMPLAN model will then display how the region will respond, economically to these initial changes.
dissolved oxygen	The amount of oxygen in the water available to aquatic organisms measured in mg/L or percent saturation.
diversion	The act of diverting water from the main river course down a water separate conveyance system.
drawdown	Lowering of the water level in a reservoir.

drop structure	A structure, often part of a dam's spillway, to pass water to a lower elevation while controlling the energy and velocity of the water as it passes over.
elutriate	Separation of fine particles into size fractions according to their rate of fall through an upward current of water.
embankment	Earth or stone fill designed to hold back water.
emergent vegetation	Aquatic plants rooted underwater that grow above (emerge from) the surface of the water (e.g., cattails).
employment (jobs)	Employment in IMPLAN is measured in number of jobs. A job is the annual average of monthly jobs in that industry (this is the same definition used by Quarterly Census of Employment Wages, Bureau of Labor Statistics, and Bureau of Economic Analysis nationally). Thus, 1 job lasting 12 months = 2 jobs lasting 6 months each = 3 jobs lasting 4 months each. A job can be either full-time or part-time.
endemic	Native to or confined to a certain region.
entrainment (of fish)	The loss of fish during water diversion due to their movement with the flow of water. Entrainment can result in mortality from direct contact with structures, from steep drops, or from stranding in areas where water does not persist, such as irrigation systems.
environmental water	The quantity and quality of instream water available to support fisheries and other aquatic resources.
epilimnion	The top-most layer in a lake stratified by temperature. It is warmer and typically has a higher pH and dissolved oxygen concentration than the lower layers (the hypolimnion).
erosion	The wearing away of the land surface by wind or water. Erosion occurs naturally from weather or runoff but is often intensified by land-clearing practices.

ESA consultation	In compliance with the Endangered Species Act, the process by which a federal agency presents information to the United States Fisheries and Wildlife Service or National Oceanic and Atmospheric Administration Fisheries Service regarding actions that may affect listed species or their designated habitat.
escapement (of fish)	That portion of an anadromous fish population that escapes the commercial and recreational fisheries and reaches the freshwater spawning grounds.
escapement floor	The lower bound of an escapement goal, which sets the number of salmonids that are not harvested and return to the river for spawning.
estuary	A partly enclosed coastal body of water with one or more rivers or streams flowing into it, and with a free connection to the open sea.
eutrophic	Waters rich in dissolved nutrients (especially nitrogen and phosphorus); leads to accelerated growth of algae and plants that depletes oxygen levels.
extirpation	Local extinction of a species over a portion of its total range.
ex-vessel value	Gross value of all fish caught within the area of analysis.
final demand	The value of goods & services produced and sold to final users (institutions) during the calendar year. This value is also equivalent to the Direct Effect of the impact.
fine sediment	Sediment with small particle size such as silts and clays.
fish ladder (fishway, fish passageway)	A structure on or around artificial barriers such as dams and locks to allow fish to move around the barrier during migration.
flume	Open-channel water conveyance system.
focal species	Species of ecological and/or human value that is of priority interest for study or management.

forebay	Water conveyance area between reservoir and power generation facilities.
fry	A juvenile salmon or steelhead.
genotype	The genetic identity of an individual.
geomorphic	Relating to surface features of a landscape.
gravel augmentation	The direct placement of spawning-size gravel into the stream channel to increase spawning habitat by increasing the amount of area with suitable substrate.
gravity arch dam	A dam that curves upstream in a narrowing curve that directs most of the water against the canyon rock walls, providing the force to compress the dam.
greenhouse gases	Gases including carbon dioxide, methane, and nitrous oxide, that prevent heat from escaping from the atmosphere, resulting in climate change (also known as global warming).
ground water recharge	The natural or intentional infiltration of surface water for the replenishment of existing natural underground water supplies.
hatchery	A place where large numbers of fish eggs are artificially fertilized and fry are hatched in an enclosed environment.
headcut	An erosional feature in waterways where an abrupt vertical drop in the stream bed occurs.
herbaceous	Referring to a plant that has leaves and stems that die down at the end of the growing season to the soil level. They have no persistent woody stem above ground.
hibernacula	A place where a hibernating animal shelters for the winter.
humic	Having a high organic carbon content.

Hydroelectric Reach	The portion of the Klamath River that includes the four most downstream dams (J.C. Boyle, Copco 1, Copco 2, and Iron Gate Dams).
hydrophilic	Plants especially suited to thrive in soils that are always wet.
hydroseeding	A planting process which utilizes a slurry of seed and mulch. The slurry is transported in a tank, either truck- or trailer-mounted and sprayed over prepared ground in a uniform layer.
hypereutrophic	Very nutrient-rich lakes characterized by frequent and severe nuisance algal blooms and low transparency.
hypolimnetic anoxia	The absence of oxygen in the lower layers of a lake or reservoir.
hyporheic	Beneath the bed of a stream, where there is mixing of shallow ground water and surface water.
hypoxia	Oxygen deficiency.
IMPLAN®	IMPact Analysis for PLANning, a regional input-output model that evaluates regional economic effects.
incidental take	The “take” (adverse effect) of a listed species that results from, but is not the purpose of, an activity. Incidental take cannot result in jeopardy to the species and must be specifically authorized in the biological opinion.
indirect effects	Related to socioeconomics, they represent the impact of local industries buying goods and services from other local industries. The cycle of spending works its way backward through the supply chain until all money leaks from the local economy, either through imports or by payments to value added (employee).
induced effects	Related to socioeconomics, they represent the response by an economy to an initial change that occurs through re-spending of income received by a component of value added (employee). The labor income is recirculated through the household spending patterns causing further local economic activity.

in situ	In the original or natural place.
intake structure	Facility designed to divert water from the river or reservoir.
ipos	Roots of the plant <i>Carum oregonum</i> , important to some Native Americans tribes.
isobath	A type of contour line connecting points of equal water depth in a body of water.
J.C. Boyle Bypass Reach	The reach of the Klamath River between J.C. Boyle Dam and J.C. Boyle Powerhouse. A bypass reach is that section of a river from which water is removed to generate hydropower. Water is often diverted from the river at the dam, transported through channels or penstocks downstream, and released back in the river at the powerhouse.
J.C. Boyle Peaking Reach	The reach of the Klamath River between the J.C. Boyle Powerhouse and the mouth of Shovel Creek. A peaking reach is that section of a river that receives the water from the generation of hydroelectric power at the powerhouse.
Keno Impoundment	The water body created by Keno Dam.
Keno Transfer	The transfer ownership and operational responsibility of the Keno facility from PacifiCorp to the United States Department of the Interior as part of Klamath Hydroelectric Settlement Agreement implementation.
Klamath Allottee	A tribal member who owns a beneficial interest in a tract of land within the original (1864) boundaries of the Klamath Indian Reservation.
Klamath Basin	The portion of land drained by the Klamath River and its tributaries. The Klamath River Basin is divided into the Upper Klamath Basin and the Lower Klamath Basin.

Klamath Hydroelectric Project	A system of hydroelectric components that includes the dams, powerhouses, and other facilities for generation of hydroelectric power on the Klamath River and developed jointly by the Bureau of Reclamation (Reclamation) and the California-Oregon Power Company (COPCO, the predecessor to PacifiCorp).
Klamath River Basin Compact	Agreement between the State of California and the State of Oregon and consented by U.S. Congress in 1957 that established the Klamath River Compact Commission to promote comprehensive development, conservation, and control of the resources of the Klamath River and to foster interstate comity between California and Oregon.
Klamath Tribes	The Tribes of the Klamath Basin include the Karuk Tribe, Yurok Tribe, Klamath Tribes (made up of the Klamaths, the Modocs, and the Yahooskin), Resighini Rancheria, Hoopa Valley Tribe, and Quartz Valley Community.
Lake Ewauna	Also known as Keno Impoundment.
labile	Active, possessing rapid turnover rates.
labor income	All forms of employment income, including Employee Compensation (wages and benefits) and Proprietor Income.
lacustrine	Of or pertaining to lakes.
Lead Agencies	The agencies with the primarily responsibility under NEPA and equivalent state environmental policy acts (e.g., California Environmental Quality Act [CEQA]) for carrying out an evaluation of the environmental effects of their decision-making and for preparation of the appropriate environmental document. For the Klamath Facilities Removal Environmental Impact Statement/Environmental Impact Report, the U.S. Department of the Interior is Lead Agency under NEPA and the California Department of Fish and Game is Lead Agency under CEQA.

lease lands	Land located near Tule Lake National Wildlife Refuge or the Lower Klamath National Wildlife Refuge, leased by Reclamation.
lentic	Of, relating to, or living in still waters (lakes, ponds, or swamps).
levee	A natural or artificial slope or wall to regulate water levels. It is usually earthen and often parallel to the course of a river or the coast.
liquid limit	The water content at which the behavior of the soil changes from a plastic to a semi-liquid state.
littoral	The zone between high tide and low tide waterlines of a lake or ocean.
lotic	Of, relating to or living in actively moving waters (streams and rivers).
Lower Klamath Basin	The portion of the Klamath River Basin downstream of Iron Gate Dam.
macroinvertebrate	Aquatic insects, worms, clams, snails, and other animals without backbones that can be seen without the aid of a microscope.
macrophyte	An aquatic plant that grows in or near water and is either emergent, submergent, or floating.
mainstem	The principal river in a basin, as opposed to the tributary streams and smaller rivers that feed into it.
microcystin	A toxin produced by the blue-green algal species <i>Microcystis aeruginosa</i> .
mitigation	The act of alleviating or lessening an adverse condition.
morphological	Related to the form of. Morphology is the study of the forms of things.
Negative Determination	A determination by the Secretary of the Interior under Section 3 of the Klamath Hydroelectric Settlement Agreement that facilities removal should not proceed.

nonpoint source pollution	A term in the Clean Water Act also called “polluted runoff,” water pollution produced by diffuse land-use activities. Occurs when runoff carries fertilizer, animal wastes, and other pollution into rivers, streams, lakes, reservoirs, and other bodies of water.
noxious weed	A plant species that has been designated by state or national agricultural authorities as a plant that is injurious to native plants, agricultural and/or horticultural crops, and/or humans and livestock.
nutrient loading	Discharging of nutrients from the watershed (basin) into a receiving water body (lake, stream, wetland).
off-Project	Not associated with (not receiving water from, in the case of irrigators) Reclamation’s Klamath Project.
ogee-type drop structure	A drop structure with a curved shape consisting of two arcs that curve in opposite directions so that their ends are parallel.
on-Project	Associated with (receiving water from, in the case of irrigators) Reclamation’s Klamath Project.
output (sales)	Related to socioeconomics, output represents the value of industry production. In IMPLAN these are annual production estimates for the year of the data set and are in producer prices. For manufacturers this would be sales plus/minus change in inventory. For service sectors production = sales. For Retail and wholesale trade, output = gross margin and not gross sales.
PacifiCorp	An electric power company in the northwestern United States that owns and operates the Klamath River dams.
palustrine	Of or pertaining to wetlands or freshwater marsh.
Parties	Signatories to the Klamath Hydroelectric Settlement Agreement.
pelagic	Relating to or occurring, living in, or frequenting the open ocean.

penstock	A pipe or conduit that carries water to a power generation turbine.
periphyton	A complex mixture of algae, bacteria, their secretions, associated detritus, and various species of microinvertebrates attached to submerged surfaces in most aquatic ecosystems.
phytoplankton	Small, photosynthetic aquatic organisms, including diatoms, green algae, and cyanobacteria (blue-green algae).
plasticity	The ability of a soil to transform from a solid state to a liquid state by adding water.
point source pollution	Pollution into bodies of water from specific discharge points such as sewer outfalls or industrial-waste pipes.
polychaete	Aquatic annelid worms belonging to the Class Polychaeta, segmented and have bristles for movement or attachment.
powerhouse	Structure that contains the power generation equipment such as the turbine, may be an enclosed building or an open area with concrete slabs and equipment.
programmatic analysis	For purposes of CEQA, the Klamath Basin Restoration Agreement analysis is programmatic, as described in Section 15168 of the CEQA Guidelines. A program-level document is appropriate when a project consists of a series of smaller projects or phases that may be implemented separately. Under the programmatic Environmental Impact Report approach, future projects or phases may require additional, project-specific environmental analysis.
Project Team	The group of lead, cooperating, and responsible agencies responsible for evaluating the alternatives in the Environmental Impact Statement/Report.

Proposed Action	One of the alternatives evaluated in the Environmental Impact Statement/Report, the Proposed Action (also known as the Full Facilities Removal of Four Dams Alternative) includes the removal of four PacifiCorp Dams (J.C. Boyle, Copco 1, Copco 2, and Iron Gate Dams) during a 20-month period which includes an 8-month period of site preparation and partial drawdown at Copco 1 and a 12-month period for full drawdown and removal of facilities. This alternative would include the complete removal of power generation facilities, water intake structures, canals, pipelines, ancillary buildings, and dam foundations.
protocol-level surveys	Standardized methods approved by the U.S. Fish and Wildlife Service or other resource agency for establishing the presence or absence of special-status species.
radial gate	Tainter gate.
Reclamation's Klamath Project	The system of reservoirs, dams, canals, and pumps built to drain and reclaim lake bed lands of the Lower Klamath and Tule Lakes, to store water of the Klamath and Lost Rivers, to divert irrigation supplies, and to control flooding of the reclaimed lands.
redd	A depression in streambed gravel dug by a female fish for depositing eggs during spawning.
regalia	Especially fine or decorative clothing.
relicensing	The administrative proceeding in which Federal Energy Regulatory Commission (FERC), in consultation with other federal and state agencies, decides whether and on what terms to issue a new license for an existing hydroelectric project at the expiration of the original license.
remediation	To address a problem. Often refers to the removal of pollution or contaminants from environmental media such as soil, ground water, sediment, or surface water for the general protection of human health and the environment.

riffle	A shallow section of river characterized by numerous small waves on the surface often caused by gravel bars.
Resource Agencies	Government entities that have jurisdictional authority over various natural resources.
Responsible Agencies	Under CEQA, the agencies with discretionary approval authority over a portion of a CEQA project such as required permits.
restoration	The return of a landscape, ecosystem, or other system to a predefined historical state.
riparian	The area adjacent to a river or stream (and sometimes along shorelines of lakes or reservoirs).
riprap	Broken stone, cut stone blocks, or rubble that is placed on slopes to protect them from erosion.
river left and right	The designated side of the river when looking downstream in the direction of flow.
river mile	Measure of distance in miles along a river from its mouth. River mile numbers begin at zero and increase further upstream.
river mouth	The place where a river ends by flowing into another body of water such as a lake, ocean, or another river.
riverine	Of or pertaining to rivers.
run (of salmonids)	A group of fish that is migrating from the ocean to spawn in the rivers or streams where they were born.
salmonid	Of, belonging to, or characteristic of the family Salmonidae, which includes salmon, trout, and whitefish.
scour	The hole left behind when sediment is washed away from the bottom of a river. Although scour may occur at any time, scour action is especially strong during floods. Swiftly flowing water has more energy than calm water to lift and carry sediment down river.

secondary effects	Related to socioeconomics, they are indirect effects plus induced effects.
Secretarial Determination	Decision by the Secretary of the Interior based on a thorough scientific review of existing science, data and other information whether removal of the dams: (1) will advance restoration of the salmonid fisheries of the Klamath Basin; and 2) is in the public interest.
sedimentation	Settling of particulate matter in water related to particle size, water velocity, and water flow.
senescence	In plants, death triggered by an increase in the enzymes that promote the breakdown of plant cells.
smolt	A juvenile salmon or steelhead migrating to the ocean and undergoing physiological changes to adapt its body from a freshwater to a saltwater environment.
soil moisture content	The weight of water contained in a sample of soil, typically expressed as a percentage of the dry weight of the soil.
spawning	The process by which fish release eggs and sperm and deposit them on the stream substrate.
special-status species	Plant and wildlife species listed as threatened or endangered under the federal or state endangered species acts. Also included are federal candidate species, federal species of concern, state sensitive species, state species of concern, and those given special status by the Bureau of Land Management, the U.S Forest Service, or Indian Tribes.
spillway	Open-channel used to convey water over a dam, typically constructed of concrete to resist scour and erosion.
stormwater	Water that is not absorbed into soil and rapidly flows downstream, increasing the level of waterways.
stratification (in lakes)	The formation of layers based on temperature, oxygen levels, salinity, and density that act as barriers to water mixing.

subsistence	The way by which a culture obtains its food.
supersaturation	When oxygen (or other substance) is more highly concentrated in water (or other substance) than is normally possible under normal temperature and pressure.
suspended sediment	Particles that settle slowly enough to be carried in flowing water.
switchyard	The enclosed areas at power stations containing switching facilities and equipment for the purpose of connecting to the transmission network.
tailrace	Open-channel area downstream of power generation turbine for return water to flow back to the river.
Tainter gate	A radial arm water control structure used to control flow into a spillway or overflow area.
talus	A deposit of broken, coarse rock found at the base of a cliff or mountain.
thalweg	The deepest part of a stream or river channel.
thermal refugia	Cool, well-oxygenated areas of rivers utilized by salmon and other species to avoid thermal stress.
thermocline	A layer within a body of water or air where the temperature changes rapidly with depth.
Tidal prism	The volume of water in an estuary or inlet between mean high tide and mean low tide, or the volume of water leaving an estuary at ebb tide.
topographical	Of or relating to the arrangement or accurate representation of the physical features of an area.
total effects	Related to socioeconomics, they are direct effects plus indirect effects plus induced effects.
total Kjeldahl nitrogen	A measure of organic nitrogen plus ammonia.
total maximum daily load (TMDL)	A regulatory term in the Clean Water Act that describes the maximum amount of a pollutant that a body of water can receive while still meeting water quality standards.

toxigenic	Producing or containing toxins.
transformer bushings	A transformer is a device that transfers electrical energy from one circuit to another; a bushing provides insulation for the transformer.
transhumance	The seasonal movement of people with their livestock over relatively short distances, typically to higher pastures in summer and to lower valleys in winter.
tributary	A stream or river that flows into a mainstem river and contributes water to it.
turbidity	A measure of the extent to which light passing through water is reduced owing to suspended materials.
Upper Klamath Basin	The portion of the Klamath River Basin located upstream of Iron Gate Dam. The Upper Klamath Basin is divided into two sub-basins: the Klamath Hydropower Reach from Iron Gate Dam to J.C. Boyle Dam and the basin upstream of J.C. Boyle Dam.
V-screen	A V-shaped screen over the water intake to prevent fish from swimming through.
volitional fish passage	The movement of migratory fish around a dam via an upstream fish ladder or downstream bypass system as opposed to being trapped and hauled around the dam or attempting to move through hydropower turbines where many would be killed. Volitional fishways allow anadromous fish to migrate when they are physiologically ready.
watershed	All the land drained by a given river and its tributaries. An entire drainage basin including all living and nonliving components of the system.
weir	A low structure built across a stream to raise the upstream water level while allowing water to flow over the top of the structure.
wocas	The nutritious seeds of the yellow pond lily, important to some Indian Tribes.

Executive Summary

ES.1 Introduction

This document, *Klamath Facilities Removal Environmental Impact Statement/ Environmental Impact Report* (EIS/EIR), has been developed in accordance with the requirements of the National Environmental Policy Act (NEPA) and the California Environmental Quality Act (CEQA) to analyze the potential impacts to the environment from the proposed removal of four PacifiCorp Dams (J.C. Boyle, Copco 1, Copco 2, and Iron Gate, collectively referred to herein as the Four Facilities) on the Klamath River under the Klamath Hydroelectric Settlement Agreement (KHSA). The KHSA is one part of a basin-wide approach to address continuing unresolved problems resulting from over-stressed water supplies and water quality concerns in the Klamath Basin, including impacts to basin fisheries.

Since 2001, the Federal Government has faced events and taken unprecedented and extraordinary actions in the Klamath Basin largely because of these unresolved problems. The following are examples of some of these events and actions:

- In spring of 2001, the Federal Government announced there would be no deliveries of water from Upper Klamath Lake or the Klamath River to the Bureau of Reclamation's (Reclamation's) Klamath Project due to the combined effects of severe drought and Federal Endangered Species Act (ESA) concerns - the first time project water deliveries were not made at a Reclamation project (very limited deliveries occurred later in the summer).
- In 2002, there was a major fish die-off in the Klamath River of adult fall-run Chinook salmon (at least 30,000 fish).
- In 2005, public health warnings to avoid contact with water in Iron Gate and Copco Reservoirs due to toxic algae blooms began being posted annually.
- In 2006, low abundance of Klamath Basin Chinook salmon led to severe restrictions on commercial and recreational harvest along 700 miles of the California and Oregon coast, as well as major reductions in Klamath River recreational and tribal fisheries.
- In 2010, there was a significant reduction in water deliveries to Reclamation's Klamath Project due to dry hydrologic conditions.
- In 2010, the Klamath Tribes limited their harvest of suckers to ceremonial use for the 25th consecutive year and experienced their 92nd year without access to salmon.

These events and actions demonstrate the need for long-term solutions that address these complex and basin-wide problems. There have been limited and piecemeal approaches that have provided interim relief or some mitigation, but the Klamath Basin faces

substantial, long-term challenges that many believe call for different and more basin-wide approaches. As stated above, the KHSA is one part of a proposed basin-wide approach to resolve these issues.

ES.1.1 Klamath Hydroelectric Settlement Agreement

The KHSA is a negotiated agreement to study the potential removal of four dams on the Klamath River and, should a decision be made to remove these dams, the agreement provides a path forward on undertaking this removal. The KHSA was signed by representatives of 45 organizations including Federal agencies, the States of California and Oregon, PacifiCorp, Indian Tribes, counties, irrigators, and conservation and fishing groups in order to address one of the most economically, environmentally, and culturally devastating water disputes in the western United States. The terms of the KHSA acknowledge, however, that there are many unknown consequences regarding the potential removal of these facilities. Thus the agreement requires that the Secretary of the Interior undertake a series of scientific studies to determine whether dam removal would meet criteria including: being in the public interest and advancing restoration of the salmon fishery. If the Secretary, in cooperation with the Secretary of Commerce and other Federal agencies as appropriate, determines that dam removal fulfills these criteria and makes a positive determination (Affirmative Secretarial Determination), the States of Oregon and California will consider whether to concur in that determination.¹ If the governors concur, dam removal will proceed in accordance with the KHSA.

This joint EIS/EIR is intended to provide the required environmental review for both the Secretarial Determination and the gubernatorial concurrences. Consequently, this EIS/EIR has been prepared by the United States Department of the Interior (DOI), as lead NEPA agency, and the California Department of Fish and Game (CDFG), as lead CEQA agency (collectively referred to herein as Lead Agencies). Recognizing that elements of the Proposed Action would occur in California and Oregon, CDFG collaborated with DOI, with input from the State of Oregon, to make a reasonable, good faith effort in disclosing all significant environmental effects of the Proposed Action. Absent certain circumstances, CEQA does not apply to any project or portion thereof located outside of California which will be subject to environmental review pursuant to NEPA (Public Resources Code § 21080(b)(14); CEQA Guidelines § 15277).

ES.1.2 Klamath Basin Restoration Agreement

The Klamath Basin Restoration Agreement (KBRA) is also a negotiated agreement that reflects a basin-wide approach to addressing the current resources challenges. The KBRA was negotiated concurrently with the KHSA and has been signed by most of the parties to the KHSA, but the Federal agencies are not yet parties to the KBRA. The

¹ There are certain conditions that must be met prior to the Secretary making this determination. One such condition is the enactment of Federal law authorizing the KHSA which has not occurred as of this time. There are also other requirements. For a complete list of these requirements, please see <http://klamathrestoration.gov/>, which has the KHSA posted in its entirety.

KBRA will be signed by Federal agencies when Congress authorizes them to do so.² The complete KBRA package entails various commitments and actions that have been or will be proposed and/or undertaken in the basin by Federal, State, local, tribal, and private interests. Some of the KBRA actions could have effects (whether adverse or beneficial) on the same environmental resources that would be affected by dam removal. Some KBRA actions are expressly preconditioned by and therefore hinge upon dam removal, and an Affirmative Secretarial Determination. Some KBRA actions are Federal but are not expressly linked to dam removal, and some actions involve only non-Federal parties.

ES.1.3 NEPA – Specific Analysis

The Federal Lead Agency, the DOI, is analyzing the KBRA as a connected action to the proposed Secretarial Determination under the KHSAs. NEPA defines connected actions as those actions that are closely related to or cannot or would not proceed unless other actions are taken previously or simultaneously (40 CFR 1508.25(a)(1)(ii)).³ Some actions or component elements of the KBRA are independent obligations and thus have independent utility from the KHSAs, but the implementation of several significant elements of the KBRA would be different, if the Secretarial Determination under the KHSAs is not to pursue full dam removal. Recognizing that implementation of many elements of the KBRA is unknown and not reasonably foreseeable at this time, the connected action analysis under NEPA is being undertaken at a programmatic level. Consequently, appropriate future project-level analysis under NEPA would be completed for the KBRA in the future as project-specific proposals are developed and no Federal action regarding KBRA implementation would be made pursuant to the analysis in this document.

NHPA Section 106 Process
DOI elected to utilize the NEPA process to meet the Federal requirements of Section 106 of the National Historic Preservation Act (NHPA) as allowed under 36 CFR Section 800.8(c). DOI defines the undertaking, for purposes of Section 106 of the NHPA, as the removal of the four PacifiCorp dams which may be a result of the Secretarial Determination. The proposed undertaking has the potential to affect historic properties triggering compliance with Section 106 of the NHPA. The analysis and consultations concerning any effects of the Proposed Action and alternatives on historic properties are integrated into the NEPA review and documentation pursuant to the criteria identified in 36 CFR Section 800.8(c)(1)-(4).

² Under the KHSAs and KBRA (Agreements) certain agencies of the United States (“Federal Agency Parties”) shall become parties to the KBRA upon enactment of authorizing legislation that authorizes and directs them to become parties (KBRA Section 1.1.2).

³ We acknowledge, however, that the KBRA could also be analyzed as a cumulative or similar action under 40 CFR 1508.25(a)(2) and (3). We note that all three definitions (connected action, cumulative actions, and similar actions) are within the section that provides parameters for the “scope” of the action, which determines both the range of alternatives and the impacts to be considered in an EIS. Ultimately, however, we believe the important point is not the labeling but the analysis and whether the decision (in this case whether to remove four dams) is informed by a EIS that is proper in scope.

For purposes of this analysis, the KBRA, a connected action, is viewed as a whole program even though some of its component parts are currently being implemented (those without a Federal nexus or not subject to environmental review) or could be implemented on an individual basis without dam removal. One of the reasons why the KBRA is treated as a whole for purposes of this EIS/EIR is that the individual activities under the KBRA would be implemented, through adaptive management and in close coordination with committees comprised of stakeholders, in a manner that seeks to attain synergy and optimize benefits through a coordinated, holistic approach to restoration and water management. Implementing those KBRA activities that are not connected to facilities removal on an individual basis without the benefit of adaptive management and stakeholder input would likely not optimize benefits.

ES.1.4 CEQA – Specific Analysis

CDFG, as Lead Agency under CEQA, is also analyzing relevant parts of the KBRA in a programmatic fashion, as described in Section 15168 of the CEQA Guidelines. This decision was made because many of KBRA's component elements have not been specified to a degree where the associated impacts would be reasonably foreseeable for purposes of this environmental analysis. The parties recognize that future project-specific analysis may be required for various components of the KBRA as they become more clearly defined and when a public entity, as defined by CEQA Guidelines Section 15379, identifies a discretionary approval pursuant to CEQA Guidelines Section 15378, which would obligate subsequent review. A program-level document is appropriate when a project consists of a series of smaller projects or phases that may be implemented separately. Under the programmatic EIR approach, future projects or phases may require additional, project-specific environmental analysis. It should also be noted that this EIR makes certain assumptions about the foreseeable effects of KBRA based on existing information, including, among other things, how the fishery and water resources programs may be designed and implemented. CDFG recognizes that subsequent environmental analysis may be required by any California public entity with an approval or permitting obligation if the circumstances specified by CEQA Guidelines Section 15162(a) are triggered.

Importantly, CDFG could have analyzed the associated impacts of the KBRA relative to the KHSA in the indirect and cumulative impacts analysis portion of the KHSA EIR as it is not affirmatively approving or carrying out any one aspect of the KBRA that would be subject to environmental review. CDFG recognizes it is not “approving” any discretionary portion of the KBRA that could alter the physical environment and that by signing the KBRA it has already executed and committed to the agreement itself. Thus, similarly to the EIS, there are no alternatives that consider what a new or revised KBRA might look in the event dams are not removed. Rather, to avoid confusion, duplication, and wasted resources, CDFG has determined that the concurrent and connected nature of the KBRA to the KHSA warrants a clear understanding of its potentially significant impacts and that the approach of programmatic analysis is equally, if not more, sufficient for providing that information to decisionmakers.

Thus, out of an abundance of caution, and to ensure full transparency, CDFG has agreed to consider significance determinations for the KBRA in a programmatic fashion. Recognizing that elements of the Proposed Action would occur in California and Oregon, CDFG collaborated with DOI, with input from the State of Oregon, to make a reasonable, good faith effort in disclosing all significant environmental effects of the Proposed Action. Absent certain circumstances, CEQA does not apply to any project or portion thereof located outside of California which will be subject to environmental review pursuant to NEPA (Public Resources Code § 21080(b)(14); CEQA Guidelines § 15277). CDFG considers the Proposed Actions by California to be implementation of the KHSA and thus has crafted alternatives only for dam removal itself, assuming that absent full or partial facilities removal the relevant elements of the KBRA will no longer be ascertainable. CDFG recognizes that in the event subsequent analysis

Klamath Hydroelectric Project

The Klamath Hydroelectric Project was constructed between 1911 and 1962 and includes eight developments: the East and West Side power facilities, and Keno, J.C. Boyle, Copco 1, Copco 2, Fall Creek, and Iron Gate Dams. Located at the upstream boundary of the Klamath Hydroelectric Project, Link River Dam and Upper Klamath Lake are not part of the project.

All of the dams, excluding Link River Dam, are owned by PacifiCorp. Link River Dam was constructed to enhance hydroelectric production at the East and Westside power plants as well as control the storage and timing of water releases downstream to better control future power production at the lower river dams. The dam is owned by Reclamation, but operated by PacifiCorp under Reclamation's direction for regulating flows and storing water in Upper Klamath Lake for irrigation use in Reclamation's Klamath Project.

Keno Dam regulates water levels of the Klamath River upstream of the dam. The facility does not include power-generating equipment. PacifiCorp operates the dam under an agreement with Reclamation to maintain stable water levels in Keno Impoundment/Lake Ewauna for consistent water delivery to dependent water users.

The dams on the mainstem of the Klamath River include: J.C. Boyle, Copco 1, Copco 2, and Iron Gate Dams (the Four Facilities), which are currently owned by PacifiCorp. The portion of the Klamath River that includes these four most downstream dams is referred to as the Klamath Hydroelectric Reach. Fall Creek Dam is on a Klamath River tributary that flows into Iron Gate Reservoir.

The purpose of the Klamath Hydroelectric Project is power generation. The installed maximum capacity of the entire project is 169 megawatts and, on average since full installation in 1963, the project produced 82 megawatts, and annually generated 716,800 megawatt hours of electricity.

is deemed appropriate, it will be required to consider any feasible alternatives, mitigation measures, and any other elements required by CEQA as the basis for any approval of such KBRA project or phase in accordance with existing law.

ES.1.5 Oregon Concurrence

The State of Oregon, and more specifically the “Klamath Team” consisting of Oregon Water Resources, Oregon Department of Fish and Wildlife, and Oregon Department of Environmental Quality, will follow a distinct process for determining concurrence with an Affirmative Determination by the Secretary of the Interior (as defined pursuant to Executive Order No. 10-10 by the Governor of Oregon) should such a determination be made.

The Klamath Team will evaluate two questions in order to determine concurrence:

1. Whether significant impacts identified in its environmental review can be avoided or mitigated as provided under State law.
2. Whether the facilities removal will be completed within the State Cost Cap.

The Klamath Team will provide the results of its evaluation in a recommendation to the Governor, for transmittal to the Secretary of the Interior as a concurrence, if appropriate.

ES.2 Background

Figure ES-1 illustrates many of the existing features of the Klamath Basin in southern Oregon and northern California. The Klamath Basin’s history, like numerous other river basins throughout the Western United States, is one of fish harvest, dam construction, timber harvest, farming, ranching, water diversion, and corresponding changes in the basin’s water quality, hydrology, and natural resources.

ES.2.1 Basin Timeline

Figure ES-2 displays a timeline of some of the events and activities within the basin which have contributed to current conditions related to water supply, fisheries, recreation, and stakeholder negotiations. Water diversions and planning for dam construction in the basin began prior to 1905, when the precursor to the Bureau of Reclamation started construction of Reclamation’s Klamath Project. Construction of the Klamath Hydroelectric Project, starting with Copco 1 Dam, began in 1911.

Figure ES-1. The Klamath Basin.

Klamath Facilities Removal
Final EIS/EIR

Figure ES-2a. Klamath Basin Timeline.

Figure ES-2b. Klamath Basin Timeline.

ES.2.2 Activities Leading to the Development of the KHSA and the KBRA

While the construction and operation of reservoirs and dams on the Klamath River facilitated development, growth, and expansion of an agricultural economy in the region, it also contributed to declines in fisheries and water quality, as well as impacts on tribal resources and culture.

As described above, construction of the dams along the mainstem of the Klamath River resulted in fisheries declines. The construction of Copco 1 Dam resulted in decimation of the Klamath Tribes' anadromous fisheries by blocking fish passage to the Upper Basin. The 1980s and 1990s witnessed declining populations and closure of Lost River and shortnose sucker fisheries as well as the Federal listing under the Endangered Species Act of both sucker species and coho salmon.

In 2008 and 2010, the United States Fish and Wildlife Service (USFWS) and the National Oceanic and Atmospheric Administration (NOAA) Fisheries Service, respectively, issued biological opinions on Reclamation's Klamath Project operations to better protect listed species. Project operations are now conducted in accordance with both opinions.

The Klamath Basin faced substantial, long-term challenges, such as the decline of fish species, posting of health advisories due to poor water quality conditions, the water delivery curtailments and other unresolved natural resource issues described under Section ES.1 and Figure ES-2. The likelihood that similar hardships would continue to occur, coupled with upcoming changes PacifiCorp would need to make in order to continue operating their hydroelectric project, led basin stakeholders to begin negotiation of a mutually beneficial agreement to try to provide enduring solutions to these longstanding challenges.

While stakeholders began efforts to reach agreement on the multifaceted problems of the basin in the 1990s, the water-related farming and fisheries crises experienced in 2001 and 2002, and expiration of PacifiCorp's licenses for its hydroelectric project on the Klamath River, provided additional impetus to reach a negotiated settlement, as discussed further below. Official negotiations leading to the KHSA and KBRA began in 2005. The KHSA grew directly out of the Federal Energy Regulatory Commission's (FERC) Alternative Dispute Resolution Procedures (18 C.F.R. 385.601, et seq.) wherein the parties, including PacifiCorp, elected to negotiate a settlement that contemplates the potential removal of PacifiCorp's hydroelectric facilities on the Klamath River as an alternative to relicensing those facilities. As stated in Section 1.2 of the KHSA, many of the parties to the settlement maintain that facilities removal will help restore basin resources and all signatory parties agree that settlement will help reduce conflicts among Klamath Basin communities. The draft KBRA was released in January 2008. The agreements were negotiated and written to be executed together and are referred to herein as the Klamath Settlement.

ES.2.2.1 FERC Relicensing

The KHSA and KBRA negotiations thus coincided with PacifiCorp's 2004 FERC relicensing application for the Klamath Hydroelectric Project. The company's original 1956 license expired in March 2006. The 1956 PacifiCorp license pre-dated many environmental laws, and did not include prescriptions (Section 18 of the Federal Power Act (FPA) [16 USC 811]) for fish passage over or around the dams. Currently, only J.C. Boyle and Keno Dams have fish passage facilities, but these fishways do not meet current passage criteria.

PacifiCorp filed an application with FERC for a new operating license for the Klamath Hydroelectric Project in 2004. The NOAA Fisheries Service recommended to FERC removal of the Four Facilities as the best alternative to contribute to restoration of all fish species of concern in the Klamath watershed under FPA Section 10(a). Concurrently, under Section 18 authority of the FPA, the NOAA Fisheries Service (the Secretary of Commerce's authority under the FPA has been delegated to the NOAA Fisheries Service and DOI prescribed mandatory fishways and passage at each mainstem dam. Flows were conditioned from J.C. Boyle Dam downstream for riparian habitat, whitewater recreation, and fisheries by DOI under Section 4(e) authority. See the text box below that describes these sections of the FPA.

The fishway prescriptions by the NOAA Fisheries Service and DOI were supported by basin tribes, fishing interests, and conservation groups to address declining fish harvests in the lower Klamath River and to reopen blocked habitat. The fishway prescriptions and DOI's mandatory conditions were challenged by PacifiCorp and others under the Energy Policy Act of 2005, in a trial-type hearing that considered disputed issues of material fact relating to the prescriptions and conditions. The resulting Administrative Law Judge decision (*In the Matter of: Klamath Hydroelectric Project, Docket Number 2006-NMFS-0001, September 27, 2006*) found that PacifiCorp failed to meet its burden of proof regarding most of the factual issues in dispute. FERC conducted environmental analysis of the proposed project, including the mandatory terms and conditions and prescriptions in 2007. The dams have been operating under an annual license since March 2006, when the original license expired.

Before FERC may issue any new license for the Klamath Hydroelectric Project, the States of Oregon and California must also separately issue water quality certifications under Section 401 of the Clean Water Act (CWA). The California State Water Resources Control Board (SWRCB) cannot issue certification until environmental documentation consistent with the requirements of CEQA, is completed. The certification proceedings are currently being held in abeyance as requested in Section 6.5 of the KHSA. In a February 2009 letter from SWRCB addressing the CEQA Notice of Preparation for an EIR for 401 water quality certification of the Klamath Hydroelectric project, it was noted that failing to process the water quality certification in a timely manner risks a FERC determination that the SWRCB has waived certification (SWRCB 2009). The State of California would then have no regulatory authority to address water quality issues associated with the Klamath Hydroelectric Project during the FERC relicensing.

The Federal Power Act

The Federal Power Act (FPA) authorizes the Federal Energy Regulatory Commission (FERC) to license hydroelectric projects in the United States.

Section 18 of the FPA states in pertinent part:

FERC “shall require the construction, maintenance, and operation by a licensee at its own expense of...such fishways as may be prescribed by the Secretary of the Interior or the Secretary of Commerce, as appropriate”

What is a fishway? Congress has defined fishways for the safe and timely upstream and downstream passage of fish to be limited to 'physical structures, facilities or devices necessary to maintain all life stages of such fish, and project operations and measures related to such structures, facilities, or devices which are necessary to ensure the effectiveness of such structures, facilities, or devices for such fish.' 1992 Energy Policy Act Pub. L. 102-486, Title XVII, Section 1701(b), 106 Stat. 3008.

Section 4(e) of the FPA provides that FERC may issue a license within a reservation (as defined in the FPA) only after finding that the license will not interfere or be inconsistent with the purpose for which such reservation was created or acquired and such license shall be subject to and contain such conditions that the Federal agency with jurisdiction over the reservation deems necessary for the adequate protection and utilization of the reservation.

Section 10(a) of the FPA requires, in relevant part, that: “[i]n order to ensure that the project adopted will be best adapted to the comprehensive plan ..., the Commission shall consider each of the following:

(2)(A) The extent to which the project is consistent with a comprehensive plan (where one exists) for improving, developing, or conserving a waterway or waterways affected by the project that is prepared by i) an agency established pursuant to Federal law that has authority to prepare such a plan; or ii) the State in which the facility is or will be located.

(2)(B) The recommendations of Federal and State agencies exercising administration over flood control, navigation, irrigation, recreation, cultural and other relevant resources of the State in which the project is located, and the recommendations (including fish and wildlife recommendations) of Indian tribes affected by the project.”

Section 10(j) of the FPA requires FERC to include conditions to adequately and equitably protect, mitigate damages to, and enhance fish and wildlife affected by the development, operation, and management of a project, based on recommendations received pursuant to the Fish and Wildlife Coordination Act (16 U.S.C. 661 et seq.) from the Department of Commerce's National Marine Fisheries Service, the Fish and Wildlife Service and State fish and wildlife agencies. If FERC believes a recommendation to be inconsistent with the FPA or other applicable law, it must attempt to resolve the inconsistency with the agency through a process defined in the FPA.

The mandatory prescriptions and conditions along with FERC's required conditions would result in significant operational changes to the hydroelectric project, substantially reducing power generation capacity (about 20 megawatts, or 24 percent of annual generation) and causing the Klamath Hydroelectric Project to operate at a net annual loss (FERC 2007). PacifiCorp estimates that it would incur relicensing capital costs in excess of \$400 million (with the majority of costs resulting from implementation of aquatic resource protection, mitigation, and enhancement measures) and \$60 million in operations and maintenance costs over a 40-year license term (Oregon Public Utilities Commission [OPUC] 2010). PacifiCorp would be allowed to recover these costs through customer charges, if approved through future Public Utilities Commission actions.

The KHSA sets a cost cap of \$450 million for removal of the Four Facilities. Of this, an amount not to exceed \$200 million would come from additional charges to PacifiCorp ratepayers residing in California and Oregon, and up to \$250 million would come from the sale of bonds in California or other appropriate financing mechanisms to cover removal costs in excess of the rate-payer contributions. The United States government would not be responsible for the costs of facilities removal.

ES.2.2.2 The Four Facilities and PacifiCorp Involvement in the KHSA/KBRA

PacifiCorp's decision to enter into the KHSA, which provides for the possible removal of the Four Facilities, reflects its assessment of a combination of regulatory requirements, including the cost and liability associated with meeting CWA Section 401 certification in California and in Oregon for renewal of FERC license P-2082, the estimated construction and operation costs to provide fishways at the Four Facilities, reductions in peaking power and overall hydropower generation, and the resulting increase to their operational costs for providing power from the Four Facilities. PacifiCorp's evaluation of the costs and risks associated with meeting those requirements under a new license lead to an assessment that the KHSA was in the best interest of its customers as compared to continuing the process of relicensing the Four Facilities (PacifiCorp 2012). As described below in Section ES.4.2, PacifiCorp is not a direct signatory of the KBRA.

Reclamation's Klamath Project

In addition to the Klamath Basin's distinctive setting, biological resources, and cultural history, the basin is the site of one of the first developments authorized under the 1902 Reclamation Act. Development and construction of what is today known as Reclamation's Klamath Project took place between 1905 and 1966, with major features of the project completed by the early 1940s. As the largest water management effort in the Upper Klamath Basin, its features include a system of reservoirs, dams, canals, and pumps (Figure 1-4). Reclamation's Klamath Project was originally authorized for the purpose of providing irrigation water to farms at a time when the frontier of the American west was still developing and increasing numbers of farmers were drawn to the fertile land in northern California and southern Oregon. Link River Dam, completed in 1921, is a major feature of Reclamation's Klamath Project. This dam is owned by Reclamation, but is operated by PacifiCorp under agreement with Reclamation.

Table ES-1 summarizes data about the Four Facilities. Figures ES-3 through ES-6 show the four dams and associated hydropower facilities.

Table ES-1. Hydroelectric Dams (Four Facilities) on the Mainstem Klamath River

Dam	Year Operational	Maximum Power Generation Capacity (megawatts)	Annual Average Generation Rate (megawatts)	Dam Height (feet)
J.C. Boyle	1958	98	38	68
Copco 1	1918	20	12	126
Copco 2	1925	27	15	33
Iron Gate	1962	18	13	194
Total	--	163	78¹	--

Source: FERC 2007

Notes: ¹ This annual average generation rate is only for the Four Facilities and does not include the Fall Creek or East and West Side Facilities. Under the agencies' mandatory prescriptions and conditions, along with FERC's required conditions, average annual generation for the entire project would drop by approximately 20 megawatts.

ES.3 Environmental Review

As described above, this EIS/EIR is being prepared in compliance with NEPA and CEQA. The DOI is Lead Agency under NEPA, and the CDFG is Lead Agency under CEQA. DOI and the CDFG are referred to together in this EIS/EIR as the Lead Agencies. The Purpose and Need for the Proposed Action (NEPA) and the Project Objectives (CEQA) are described below, and together form the basis for alternatives development and impact analysis considered in this EIS/EIR.

NEPA Purpose and Need

The need for the Proposed Action is to advance restoration of the salmonid fisheries in the Klamath Basin consistent with the KHSA and the connected KBRA. The purpose is to achieve a free flowing river condition and full volitional fish passage as well as other goals expressed in the KHSA and KBRA. By the terms of the KHSA, the Secretary will determine whether the Proposed Action is appropriate and should proceed. In making this determination, the Secretary will consider whether removal of the Four Facilities will advance the restoration of the salmonid fisheries of the Klamath Basin, and is in the public interest, which includes but is not limited to consideration of potential impacts on affected local communities and Tribes.

CEQA Project Objectives

As required by CEQA, a Lead Agency must identify the objectives sought by the proposed project. For this project, CDFG as Lead Agency has identified the following objectives:

1. Advance restoration of the salmonid fisheries in the Klamath Basin.
2. Restore and sustain natural production of fish species throughout the Klamath Basin in part by restoring access to habitat currently upstream of impassable dams.
3. Provide for full participation in harvest opportunities for sport, commercial, and tribal fisheries.
4. Establish reliable water and power supplies, which sustain agricultural uses and communities and NWRs.
5. Improve long-term water quality conditions consistent with designated beneficial uses.
6. Contribute to the public welfare and the sustainability of Klamath Basin communities.
7. To be consistent with the goals and objectives of KHSA and KBRA.

ES.4 Klamath Settlement Agreements

ES.4.1 Klamath Hydroelectric Settlement Agreement

The KHSA establishes the process for additional studies, the development of a Detailed Plan for dam removal and environmental review to support the Secretary's Determination⁴ as to whether removal of the Four Facilities on the Klamath River that are owned by PacifiCorp will accomplish the following two goals: 1) to advance restoration of the salmonid fisheries of the basin, and 2) be in the public interest, which includes, but is not limited to, consideration of the potential impacts on affected local communities and Indian Tribes.

The KHSA also includes provisions for the interim operation of the Four Facilities by PacifiCorp and the process to transfer, decommission, and remove the dams in the event of an Affirmative Determination.

ES.4.2 Klamath Basin Restoration Agreement

Concurrently with the signing of the KHSA, the same Parties, with the exception of the Federal Government and PacifiCorp, signed an accompanying agreement—the KBRA. The KBRA includes interrelated plans and programs intended to benefit fisheries throughout the basin,

Secretarial Determination and Connected Actions

If the Secretary publishes an Affirmative Determination, and the Governors of Oregon and California concur, the process for facilities removal will proceed. The Secretary will also concurrently designate the dam removal entity. The dam removal entity, once identified, would refine the Detailed Plan to create a Definite Plan for Facilities Removal including the methods for removal and estimated costs.

In addition to the decommissioning and removal of the four hydroelectric dams, actions connected to an Affirmative Determination would include the transfer of Keno Dam ownership from PacifiCorp to DOI, Eastside/Westside Facilities, and the KBRA.

An Affirmative Secretarial Determination and Federal authorizing legislation are two early key milestones towards full implementation of the KBRA.

A Negative Determination would be a potential termination event for the KHSA and facilities removal would likely not proceed as per the KHSA. The FERC relicensing process would continue.

⁴ As defined in the KHSA, there are two different determinations on removal of the Four Facilities that the Secretary could reach: 1) Affirmative Determination: A determination by the Secretary under Section 3 of the KHSA that Facilities Removal should proceed; and, 2) Negative Determination: A determination by the Secretary under Section 3 of the KHSA that Facilities Removal should not proceed. The Secretary bases his determination on whether the conditions of Section 3.3.4 of the KHSA have been met and whether, in his judgment, Facilities Removal will accomplish the two goals stated above in Section ES.2.1. In the event of an Affirmative Determination, California and Oregon each shall provide Notice to the Secretary and other Parties as to whether the State concurs with the Affirmative Determination. In its concurrence, each State shall consider whether: 1) significant impacts identified in its environmental review can be avoided or mitigated as provided under State law; and 2) Facilities Removal will be completed within the State Cost Cap (KHSA Section 3.3.5A). If the Secretary determines not to proceed with Facilities Removal, the KHSA terminates unless the Parties agree to a cure for this potential termination event (KHSA Section 3.3.5B).

water and power users in the Upper Klamath Basin, counties, Indian Tribes, and basin communities. The KBRA brought many parties together to support one another's efforts to restore fisheries in the Klamath Basin and provide for sustainable communities and National Wildlife Refuges.

Implementation of the KBRA is intended to accomplish the following:

1. Restore and sustain natural fish production and provide for full participation in ocean and river harvest opportunities of these fish.
2. Establish reliable water and power supplies for agricultural uses, communities, and National Wildlife Refuges (NWRs).
3. Contribute to public welfare and sustainability of all communities through reliable water supply; affordable electricity; programs to offset potential property tax losses and address economic development issues in counties; and efforts to support tribal fishing and long-term economic self-sufficiency.

The key negotiated outcomes of the KBRA include reciprocal agreements under which the Klamath, Karuk, and Yurok Tribes would not exercise water right claims that would conflict with water deliveries to Reclamation's Klamath Project water users; and project water users accept a limitation on diversions from Upper Klamath Lake and Klamath River and develop a program that will allow them to operate within those limitations through the use of other supplies, efficiency measures, voluntary reductions in demand, and other measures. As a result, there would be more support for fisheries restoration programs, greater certainty about water deliveries at the beginning of each growing season, and agreement and assurances that certain of the parties will work collaboratively to resolve outstanding water-right contests pending in the Oregon Klamath Basin Adjudication. In addition, the KBRA includes an Off-Project voluntary Water Use Retirement Program in the Upper Klamath Basin (the portion of the Klamath Basin located upstream of Iron Gate Dam) three restoration projects intended to increase the amount of water storage in the Upper Klamath Basin, regulatory assurances, county and tribal economic development programs, and tribal resource management programs.

Copies of the KHSAs and KBRA in their entirety are available electronically at: <http://klamathrestoration.gov/>.

ES.5 Alternatives Development

As part of the environmental review process, the Lead Agencies developed a full range of alternatives. A detailed description of this process can be found in this EIS/EIR, Appendix A, titled Final Alternatives Report.

ES.5.1 Public Scoping and Alternatives Identification

The Lead Agencies held seven public scoping meetings in locations around the Klamath Basin to receive input on alternatives and concerns regarding the project purpose, needs and objectives. Written and verbal comments were accepted at each meeting and comments were also received by mail and electronically throughout the scoping period of June 14, 2010, through July 21, 2010. A Scoping Report that summarizes all comments received through July 21, 2010, was published in September 2010 and is available on the project Web site (<http://klamathrestoration.gov/>) (DOI 2010).

Following the scoping process, the Lead Agencies, along with the cooperating and responsible agencies, identified a wide range of alternatives that represent diverse viewpoints and needs, including alternatives suggested during the EIS/EIR public scoping process. This resulted in a set of 18 potential alternatives to be considered for detailed analysis (the initial list of action alternatives is described in Appendix A, Final Alternatives Report). The Lead Agencies applied a screening process to the 18 potential alternatives to determine which alternatives should move forward for further analysis. In order to determine which alternatives met all or most of the purpose and need/project objectives, and were potentially feasible, specific screening considerations were created based on NEPA (40 CFR Part 1502.14(a)) and CEQA guidance (CEQA Guidelines, §15126.6 (a)). Under CEQA, alternatives do not need to meet all of the project objectives; alternatives should be included if they can meet most of the objectives and avoid or substantially lessen significant environmental impacts of the project. Figure ES-7 illustrates the process that the Lead Agencies conducted to identify and screen alternatives and to select alternatives for more detailed analysis.

Figure ES-7. Alternatives Development and Screening Process.

After the process of initial alternative screening, four action alternatives in addition to the No Action/No Project Alternative (Alternative 1) were selected to move forward for more detailed analysis in the EIS/EIR. Alternatives 2 and 3, the Proposed Action and Partial Facilities Removal, both fully meet the purpose and need/project objectives. While Alternative 4, Fish Passage at Four Dams and Alternative 5, Remove Copco 1 and Iron Gate Dams, Construct Fish Passage at J.C. Boyle and Copco 2 Dams, do not fully meet the purpose and need/project objectives, both alternatives were moved forward to the EIS/EIR for further review because at the time of developing a reasonable range of alternatives the Lead Agencies recognized the potential for Alternatives 4 and 5 to have fewer short-term adverse environmental impacts than the Proposed Action.

Consideration of these alternatives would give the Secretary a reasonable range of alternatives to inform a Secretarial Determination. Analysis of these alternatives will

provide the Secretary with information needed to make a decision, and potentially to mix and match elements of the alternatives, if needed, to create an alternative that would reduce environmental impacts and increase environmental benefits.

ES.6 Alternatives Receiving Full Analysis in the EIS/EIR

The EIS/EIR analyzes five alternatives in detail, including the No Action/No Project Alternative.

ES.6.1 Alternative 1 - No Action/No Project Alternative

NEPA requires an EIS to “include the alternative of no action” (40 CFR Part 1502.14(d)). CEQA requires an EIR to include a No Project Alternative. CEQA Guidelines Section 15126.6(e)(2) states that “The ‘no project’ analysis shall discuss the existing conditions at the time the notice of preparation is published, or if no notice of preparation is published, at the time environmental analysis is commenced, as well as what would be reasonably expected to occur in the foreseeable future if the project were not approved, based on current plans and consistent with available infrastructure and community services.” For the Klamath Facilities Removal EIS/EIR, NEPA’s No Action Alternative and CEQA’s No Project Alternative describe the same conditions, and this alternative is referred to as the No Action/No Project Alternative.

The No Action/No Project Alternative represents the state of the environment without the Proposed Action or any of the alternatives. For the purposes of this analysis, the No Action/No Project Alternative will continue current operations with the Four Facilities remaining in place and PacifiCorp operating under the current annual license. The existing license has no requirements for additional fish passage or implementation of the agencies’ mandatory prescriptions and conditions that are currently before FERC in the relicensing process. PacifiCorp would continue to coordinate with Reclamation to operate the Klamath Hydroelectric Project in compliance with the existing NOAA Fisheries Service and USFWS biological opinions issued for Reclamation’s Klamath Project Operation Plan. PacifiCorp would also continue to fund the operation of the Iron Gate Hatchery under its current operations.

The KBRA is not included in the No Action/No Project Alternative. However, the No Action/No Project Alternative would include the ongoing resource management activities (these actions are described in further detail in Chapter 2 of this EIS/EIR). These resource management actions were started or were under consideration before the KBRA was developed and will move forward at some level even without the KBRA.

The No Action/No Project Alternative also includes “reasonably foreseeable actions” that are independent of FERC licensing and are expected to occur throughout the period of analysis (2012 to 2061). Reasonably foreseeable actions include full implementation of the Total Maximum Daily Load (TMDL) provision of the Clean Water Act (Section 303(d)) issued by the Oregon Department of Environmental Quality (ODEQ) and

California North Coast Regional Water Quality Control Board (CNCRWQCB) for impaired water bodies. There are currently nine TMDLs established in the Klamath Basin (see Section 3.2.2.4). Under the No Action/No Project Alternative, full attainment of these TMDLs would result in long-term water quality improvements in the basin; however, implementation mechanisms, funding, and timing are currently unknown

The ongoing resource management activities, TMDLs, Interim Measures, biological opinions, and other regulatory conditions described for this alternative would also occur under Alternatives 2, 3, 4, and 5.

ES.6.2 Alternative 2 - Full Facilities Removal of Four Dams (Proposed Action)

The Full Facilities Removal of Four Dams Alternative (the Proposed Action) includes the removal of the Four Facilities during a 20-month period which includes an 8-month

Figure ES-8. Simulation of Iron Gate Dam Before and After Full Facilities Removal.

period of site preparation and partial drawdown at Copco 1 and a 12-month period for full reservoir drawdown and removal of the Four Facilities. This alternative would include the complete removal of the dams, power generation facilities, water intake structures, canals, pipelines, ancillary buildings, and dam foundations to create a free-flowing river. Preparation for dam removal would begin in May 2019 for Iron Gate Dam and June 2019 for Copco 1 Dam. Deconstruction efforts for the J.C. Boyle and Copco 2 Facilities would commence after January 1, 2020, and all four dams would be completely removed by December 31, 2020. This alternative would include implementation of the KBRA and the transfer of Keno Dam to DOI as connected actions. Figure ES-8 illustrates what full facilities removal would look like at Iron Gate Dam.

ES.6.2.1 KBRA

The KBRA is being analyzed in this EIS/EIR as a connected action to the Proposed Action. Full implementation of the KBRA and the KHSA is dependent on an Affirmative Determination.

Table ES-2 provides a summary of KBRA programs. The programs with sufficient detail to investigate for potential environmental effects are analyzed in this EIS/EIR. These programs include the following (a more detailed description of the approach to analysis of the KBRA is in Section 3.1 of this EIS/EIR):

ES.6.2.1.1 Fisheries Program

The Fisheries Program includes habitat restoration throughout the basin; a fisheries reintroduction and management plan; a fisheries monitoring plan; and actions intended to improve flow conditions and water quality for fish. Full attainment of the TMDLs described under the No Action/No Project Alternative would result in long-term water quality improvements in the basin and implementation of the KBRA is anticipated to accelerate these TMDLs.

ES.6.2.1.2 Water and Power Programs

The Water and Power Programs include an

Table ES-2. KBRA Program Summary

Fisheries Program:
Fish Habitat Restoration Activities ¹
Fisheries Restoration Phase I Plan
Fisheries Restoration Phase II Plan
Fisheries Reintroduction Plan – Phase I, Oregon
Fisheries Reintroduction Plan – Phase II, Oregon
Fisheries Reintroduction Plan – California
Fisheries Monitoring Plan
Additional Water Storage Projects:
Williamson River Delta Project
Agency Lake and Barnes Ranches Project
Wood River Wetland Restoration Project
Future Storage Opportunities ²
Water and Power Programs:
Water Diversion Allocations for Reclamation’s Klamath Project and National Wildlife Refuges ³
Groundwater Technical Investigations
On-Project Plan
Water Use Retirement Program
Off-Project Water Settlement
Off-Project Reliance Program
Power for Water Management Program
Drought Plan
Emergency Response Plan
Climate Change Assessment
Environmental Water Management ⁴
Interim Flow and Lake Level Program
Regulatory Assurances Programs:
Fish Entrainment Reduction
General Conservation Plan or Habitat Conservation Plan
County and Tribal Programs:
Klamath County Economic Development Plan
California Water Bond (Siskiyou County Economic Development Funding)
Tribal Programs Fisheries and Conservation Management
Tribal Programs Economic Revitalization
Mazama Forest Project
Klamath Tribes Interim Fishing Site

Notes:

1. While on-going fish habitat restoration activities are not part of the Proposed Action because they are conducted under current authorities and funding levels, the scope of these activities would be increased in magnitude and accelerated through implementation of the KBRA. Habitat restoration under the Proposed Action would be guided by the Fisheries Restoration Plan to be developed under the KBRA.
2. Development of additional storage is also intended to restore habitats for endangered suckers, and would occur with implementation of KBRA and associated funding.
3. During the Interim Period, water diversion limitations to Reclamation’s Klamath Project water users would conform to the limits described in the Diversion Limitations section as closely as possible. However, before full implementation of the On-Project Plan, it might not be possible to fully comply with the diversion limitations in all years.
4. The Environmental Water Management program would support the development and implementation of TMDLs on the Klamath River and actions that protect water quality generally (KBRA Section 20.5.4).

agreement regarding limitations on water diversions to Reclamation's Klamath Project, and delivery commitments for Tule Lake and Lower Klamath Lake NWRs. The programs also include a voluntary Water Use Retirement Program in the Upper Basin to increase inflow into Upper Klamath Lake and to provide a basis for further efforts among certain parties to work collaboratively for more reliable sources of water for fish harvests and agriculture. Additionally, there are agreements and assurances to resolve outstanding water right contests in the Oregon Klamath Basin Adjudication process.

ES.6.2.1.3 County and Tribal Programs

County and tribal programs include economic development for local governments and tribes; regulatory assurances that adverse impacts on local communities would be minimized; and tribal fisheries and natural resource conservation.

ES.6.3 Alternative 3 - Partial Facilities Removal of Four Dams

The Partial Facilities Removal of Four Dams Alternative would include removal of enough of each dam to allow free-flowing river conditions and volitional fish passage for all Klamath River anadromous species at all times. Under this alternative, portions of each dam facility would remain in place, including ancillary buildings and structures such as powerhouses, foundations, tunnels, and pipes. Some of these remaining features would require perpetual maintenance and security measures to prevent unauthorized entry and safety hazards. All tunnel openings would be sealed and all potentially hazardous materials found in powerhouses and machinery would be removed prior to final decommissioning and securing of buildings.

The schedule for Partial Facilities Removal of Four Dams would be the same as for the Proposed Action (the Full Facilities Removal of Four Dams Alternative). The Partial Facilities Removal of Four Dams Alternative also includes the connected actions of the transfer of Keno Dam to DOI and implementation of the KBRA (as in the Proposed Action).

Under Alternative 3, full attainment of the TMDLs, as described under the Proposed Action would result in long-term water quality improvements in the basin; implementation of the KBRA is anticipated to accelerate these TMDLs through the provision of environmental water (KBRA Section 20.5.4) and other KBRA programs.

ES.6.4 Alternative 4 - Fish Passage at Four Dams

The Fish Passage at Four Dams Alternative would include construction of fish passage facilities at each of the Four Facilities. This alternative would retain all hydropower generating facilities and operations; although it is assumed that operations would change in response to DOI mandatory flow conditions and the NOAA Fisheries Service and DOI fishway prescriptions. The Lead Agencies used the prescriptions developed during the FERC relicensing process to describe the facilities needed to achieve fish passage and required flow conditions. The prescriptions also included flow and operational requirements that are included in this alternative. For the purposes of analysis in this

EIS/EIR, however, Alternative 4 has been developed with some assumptions regarding details and feature designs for purposes of this analysis that are not included or not yet determined for the fishway prescriptions and do not reflect any final decision by NOAA Fisheries Service or USFWS regarding any differences from the express text of the fishway prescriptions or how any decision may be made under the terms of the fishway prescriptions. Figure ES-9 shows an example of a cast-in-place pool and weir fish ladder that is similar to that proposed for upstream fish passage at all four dams under this alternative.

Typical downstream passage would include screening the fish away from the intake structures for the power generation facilities and the spillway modifications (if they are unsuitable for downstream passage).

Figure ES-9. Example of Cast-In-Place Pool and Weir Fish Ladder.

Implementation of this alternative would require licensure of the project by FERC to a Hydropower Licensee including 401 certifications. To meet essential flows in the bypass reaches, less water would pass through the power generating facilities than under current conditions, reducing power production. In addition, this alternative would result in restricted project ramping rates and would only allow peaking one day per week.

The Fish Passage at Four Dams Alternative would not satisfy the conditions in the KHSA. Consequently, it is assumed that the KBRA and the Keno Dam Transfer would not be fully implemented. For the purposes of this analysis, alternatives that would not result in full implementation of the KHSA do not include the KBRA as a connected action to the alternative. Additionally, the transfer Keno Dam to DOI would not move forward as a connected action.

This alternative would follow the schedule prescribed in the FERC relicensing process. The prescriptions include a schedule for implementation and prescribe that downstream facilities be installed prior to upstream passage facilities (DOI and NOAA Fisheries Service 2007). Table ES-3 shows the schedule for construction of the fish passage facilities at each dam, based on these constraints.

Under Alternative 4, full attainment of the TMDLs described under the No Action/No Project Alternative would result in long-term water quality improvements in the basin; but, the pace of achieving these improvements and the implementation mechanisms are unknown.

Table ES-3. Timetable for Fish Passage Improvements at each Dam from Date of FERC License Renewal

Dam	Upstream Fish Passage	Spillway Modifications ¹	Tailrace Barrier ¹	Screens and Bypass
J.C. Boyle	4 years	4 years	4 years	4 years
Copco 1	6 years	6 years	8 years	6 years
Copco 2	6 years	6 years	8 years	6 years
Iron Gate	5 years	5 years	N/A	5 years

Key:

N/A: Not Applicable

Notes:

1. The prescriptions require studies to determine the need for and design of spillway modifications and tailrace barriers. The modified prescriptions provide that the applicant is allowed to perform site-specific studies to determine if spillway modifications and tailrace barriers are necessary at the developments where these are prescribed. However, the modified prescriptions provide that spillway modifications and tailrace barriers shall be constructed and operated unless and until USFWS and NOAA Fisheries Service determine based on any such site-specific studies that any prescribed spillway modifications or tailrace barriers are unnecessary.

ES.6.5 Alternative 5 - Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative includes the full removal of the Iron Gate and Copco 1 facilities and installation of upstream and downstream fish passage facilities at both the J.C. Boyle and Copco 2 Dams. Implementation of this alternative would provide fish passage while retaining some hydropower generation capacity, and would improve water quality (specifically, dissolved oxygen, water temperatures, and algal toxins) through removal of the two largest reservoirs. To meet essential flows in the bypass reaches, less water would pass through the power generating facilities at the J.C. Boyle and Copco 2 developments and power production would be reduced as compared to current conditions.

Similar to the Fish Passage at Four Dams Alternative, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would incorporate most of the DOI and NOAA Fisheries Service prescriptions from the FERC relicensing process related to fish passage at J.C. Boyle and Copco 2 Dams (see Attachment B of Appendix A for a list of conditions and prescriptions). Alternative 5 would not incorporate the conditions and prescriptions related to peaking power at J.C. Boyle and recreation releases. In Alternative 5, Copco 2 Dam would be the only dam remaining downstream from J.C. Boyle Dam. Copco 2 Reservoir is very small, and does not have adequate capacity to reregulate flows associated with peaking operations so that they are suitable for fish downstream. Therefore, Alternative 5 would not include peaking operations or recreation releases on any days at J.C. Boyle Dam.

Implementation of this alternative would require licensure by FERC, including 401 certifications, for the facilities that will continue to generate power. The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would not satisfy the purposes of the KHSA to restore free flowing river conditions. Consequently, it is

assumed in this analysis that the KBRA and Keno Dam Transfer would not be fully implemented. This alternative would follow a schedule similar to that of the Proposed Action, and could be completed by December 2020.

Under Alternative 5, full attainment of these TMDLs would result in long-term water quality improvements in the basin; but, the pace of achieving these improvements and the implementation mechanisms are unknown.

ES.7 Effects of the No Action/No Project, Proposed Action, and Action Alternatives

This section describes the significant and unavoidable adverse impacts under NEPA and CEQA; provides a comparison of the beneficial effects under each of the alternatives; presents the environmentally preferable/superior alternative; and, summarizes the major controversies and issues raised by agencies and the public.

ES.7.1 Significant Environmental Effects that Cannot be Avoided

Significant environmental effects that cannot be avoided by redesigning the project, changing the nature of the project, or implementing mitigation measures must be disclosed in an EIS/EIR. CEQA Guidelines (Section 15126.2 (b)) require discussion of significant environmental effects that cannot be avoided, as well as significant environmental effects that can be mitigated but not reduced to an insignificant level. NEPA regulations also require a discussion of any adverse impacts that cannot be avoided as a result of the Proposed Action (40 Code of Federal Regulations Part 1502.16). By satisfying the CEQA requirements on discussion of significant environmental effects that cannot be avoided, the NEPA requirement to disclose adverse impacts is also met. These impacts are summarized in Table ES-4 for the purposes of NEPA and CEQA.

Several categories of resources discussed in this EIS/EIR are analyzed pursuant only to NEPA. The adverse environmental effects specific only to NEPA that cannot be avoided as a result of the Proposed Action are summarized in Table ES-5.⁵

A full listing of all impacts, including those that can be reduced to a less than significant level, is presented in Chapter 5 of this EIS/EIR.

The specific approach used to evaluate environmental effects of each alternative relative to each environmental resource is explained in Section 3.1 and in the resource sections throughout Chapter 3.

⁵ Effects relative to tribal trust resources are not displayed in this table given that no new adverse effects were identified relative to the alternatives analyzed in this EIS/EIR. Section 3.12, Tribal Trust, of this EIS/EIR does, however, summarize the existing and ongoing tribal trust impacts present in the Klamath Basin.

Table ES-4. Summary of Significant Environmental Effects that Cannot be Avoided Relative to CEQA and NEPA

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
3.2 Water Quality				
<i>Suspended Sediments</i>				
Upper Klamath Basin (in the Hydroelectric Reach)				
Draining the reservoirs and release of sediment could cause short-term increases in suspended material in the Hydroelectric Reach downstream from J.C. Boyle Dam.	2, 3, 5	S (short term ¹)	None	S (short term)
Lower Klamath Basin				
Draining the reservoirs and release of sediment could cause short-term increases in suspended material in the Lower Klamath River and the Klamath Estuary.	2, 3, 5	S (short term)	None	S (short term)
<i>Dissolved Oxygen</i>				
Upper Klamath Basin				
Draining the reservoirs and release of sediment could cause short-term increases in oxygen demand (Immediate Oxygen Demand [IOD] and Biological Oxygen Demand [BOD]) and reductions in dissolved oxygen in the Hydroelectric Reach downstream from J.C. Boyle Reservoir.	2, 3, 5	S (short term)	None	S (short term)
Lower Klamath Basin				
Dam removal and sediment release could cause short-term increases in oxygen demand (Immediate Oxygen Demand [IOD] and Biological Oxygen Demand [BOD]) and reductions in dissolved oxygen in the lower Klamath River, the Klamath Estuary, and the marine nearshore environment.	2, 3, 5	S (short term) lower Klamath River from Iron Gate Dam to Clear Creek	None	S (short term) lower Klamath River from Iron Gate Dam to Clear Creek

¹ Short term is defined as <2 years.

Table ES-4. Summary of Significant Environmental Effects that Cannot be Avoided Relative to CEQA and NEPA

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
3.3 Aquatic Resources				
<i>Critical Habitat</i>				
Reservoir drawdown associated with dam removal could alter the quality of critical habitat.	2, 3, 5	S (short term) for coho	None	S (short term) for coho
<i>Essential Fish Habitat</i>				
Reservoir drawdown associated with dam removal could alter the quality of EFH.	2, 3, 5	S (short term) Chinook and coho	None	S (short term) for Chinook and coho
<i>Species Impacts</i>				
<u>Coho Salmon</u>				
Reservoir drawdown associated with dam removal could alter SSCs and bedload sediment transport and deposition and affect coho salmon.	2, 3, 5 (would only remove Copco 1 and Iron Gate)	S (short term) Upper Klamath River, Mid-Klamath River, Shasta River, and Scott River population units	AR-1: Protection of mainstem spawning; AR-2: Protection of outmigrating juveniles; AR-3: Fall flow pulses; AR-4: Hatchery management	S (short term) Upper Klamath River, Mid-Klamath River, Shasta River, and Scott River population units
<u>Steelhead</u>				
Reservoir drawdown associated with dam removal could alter SSCs and bedload sediment transport and deposition and affect steelhead in the short term.	2, 3, 5	S (short term) summer and winter steelhead	AR-1: Protection of mainstem spawning; AR-2: Protection of outmigrating juveniles; AR-3: Fall flow pulses; AR-4: Hatchery management	S (short term) summer and winter steelhead
<u>Pacific Lamprey</u>				
Reservoir drawdown associated with dam removal could alter SSCs and bedload sediment transport and deposition and affect Pacific lamprey in the short term.	2, 3, 5	S (short term)	AR-2: Protection of Outmigrating Juveniles; AR-5: Pacific lamprey capture and relocation.	S (short term)
<u>Green Sturgeon</u>				
Reservoir drawdown associated with dam removal could alter SSCs and bedload sediment transport and deposition and affect green sturgeon.	2, 3, 5	S (short term)	AR-3: Fall flow pulses	S (short term)

Table ES-4. Summary of Significant Environmental Effects that Cannot be Avoided Relative to CEQA and NEPA

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
<u>Freshwater mussels</u>				
Reservoir drawdown associated with dam removal could alter SSCs and bedload sediment transport and deposition and affect freshwater mussels in the short term.	2, 3, 5	S (short term)	AR-7: Freshwater mussel relocation	S (short term)
<u>Benthic Macroinvertebrates</u>				
Reservoir drawdown associated with dam removal could alter SSCs and bedload sediment transport and deposition and affect macroinvertebrates below Iron Gate.	2, 3, 5	S (short term)	None	S (short term)
3.4 Algae				
<u>Hydroelectric Reach</u>				
Conversion of the reservoir areas to a free-flowing river, and the elimination of hydropower peaking operations could cause long-term increases in nutrient levels and biomass of nuisance periphyton in low-gradient channel margin areas within the Hydroelectric Reach downstream from J.C. Boyle Dam. ²	2, 3, 5 ³	S (long term ⁴)	None	S (long term)

²Periphyton are algae that grow attached to rocks and other substrates on a riverbed. Although sometime these species cause nuisance conditions, they are rarely considered toxic. Increased non-toxic periphyton biomass would not lead to increases in algal toxins in the Klamath River. Blooms of phytoplankton (suspended algae) occurring in the calm, lake-like waters are responsible for the production of algal toxins, such as microcystin, in the Klamath River downstream from Iron Gate Dam. Noxious phytoplankton would not thrive in the free flowing river following dam removal.

³An editorial clarification was made to this determination for Alternative 5 in Section 3.4, Algae. As indicated by the analysis under the Proposed Action in Section 3.4, Algae, the determination for Alternative 5 in the Hydroelectric Reach from Copco 1 Reservoir to Iron Gate Reservoir should also have been a significant effect.

⁴Long term is defined as 2-50 years.

Table ES-4. Summary of Significant Environmental Effects that Cannot be Avoided Relative to CEQA and NEPA

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
3.9 Air Quality				
Vehicle exhaust and fugitive dust emissions from dam removal activities could increase emissions of VOC, NOx, CO, SO ₂ , PM ₁₀ , and PM _{2.5} to levels that could exceed Siskiyou County's thresholds of significance.	2, 3	S (short term)	AQ-1: MY 2015 or newer engines for offroad construction equipment AQ-2: MY 2000 or newer engines for on-road construction equipment AQ-3: MY 2010 or newer engines for haul trucks	S (short term)
KBRA – Programmatic Measures				
Construction activities associated with the KBRA programs could result in temporary increases in air quality pollutant emissions from vehicle exhaust and fugitive dust.	2, 3	S(short term)	AQ-1: MY 2015 or newer engines for offroad construction equipment AQ-2: MY 2000 or newer engines for on-road construction equipment AQ-3: MY 2010 or newer engines for haul trucks	S ⁵ (short term)

ES.7.2 Synopsis of Major Impacts and Benefits of the Alternatives

This section presents a synopsis of major impacts and benefits for each alternative with a focus on aquatic resources and water quality. (All of the significant adverse impacts that cannot be avoided for all resource categories are listed in Table ES-4 and Table ES-5). This summary section presents impacts and benefits incrementally to illustrate potential key benefits and impacts that may occur under each alternative. Though impacts to all resources will ultimately be considered by the Secretary of the Interior when making the Determination on whether or not the Proposed Action is in the public interest, this summary focuses on restoring fisheries and improving water quality (fishery and water quality benefits are also summarized in Table ES-6). A synthesis of this information is particularly important to address the question of whether and to what degree an alternative may advance the restoration of the salmonid fisheries of the Klamath Basin and to determine which alternative may be environmentally preferable. In addition, the Affected Environment/Existing Conditions is summarized because it is a valuable point of comparison. (For more detail on each alternative and how alternatives were selected refer to ES.5 Alternatives Development and Chapter 2 Proposed Action and Description of Alternatives).

The structure of the section is as follows:

- Affected Environment/Existing Conditions;
- Alternative 1 (No Action/No Project Alternative);
- Alternative 4 (Fish Passage at Four Dams Alternative);
- Alternative 5 (Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate);
- Alternatives 2 (Full Facilities Removal of Four Dams (Proposed Action)) and 3 (Partial Removal of Four Dams);
- Comparison of Alternative 2 and 3

Under NEPA (40 CFR Part 1502.16, Environmental Consequences), a discussion of the environmental impacts of the alternatives, including the Proposed Action, should be included. A discussion of the potential beneficial effects of the alternatives is also valuable for decisionmakers when comparing and contrasting alternatives and determining the best course of action.

CEQA Guidelines require the balancing, as applicable, of the economic, legal, social, technological, or other benefits of a proposed project against its unavoidable environmental risks when determining whether to approve a project (Section 15093 (a)-(c)). If the specific benefits, including region-wide or statewide environmental benefits of a proposed project outweigh the unavoidable adverse environmental effects, the

adverse environmental effects may be considered “acceptable.” When a lead agency approves a project which will result in the occurrence of significant effects which are identified, but not avoided or substantially lessened, the lead agency under CEQA shall state in writing the specific reasons to support its action based on the final EIS/EIR or other information in the record. This statement becomes the statement of overriding considerations as required under CEQA.

As illustrated throughout this Executive Summary, many measures agreed upon in the KHSA and KBRA centered on improving and resolving issues of low or declining fish populations and fisheries, inadequate water supplies, and degraded water quality. The primary goal of these agreements is to improve the condition and reliability of these basin resources and thereby benefit the communities who rely on them, or historically depended on them, for a way of life. This includes tribal, fishing, farming, and recreational communities throughout the Klamath Basin.

One example of the inter-relatedness of basin resources and communities can be illustrated by evaluating the impacts and benefits of the alternatives on tribal communities where environmental justice is a concern. Reversing the consequences of barriers to fish passage, degraded fish habitat, and degraded water quality throughout the basin could result in great benefit to tribal communities relying on fish, shellfish, riparian plants, clean water, and other resources for their subsistence, ceremonies, physical health, way of life, and spiritual well-being. While sediment release and other construction related activities during dam removal could cause short-term (1 to 2 years) adverse impacts on fisheries downstream from the Hydroelectric Reach, salmon and other aquatic resources would be expected to return to population levels observed prior to dam removal (in 2010 when the Notice of Preparation was issued) within 5 years, and would provide long-term benefits to Indian Tribes for 50 years and beyond (these effects for Indian Tribes are analyzed in Section 3.16).

Because restoring fisheries, improving water quality, and helping communities are major goals of the Proposed Action and of the action alternatives, the major long-term benefits and impacts of each alternative are summarized below relative to these goals.

ES.7.2.1 Existing Conditions/Affected Environment

The Klamath Basin currently suffers from degraded fisheries, excessive exposure of salmon to disease, degraded habitat quality (including altered flows, water temperatures, river channel structure, and invasive species), blocked access to historical habitat, and degraded water quality (including problems with dissolved oxygen, pH, nutrient enrichment, algal growth, and algal toxins). Major water quality problems exist in Upper Klamath Lake, Keno Impoundment/Lake Ewauna, and the reservoirs in the Hydroelectric Reach, as well as the Lower Klamath Basin downstream from Iron Gate Dam.

Results of these impaired water quality and habitat conditions include fish die-offs, listings under ESA and the California Endangered Species Act (CESA), health advisory postings for algal toxins in Copco 1 and Iron Gate reservoirs since 2005, and commercial fishing closures. Circumstances for salmonid fisheries and threatened and endangered

species in the Klamath Basin are not improving. In addition, basin water supplies are over-allocated and do not meet all user needs; these challenges have been particularly acute in dry years. Water shortages, combined with the need to provide water to address the needs of ESA-listed species (suckers in Upper Klamath Lake and coho salmon in the Klamath River), national wildlife refuges, and farming communities have led to the reduction of irrigation water deliveries to farmers in dry years. In short, existing conditions represent a continued hardship for fishing, farming, tribal, and recreational communities. In particular, the Klamath Tribes have had to bear the hardship of being without salmon in the Upper Basin for nearly 100 years and without harvestable sucker populations for 25 years; these species are fundamental to their diet, their ceremonies, and their cultural well-being.

ES.7.2.2 Alternative 1 (No Action/No Project Alternative)

Alternative 1 (No Action/No Project Alternative) is continued operation of the Klamath Hydroelectric Project under an annual license issued by FERC and would result in the continuation of many of the conditions described under Existing Condition/Affected Environment. This alternative would continue to block anadromous fish access to over 420 miles of historical habitat, including low gradient habitat of critical importance to spawning and rearing under Copco 1 and Iron Gate reservoirs. Also, access to cold water springs (areas of groundwater discharge), particularly in the Upper Basin, would continue to be blocked. These cold water springs offer some protection to aquatic species against the future changes associated with climate change and improve winter growth opportunities for rearing fish. Disease problems associated with crowding of fish below Iron Gate Dam, atypically stable flows, disrupted sediment transport processes, and over-abundance of intermediate hosts for fish disease would persist. Iron Gate hatchery juvenile production as mitigation for 16 miles of habitat loss would continue, but would also exacerbates fish disease. For resident fish in the Hydroelectric Reach, the current adverse effects of peaking and those of entrainment into hydroelectric facilities would continue. Implementation of TMDLs in Oregon and California over the next 50 years would be expected to help alleviate some of basin-wide water quality problems, although the implementation and timing of TMDL-related actions is unknown and effective improvements could take decades to achieve. Furthermore, to date there are no proposed management actions that would achieve the temperature allocations assigned to Copco 1 and Iron Gate reservoirs under the TMDLs. The effects of climate change over the next 50 years could dampen potential benefits from TMDLs, which would continue current conditions responsible for depressed populations of certain species like Chinook or steelhead and would reduce opportunities to improve survival of ESA-listed fish.

As the FERC relicensing process would continue following a Negative Determination on dam removal from the Secretary, Alternative 1 is not likely to continue as the status quo; however, if a new long-term FERC license is issued, it would be contingent on facility operations being compliant with all other applicable laws and regulations, including the Clean Water Act and the Endangered Species Act, making it difficult to predict when a new license might be implemented. For this analysis, the assumption for the next 50 years is that all the dams and the associated reservoirs remain and continue to operate

under annual licenses and without construction of any new fish passage facilities. This would preserve the existing hydroelectric power generation capacity and allow use of reservoirs and peaking flows for recreational purposes (the significance of these effects is analyzed in Sections 3.18 and 3.20, respectively). The recreational value of these reservoirs, however, has been diminished in recent years (since 2005) due to the documented growth of toxic algae in Copco 1 and Iron Gate reservoirs and health advisory postings to that effect, conditions that can be expected to persist in the future without significant progress on nutrient reduction in the reservoirs such as through the TMDL process.

Alternative 1 would not result in the short-term negative impacts related to construction activities or short-term impacts to fish from the downstream transport of sediment during reservoir drawdown. Also Alternative 1 does not include the full implementation of KBRA. The ongoing resource management activities, ongoing Interim Measures, TMDLs, biological opinions, and other regulatory conditions described for this alternative would also occur under Alternatives 2, 3, 4, and 5

ES.7.2.3 Alternative 4 (Fish Passage at Four Dams Alternative)

Alternative 4 would require the long-term licensure of the Hydroelectric Project by FERC to a Hydropower Licensee; although, it is assumed that operations of the Four Facilities would change in response to DOI mandatory flow conditions and NOAA Fisheries Service and DOI fishway prescriptions. Alternative 4 would eventually result in the same benefits to water quality from TMDL implementation as Alternative 1; however the same limitations as Alternative 1 on achieving water quality objectives in the Hydroelectric Reach and downstream would also apply. Specifically, there are no proposed management actions that would achieve the temperature allocations assigned to Copco 1 and Iron Gate reservoirs under the TMDLs, and control of toxic blooms of cyanobacteria would not be expected to diminish in the future without significant progress on nutrient reduction in the reservoirs, which could take decades to achieve. The creation of volitional fish passage for salmonids at each of the Four Facilities under this alternative would provide access to at least 420 miles of historical habitat above Iron Gate Dam to anadromous fish. Consequently, the size and diversity of these populations would increase. Implementation of Alternative 4 and access to Upper Basin habitat would reduce the concentration of fish carcasses which are linked to the transmission of fish disease from adult salmon to juvenile salmon. In addition, fish would gain access to cold water springs, particularly in the Upper Basin, offering some protection against the predicted future changes associated with climate change and improved winter growth opportunities for rearing fish. The adverse effects of peaking would be largely eliminated (only one day a week) and those of entrainment into hydroelectric facilities would be largely eliminated.

Iron Gate Hatchery would continue to mitigate for the loss of production of salmonids from the 16 miles of habitat lost between Iron Gate and Copco 2 dams.

NOAA Fisheries Service and DOI prescriptions include a measure to trap and haul fall-run Chinook salmon upstream and downstream around Keno Impoundment. The

prescriptions call for seasonal trap and haul operations from June 15 to November 15 when water quality conditions are not suitable for fish (dissolved oxygen concentration less than 6 milligrams per liter [mg/L] or temperature above 20 degrees Celsius) (DOI 2007; NOAA Fisheries Service 2007).

Alternative 4 would retain the majority (80%) of hydroelectric power generation capacity and project reservoirs would remain in place and would continue to be used for recreational purposes (the significance of these effects is analyzed in Sections 3.18 and 3.20, respectively) over the next 50 years. Alternative 4 would not result in short-term impacts to fish from downstream transport of sediment during reservoir drawdown and dam removal.

ES.7.2.4 Alternative 5 (Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate)

Alternative 5 would result in the same benefits as Alternative 4 for anadromous fish; however, removal of Copco 1 and Iron Gate Dams would provide additional benefits. Fish would be able to migrate upstream and downstream more efficiently through a greater length of natural river channel and through fewer constructed fish passage facilities to use habitat in the Upper Basin. Alternative 5 would create access to at least 420 miles of historical habitat above Iron Gate Dam for anadromous fish. This would include access to low gradient historical habitat of critical importance to spawning and rearing under Copco 1 and Iron Gate Reservoirs. This additional habitat would facilitate greater dispersion of spawning adult salmonids than under Alternative 4, thereby reducing the incidence of disease. Disease risks to resident fish would be low and the establishment of a disease hot spot for *C. shasta* above the current location of Iron Gate Dam would be unlikely. In addition, fish would gain access to cold water springs, particularly in the Upper Basin, offering improved winter growth opportunities for rearing fish and some protection against future changes associated with climate change. The adverse effect of peaking flows, stranding, and entrainment of fish into hydroelectric facilities would also be eliminated.

The Hydropower Licensee would continue to fund operating Iron Gate Hatchery to meet current mitigation requirements until Iron Gate Dam is removed, after which time the hatchery would not be funded by Hydropower Licensee and is assumed to be closed.

NOAA Fisheries Service and DOI prescriptions would also be applicable to Alternative 5. Therefore, Alternative 4 and 5 include a measure to trap and haul fall-run Chinook salmon upstream and downstream around Keno Impoundment. The prescriptions call for seasonal trap and haul operations from June 15 to November 15 when water quality conditions are not suitable for fish (dissolved oxygen concentration less than 6 mg/L or temperature above 20 degrees Celsius) (DOI 2007; NOAA Fisheries Service 2007).

By removing the two largest reservoirs in the Hydroelectric Reach, many of the water quality impairments caused by impounding water, including high pH, altered patterns for

water temperatures, elevated water temperatures in the fall, low dissolved oxygen, and the presence of algal toxins, would be largely eliminated within and below the Hydroelectric Reach.

While water quality problems would improve as a result of draining Copco 1 and Iron Gate reservoirs, Alternative 5 would also eliminate recreational uses such as flatwater fishing in these reservoirs and could decrease the value of property with access to, or views of, the reservoirs. Decreased recreational opportunities could have related effects on other resources analyzed in this EIS/EIR (i.e., Socioeconomics and Recreation, analyzed in detail in Sections 3.15 and 3.20, respectively).

The release of sediments stored behind Copco 1 and Iron Gate dams would have negative impacts on fish and water quality in the short term (< 2 years) but would provide longer term benefits in the form of increased habitat complexity and increased movement of larger sediment substrate along the river bed (bedload transport), reductions in fish disease, and the nearly complete elimination of toxic algal blooms in the Hydroelectric Reach and downstream. Some chemicals are present in reservoir sediments at concentrations below critical screening levels for freshwater and marine disposal and do not preclude sediment release downstream.

Removal of Copco 1 and Iron Gate dams and the loss of peaking flows at J.C. Boyle dam would significantly decrease the amount of hydroelectric power generated by the Klamath Hydroelectric Project. However this alternative does maintain reservoir recreation opportunities at J.C. Boyle Reservoir.

ES.7.2.5 Alternatives 2 (Full Facilities Removal of Four Dams (Proposed Action)) and Alternative 3 (Partial Removal of Four Dams)

Alternatives 2 and 3 would have the benefits of Alternatives 4 and 5 for anadromous fish; however, Alternatives 2 and 3 would provide additional fisheries and water quality benefits. Table ES-6 below summarizes the expected major benefits to salmonids and water quality for all five alternatives in this EIS/EIR as compared to existing conditions.

All action alternatives would provide access to at least 420 miles of historical habitat above Iron Gate Dam for anadromous fish. Additionally under Alternatives 2 and 3, anadromous fish would access low gradient historical habitat of critical importance to spawning and rearing under Copco 1 and Iron Gate Reservoirs. Consequently, the size and diversity of these populations would increase. Removing all Four Facilities would provide for a free-flowing river below Keno dam and would optimize the efficiency of fish migration to and from the Upper Basin as well as through the entire Hydroelectric Reach. In addition, fish would gain access to cold water springs in the Hydroelectric Reach and the Upper Basin, offering improved winter growth opportunities for rearing and some protection against future changes associated with climate change. The entire river from Keno Dam to the Pacific Ocean would therefore become a well-connected, free-flowing river and would provide new fish habitat in the Hydroelectric Reach. Dam removal would maximize the recruitment of gravel within and below the Hydroelectric Reach, which would benefit fish spawning and rearing. Additionally, Alternatives 2 and

3 would create a more natural flow pattern and more bedload transport. The occurrence of juvenile salmon fish disease is anticipated to be reduced as a result of changes in the overall dispersal of adult salmon carcasses, increases in bedload and sediment transport, and reductions in food resources for the intermediate fish disease host. While there is some uncertainty associated with the cycle of disease in juvenile salmon, a reduction in fish disease is likely and this would create better conditions for fish migration, rearing, and spawning. These alternatives would likely eliminate concentrations of carcasses and disease associated with Iron Gate Hatchery. Similarly to Alternative 5, the adverse effects of peaking and entrainment into hydroelectric facilities would also be eliminated. Disease risks to resident fish would be low and the establishment of a disease hot spot for *C. shasta* above the current location of Iron Gate Dam would be unlikely. Also, Alternatives 2 and 3 include implementation of all Interim Measures funded by PacifiCorp for the period 2012 through 2020 to improve fish habitat, water quality, and to fund monitoring and critical research.

Similarly to Alternative 5, the release of sediments stored behind Copco 1 and Iron Gate dams would have negative impacts on fish and water quality in the short term (< 2 years) but would provide longer term benefits in the form of increased habitat complexity and increased movement of larger sediment substrate along the river bed (bedload transport), reductions in fish disease, and the nearly complete elimination of toxic algal blooms in the Hydroelectric Reach and downstream. Some chemicals are present in reservoir sediments but at concentrations below critical screening levels for freshwater and marine disposal and do not preclude sediment release downstream.

Alternatives 2 and 3 would eliminate the recreational benefits of project reservoirs such as fishing and some white water recreation opportunities related to peaking flows in the Hydroelectric Reach; however partial and full facilities removal would create new recreational benefits along the Hydroelectric Reach including additional river access and rafting opportunities in the bypassed reaches (the significance of these effects is analyzed in Section 3.20). Because of the elimination of the reservoirs and changes to recreational amenities, Alternatives 2 and 3 would decrease the value of properties with access to or views of the reservoirs. Alternatives 2 and 3 eliminate all hydropower production from the Four Facilities beginning in 2020.

Implementation of KBRA projects and programs under Alternatives 2 and 3 would accelerate basin-wide habitat restoration for fish and accelerate improvement of basin-wide water quality. In the Upper Basin, the KBRA would support water quality improvements in Upper Klamath Lake and Keno Reach, which would benefit migrating salmon and steelhead populations and resident sucker populations in Upper Klamath Lake. The KBRA Fisheries Reintroduction and Management Plans could have direct benefits for salmon by accelerating their reintroduction to the Upper Basin and by providing for fish population monitoring to optimize adaptive management of restoration activities.

Within 6 months of an Affirmative Determination by the Secretary of the Interior, PacifiCorp would propose a post Iron Gate Dam Mitigation Hatchery Plan that would

ensure hatchery mitigation goals are met for 8 years following dam removal. After 8 years, continued hatchery operations would depend largely on: 1) realized and projected benefits of restored access to additional habitat above the current location of IGD; 2) the success of habitat restoration efforts through the KBRA; and 3) the success of the reintroduction program identified in the KBRA.

Following dam removal seasonal trap and haul operations, primarily for fall-run Chinook salmon may occur around Keno Dam and Keno Impoundment/Lake Ewauna until water quality conditions are sufficiently improved to allow for safe passage of fish. A variety of release and rearing strategies would be utilized to optimize success; however, the KBRA does not contain specifics on the development nor implementation of these strategies.

Effects downstream from Iron Gate Dam would include increased production of Chinook salmon due to more favorable flows associated with KBRA and improved habitat condition. In particular, these alternatives would also improve survival of smolts emigrating from downstream tributaries, such as the Scott and Shasta rivers, due to improved Klamath River flows and disease conditions. Restoration of runs in these two tributaries is the goal of extensive restoration programs.

Both Alternatives 2 and 3 fulfill three key criteria described in the Purpose and Need (Sections ES.3 and 1.5.2.1):

- Establishes a free-flowing condition on the Klamath River from the Keno Dam (River Mile 240) to the Pacific Ocean.
- Allows for full volitional fish passage from the Upper Basin to the Lower Basin of the Klamath River.
- Leads to implementation of KBRA.

Alternatives 2 and 3 have effectively the same in-river effects (i.e., fisheries, habitat, or water quality); any differences between these alternatives are related to societal aspects (scenic, economic, or recreation), as described in Section ES.7.2.6.

Table ES-6. Summary of Major Long-Term Benefits for Salmonid Restoration and Water Quality

Major long-term benefits of alternatives for water quality and salmonids as compared to existing conditions (baseline)	Alternative 1	Alternatives 2 and 3	Alternative 4	Alternative 5
Water Quality Benefits				
River no longer exceeds OR and CA water temperature, nutrient, dissolved oxygen, pH, and chlorophyll-a TMDL allocations (may not occur by 2061), improving water quality basin wide	X ¹	X	X	X
Accelerates when river no longer exceeds OR and CA water temperature, nutrient, dissolved oxygen, pH, and chlorophyll-a TMDL allocations through the KBRA Fisheries Restoration Plan, improving water quality basin wide		X		
Largely eliminates in 2020 elevated late summer/fall water temperatures in and below the Hydroelectric Reach by removing the largest reservoirs		X		X
Largely eliminates 2020 dissolved oxygen and pH problems produced in reservoirs in the Hydroelectric Reach and transported downstream		X		X
Largely eliminates in 2020 algal toxins produced in the Hydroelectric Reach and transported downstream ³		X		X
Salmonid Benefits				
Iron Gate hatchery smolt production as mitigation for 16 miles of habitat loss would continue	X		X	
Expands access to at least 420 miles of anadromous salmonid habitat and associated smolt production above Iron Gate Dam and development of diverse life histories		X	X	X
Anadromous fish would access low gradient historical habitat of critical importance to spawning and rearing under Copco 1 and Iron Gate Reservoirs		X		X
Provides fish with access to thermal refuge areas that are buffered from future effects from climate change		X	X	X
Provides for natural recruitment of spawning gravel and river processes within and below the Hydroelectric Reach through dam removal		X		Partial ²
Accelerates in 2012 restoration of fish habitat throughout the basin through the KBRA Fisheries Restoration Plan		X		
Accelerates the reintroduction of anadromous fish through the KBRA Fisheries Reintroduction Plan and is consistent with the optimal production from habitat for these species		X		

Table ES-6. Summary of Major Long-Term Benefits for Salmonid Restoration and Water Quality

Major long-term benefits of alternatives for water quality and salmonids as compared to existing conditions (baseline)	Alternative 1	Alternatives 2 and 3	Alternative 4	Alternative 5
Expands opportunity to create springtime flushing flows (KBRA Environmental Water Program) and to increase flow variability and bed movement (with dam removal), which reduce juvenile salmon disease below the Hydroelectric Reach		X		Partial
Provides opportunity to reduce juvenile salmon disease by allowing volitional fish passage through the Hydroelectric Reach and decreasing crowding of adult salmon/carcasses		X	X	X
KBRA funding would increase habitat restoration funding, coordination, and monitoring in the Klamath River watershed.		X		
Improves survival of smolts emigrating from tributaries downstream from Iron Gate Dam, such as the Scott and Shasta rivers, where extensive investment in restoration is underway and continuing		X	Partial	Partial
Provides volitional fish passage through the Hydroelectric Reach		X	X	X
Provides optimal anadromous fish passage to and from at least 420 miles of historical habitat above Iron Gate Dam by creating a free flowing river in the Hydroelectric Reach in 2020		X		
Accelerates the effective use of the Upper Basin by salmonids through the KBRA Fisheries Reintroduction and Management Plan		X		
Improves base flows for salmonids, particularly in drought years, through KBRA Water Resources Program		X		
Eliminates adverse effects of hydroelectric peaking and stranding of fish in the Hydroelectric Reach		X	Partial	X
Eliminates entrainment mortality of resident fish		X	X	X
Reduces concentration of myxospores associated with carcasses accumulating below hatchery facilities, thus reducing disease		X		X

Notes:

- 1 "X" means the alternative provides this benefit.
- 2 "Partial" means the alternative provides only some of the benefit.
- 3 Periphyton are algae that grow attached to rocks and other substrates on a riverbed. Although sometime these species cause nuisance conditions, they are rarely considered toxic. Increased non-toxic periphyton biomass would not lead to increases in algal toxins in the Klamath River. Blooms of phytoplankton (suspended algae) occurring in the calm, lake-like waters are responsible for the production of algal toxins, such as microcystin, in the Klamath River downstream from Iron Gate Dam. Noxious phytoplankton would not thrive in the free flowing river following dam removal.

ES.7.2.6 Comparing Alternatives 2 and 3

There are many similarities in the benefits and potential impacts of Alternatives 2 and 3. The main difference between the alternatives is that Alternative 3 would leave some ancillary structures in place, such as powerhouse buildings, pipelines, and penstocks, but both alternatives would create a free-flowing river from Keno Dam to the Pacific Ocean and eliminate any passage barriers to fish on the main stem Klamath River.

Given the fact that fewer structures would be removed under Alternative 3 compared to Alternative 2, there would be fewer short-term environmental impacts associated with construction activities and the use of heavy equipment. Thus, impacts related to the release of greenhouse gases, noise, and ground and land disturbance would be diminished and there would be less likelihood of displacing cultural resources or human remains (impacts to Cultural Resources are analyzed in Section 3.13). However, leaving various ancillary structures in place has the potential to interfere with wildlife movement, aesthetic quality, public safety, and would require some level of long-term maintenance.

Table ES-7 below compares the effect of Alternative 2 and 3 for all resource categories in this EIS/EIR.

Table ES-7. Detailed Comparison of Alternative 2 and Alternative 3

Resource Category:	Alternative 2 (Alt 2) - Full Facilities Removal	Alternative 3 (Alt 3) - Partial Facilities Removal
Water Quality (Section 3.2)	Both Alt 2 and Alt 3 result in a sediment release from reservoir drawdown which will have similar short-term water quality impacts. In the long-term, both Alt 2 and Alt 3 would result in increased spring time water temperatures and changes in daily variation in water temperature. These changes would mean that water temperature patterns in the Klamath River would be restored to normal pre-dam conditions.	
Aquatic Resources (Section 3.3)	Both Alt 2 and Alt 3 result in a sediment release from the drawdown of the reservoir which will have similar short-term aquatic resource impacts. In the long-term, the increase in the total amount of habitat, reestablishment of bedload sediment transport, reduced transmission of disease, and the improvements in water quality condition will benefit aquatic resources.	
Algae (Section 3.4)	Both Alt 2 and Alt 3 result in increased spring time water temperatures and change daily variation in water temperature. These changes would mean that water temperature patterns in the Klamath River Hydroelectric Reach would be restored to more natural conditions. Similarly the dominant algae would shift from noxious, and at times toxic, lake algae to algae found in moving water.	
Terrestrial Resources (Section 3.5)	Short-term construction impacts to terrestrial resources from Alt 2 maybe higher due to effects from more truck trips and reduction in bat habitat.	Reduced impacts to terrestrial plants and wildlife through reduced construction truck trips. Retained structures for use as a bat habitat.
Flood Hydrology (Section 3.6)	Both Alt 2 and Alt 3 result in a small increase in the peak 100 year flood and change in flood timing. However with mitigation this impact is less than significant.	

Table ES-7. Detailed Comparison of Alternative 2 and Alternative 3

Resource Category:	Alternative 2 (Alt 2) - Full Facilities Removal	Alternative 3 (Alt 3) - Partial Facilities Removal
Groundwater (Section 3.7)	The dam removal and drawdown described in both Alt 2 and Alt 3 have a decline in the water table surrounding the reservoirs potentially affecting adjacent wells. However with mitigation this impact is less than significant.	
Water Rights/Water Supply (Section 3.8)	Both Alt 2 and Alt 3 result in a sediment release which has a similar very slight impact on water supply in-takes located in the Klamath River downstream from Iron Gate Dam. However with mitigation this impact is less than significant. Removal of the Four Facilities would also require the relocation of the City of Yreka's water supply pipeline. The programmatic analysis of this action showed that design measures incorporated into the project description reduce the potential effects of this action to a less than significant level. Additional environmental compliance will be required for the pipeline relocation.	
Air Quality (Section 3.9)	Greater emissions from short-term construction activities.	Reduced VOC, NOx, CO, SO2, PM10 and PM2.5 emissions due to shorter duration construction activities.
Greenhouse Gases/Climate Change (Section 3.10)	Greater emissions from short-term construction activities.	Short-term reduction in greenhouse gas emissions due to reduced construction activities.
Geology, Soils, and Geologic Hazards (Section 3.11)	The dam removal and drawdown described in both Alt 2 and Alt 3 could cause instability surrounding the reservoirs. However with mitigation this impact is less than significant.	
Tribal Trust (Section 3.12)	Both Alt 2 and Alt 3 result in benefits to aquatic resources and water quality which benefit Indian Trust Assets.	
Cultural/Historic Resources (Section 3.13)	Greater disturbance to archaeological and historic sites given wider and deeper APE footprint. No retention of historic structures.	Reduced disturbance to archaeological and historic sites given less aerial extent of excavation. Some historic structures at Copco 1 (built in 1918) are retained.
Land Use, Agricultural, and Forest Resources (Section 3.14)	Slightly more open space for public use through removal of all facilities; however buried facilities may have some associated access restrictions.	Slightly less open space for public use; retained facilities will be fenced off from public use limiting access to some additional areas.
	Fisheries: Improvements to commercial, recreational and tribal fisheries due to habitat expansion and improvement.	Fisheries: Same as Alt 2.
Socioeconomics (Section 3.15)	Community economic impacts (employment, labor income, output): Positive short- and medium-term impacts due to construction, mitigation and KBRA expenditures. Some long-term negative impacts due to reduced expenditures for reservoir and whitewater recreation and dam operations and maintenance. Some long-term positive impacts due to increased expenditures for commercial and recreational fisheries, irrigated agriculture, and refuge recreation.	Community economic impacts (employment, labor income, output): Same as Alt 2

Table ES-7. Detailed Comparison of Alternative 2 and Alternative 3

Resource Category:	Alternative 2 (Alt 2) - Full Facilities Removal	Alternative 3 (Alt 3) - Partial Facilities Removal
	Tribes: Improvements to tribal fisheries and to cultural practices involving fish or water contact.	Tribes: Same as Alt 2.
	Costs: Most probable estimate of construction and mitigation costs (2020 dollars) = \$292 million. Costs to be divided between PacifiCorp ratepayers (\$200 million) and State of California. KBRA is connected action which will require Federal funding.	Costs: Most probable estimate of construction, life cycle and mitigation costs (2020 dollars) = \$247 million. Life cycle costs pertain to perpetual maintenance and security for ancillary structures that are not removed. Costs to be divided between PacifiCorp ratepayers (\$200 million) and State of California. KBRA costs are the same as Alt 2.
Environmental Justice (Section 3.16)	Greater traffic, noise, and vibration could disproportionately effect tribal communities.	Reduced traffic, noise, and vibration could reduce disproportionate effects.
Population & Housing (Section 3.17)	The availability of housing is slightly reduced during construction. However because Alt 2 and Alt 3 have identical peak worker totals the effects are similar.	
Public Utilities (Section 3.18)	Higher volume of construction waste for disposal which would result in greater effects on area landfills.	Lower volume of construction waste for disposal which would result in reduced effects on area landfills.
Public Safety (Section 3.18)	Slightly more short term public safety effects associated with greater traffic. No retained above ground structures improves public safety in the long term.	Reduced traffic would reduce the public safety effects from short-term construction traffic. Under Alt 3 in the long term, there is the risk that facilities that were secured in place could cause an attractive nuisance and public safety effects. Resolving an attractive nuisance issue would fall to the entity ultimately responsible for management of those lands.
Scenic Quality (Section 3.19)	Removal of all structures could improve scenery however some historic properties provide positive scenery attributes.	Retaining some structures could conflict with the surrounding terrain, however some historic properties provide positive scenery* attributes.
Recreation (Section 3.20)	Removal of JC Boyle dam will permanently reduce the number of days with acceptable flows for whitewater boating at Hell's Corner Reach. Both Alt 2 and Alt 3 result in the elimination of reservoir related recreation.	
Toxic/ Hazardous Materials (Section 3.21)	Both Alt 2 and Alt 3 require disposal of a similar amount of hazardous materials.	
Traffic and Transportation (Section 3.22)	Greater traffic and road wear generation.	Reduced traffic and road wear generation due to reduced construction activities
Noise and Vibration (Section 3.23)	Greater noise and vibration generation.	Reduced noise and vibration generation due to reduced construction activities
Color Code Description Key	Less preferred condition for this resource category	Preferred condition for this resource category

ES.7.3 NEPA Environmentally Preferable/Preferred Alternative

ES.7.3.1 Environmentally Preferable Alternative

NEPA requires that DOI identify the alternative or alternatives that are environmentally preferable in the Record of Decision (ROD) (40 CFR Part 1505.2(b)). The environmentally preferable alternative generally refers to the alternative that would result in the fewest adverse effects to the biological and physical environment. It is also the alternative that would best protect, preserve, and enhance historic, cultural, and natural resources. Although this environmentally preferable alternative must be identified in the ROD, it need not be selected for implementation. For the purposes of NEPA, DOI will identify an Environmentally Preferable Alternative in the ROD associated with this EIS/EIR.

ES.7.3.2 Preferred Alternative

Both Alternative 2 and Alternative 3 include removal of the Four Facilities and implementation of KBRA and both alternatives more fully meet the Purpose and Need (Sections ES.3 and 1.5.2.1). Some key benefits provided by implementation of Alternative 2 and Alternative 3 include (for a full discussion of the Alternatives, see Chapter 3):

- Provides optimal anadromous fish passage to and from at least 420 miles of historical habitat above Iron Gate Dam by creating a free flowing river in the Hydroelectric Reach in 2020
- Anadromous fish would access low gradient historical habitat of critical importance to spawning and rearing under Copco 1 and Iron Gate Reservoirs
- Provides for natural recruitment of spawning gravel and river processes within and below the Hydroelectric Reach through dam removal
- Largely eliminates in 2020 elevated late summer/fall water temperatures in and below the Hydroelectric Reach by removing the largest reservoirs
- Largely eliminates 2020 dissolved oxygen and pH problems produced in reservoirs in the Hydroelectric Reach and transported downstream
- Largely eliminates in 2020 algal toxins produced in the Hydroelectric Reach and transported downstream
- Reduces concentration of myxospores associated with carcasses accumulating below hatchery facilities, thus reducing disease

Removal of the Four Facilities and implementation of KBRA are important components of a durable, long-term solution for local communities and tribes regarding the development, administration, allocation, and advancement of water and native fishery resources of the Klamath Basins. Alternative 2 and Alternative 3 provide a greater opportunity for expanding restoration of salmonids, which, over time would improve harvest opportunities of salmonids, and when compared to the other alternatives, resolve more societal hardships and conflicts that result from over-allocation of scarce natural resources.

Although Alternative 2 and Alternative 3 are similar, Alternative 2 would remove nearly all structures associated with the Four Facilities, while Alternative 3 would allow some structures to remain. By leaving no structures along the shore of the Klamath River, Alternative 2 leads to positive permanent changes in the human environment such as improvements to scenic quality, less long-term maintenance by land-management agencies, and is more protective of public safety. For these reasons Alternative 2 is the preferred alternative.

ES.7.4 CEQA Environmentally Superior Alternative

Section 15126.6(e)(2) of the CEQA Guidelines requires agencies to identify the environmentally superior alternative in a Draft EIR. If the No Project Alternative is the environmentally superior alternative, an additional environmentally superior alternative must be identified among the other alternatives.

CDFG has identified Alternative 3 (Partial Facilities Removal of Four Dams) as the environmentally superior alternative. All of the alternatives evaluated in the EIS/EIR, including for the No Action/No Project Alternative, have significant unavoidable environmental impacts as identified in Section 5.5. Alternative 2 (Full Facilities Removal of Four Dams, the Proposed Action), Alternative 3, and Alternative 5 (Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate) would have the most short-term significant and unavoidable impacts among the alternatives. These impacts would largely be limited to the time frame of direct dam deconstruction actions and sediment release. After dam deconstruction, impacts would include the loss of reservoir recreation and local economic impacts. Alternatives 2, 3, and 5 would significantly improve water temperature, dissolved oxygen, and algal toxins for aquatic resources and reduce the incidence of fish disease in juvenile salmon by removing the two largest reservoirs—Copco I and Iron Gate. Alternatives 4 and 5 would maintain some power production and recreational benefits thereby reducing local economic impacts.

Although the No Action/No Project Alternative will have no change from existing conditions resulting from construction, this alternative is not the environmentally superior alternative when compared to the Proposed Action, which is intended to improve environmental conditions. Alternative 3 is the environmentally superior alternative when compared with the Proposed Action (Alternative 2) because it would:

- Reduce the air quality impacts from emissions of volatile organic compounds (VOCs), nitrogen oxides (NO_x), carbon monoxide (CO), sulfur dioxide (SO₂), particulate matter < 10 microns (PM₁₀), and particulate matter < 2.5 microns (PM_{2.5}) from reduced construction activities;
- Reduce the contribution to greenhouse gas emissions from reduced construction activities;
- Reduce noise and vibration from reduced construction activities;
- Reduce impacts to terrestrial plants and wildlife from fewer truck trips;
- Reduce disturbance to archaeological and historic sites from fewer truck trips;

- Retain structures for roosting bats; and
- Retain some historically significant structures at the Four Facilities.

Alternative 3 would provide similar long-term benefits when compared with Alternative 2, but would reduce some short-term and long-term impacts because it involves less construction. In summary, Alternative 3 is considered the environmentally superior alternative among all the alternatives because it provides long-term beneficial environmental effects, while reducing some of the short-term significant effects of the Proposed Action (Alternative 2).

ES.7.5 Controversies and Issues Raised by Agencies and the Public

CEQA requires disclosure of the controversial project issues raised by agencies and the public. Table ES-8 (also Chapter 5, Table 5-4) presents a summary of some of the controversial issues and the timeline or process in which they will be addressed, or the document in which they are addressed. The issues were identified during the scoping period and in other forums for public involvement. These are opinions and issues raised by agencies and members of the public and do not necessarily represent the position of the Lead Agencies. Additionally, Table ES-8 is not a summary of findings or determinations from the analysis in this EIS/EIR. See the Scoping Report (located online at: <http://klamathrestoration.gov/>) for further information on issues identified by agencies and the public during the public scoping process (DOI 2010).

Table ES-8. Summary of Controversies and Issues Raised by Agencies and the Public¹

Issue	Summary of Issue	Timeline for Addressing or Document/Section Addressing Issue
Loss of Renewable Power Supply	Loss of the Klamath Hydroelectric Project will result in the loss of renewable power. The specific makeup of new power supplies is not certain and may come from non-renewable sources.	Greenhouse Gases/Global Climate Change (Section 3.10.4.3) Public Health and Safety, Utilities and Public Services, Solid Waste, Power (Section 3.18.4.3)
Regional Economic Impacts	Loss of the Klamath Hydroelectric Project, lost power generation, and impacts to the local real estate market will negatively and disproportionately affect resource-based economies of local communities, many of which are struggling economically.	Socioeconomics (Section 3.15.4.3)
Sediment Impacts from Dam Removal	Sediment release during dam removal will have significant and deleterious effects on the aquatic environment from Iron Gate Dam to the Pacific Ocean during the period of dam removal.	Water Quality (Section 3.2.4.3) Aquatic Resources (Section 3.3.4.3) Appendix C

Table ES-8. Summary of Controversies and Issues Raised by Agencies and the Public¹

Issue	Summary of Issue	Timeline for Addressing or Document/Section Addressing Issue
Historic Anadromous Fish Distribution in the Upper Klamath Basin	Dam removal would open large areas of the Upper Klamath Basin watershed to anadromous fish. The historical distribution of anadromous fish above the dams has been questioned.	Chapter 1, Introduction Aquatic Resources (Section 3.3.4.3)
KBRA Effects	The KBRA may not produce enough social and economic benefits from implementation.	Socioeconomics (Section 3.15.4.3)
KBRA Effects on Environmental Justice and Federal Trust Responsibilities	The KBRA would result in the "termination" of tribal fishing and water rights and the Federal trust responsibilities for those rights and resources, further exacerbating the environmental justice issues associated with declining anadromous fisheries and water quality in the Klamath Basin that have affected tribal practices, health, and cultural traditions	Water Rights and Water Supply (Section 3.8) Indian Trust Assets(Section 3.16)
Loss of Reservoir Environment	Dam removal will result in a loss of the three largest reservoirs, affecting individuals that live on or near the reservoirs and who value the reservoirs' aesthetic and recreational value.	Land Use, Agricultural, and Forest Resources (Section 3.14.4.3) Scenic Quality (Section 3.19.4.3) Recreation (Section 3.20.4.3)
Flood Risk	Dam removal will increase the incidence and magnitude of flooding to downstream communities.	Flood Hydrology (Section 3.6.4.3)
FERC Relicensing	In the event of a Negative Secretarial Determination, PacifiCorp would continue to seek a new license from FERC for operation of the Klamath Hydroelectric Project. The outcome of this process is not known but could be the continued operation of the dams under a new license that includes the agencies' mandatory conditions and prescriptions.	Chapter 2, Proposed Action and Description of Alternatives
Agriculture and Refuge Management contributes to poor water quality in Keno and Upper Klamath Lake	Runoff from agriculture and refuges results in poor water quality in Keno Impoundment/ Lake Ewauna and in the mainstem Klamath River. This causes fish stress, disease and mortality. Continued farming and ranching in the Tule Lake National Wildlife Refuge and Lower Klamath Lake National	Water Quality (Section 3.2.4.3) Aquatic Resources (Section 3.3.4.3)

Table ES-8. Summary of Controversies and Issues Raised by Agencies and the Public¹

Issue	Summary of Issue	Timeline for Addressing or Document/Section Addressing Issue
	Wildlife Refuge under the KBRA would inhibit fish species reintroduction and survival.	
Water Quality Conditions in Keno Impoundment and Upper Klamath Lake would not allow sound fish passage	Low levels of dissolved oxygen and high water temperatures during certain times of year would adversely affect passage of fish through Keno Impoundment and Upper Klamath Lake.	Water Quality (Section 3.2.4.3) Aquatic Resources (Section 3.3.4.3)
Changes in Types and Amounts of Whitewater Boating	Peaking flows from operation of the hydroelectric project currently allow for commercial whitewater boating in mid- to late-summer.	Socioeconomics (Section 3.15.4.2) Recreation (Section 3.20.4.3)
Resolution 10-185 of Siskiyou County Board of Supervisors Calling for an Advisory Election with Respect to the Removal of the Dams on the Klamath River on November 2, 2010 (Measure G).	Siskiyou County held an advisory vote on November 2, 2010 regarding dam removal. The ballot asked "Should the Klamath River Dams (Iron Gate, Copco 1, and Copco 2) and associated hydroelectric facilities be removed – Yes or No?" Of the 25,922 registered voters in the County, 17,206 (66.4%) participated in this vote. The results: Of the 17,206 who voted, 13,566 residents (78.84%) voted No to dam removal, while 3,640 (21.86 %) voted Yes.	While this is not an environmental impact issue and is not specifically addressed as part of this EIS/EIR, the Secretary of the Interior will consider this when making his determination.
"Siskiyou County Water Users Association, Inc. v. California Natural Resources Agency, et al." (Other Defendants are Lester Snow, Secretary of California Natural Resources Agency, Governor Schwarzenegger, DFG, DFG's Director, Humboldt County, Tule Lake Irrigation District, and Westside Improvement District).	This case was originally filed in Sacramento Superior Court on August 16, 2010. The original lawsuit asserted that approval of the KHSAs and KBRA violated CEQA, and that DFG is the wrong Lead Agency. The trial court ruled that appellant's claims were time barred because a valid Notice of Determination had been filed, and that a challenge to the Lead Agency designation was not ripe for review. That ruling has been appealed to the Third Appellate District Court of Appeal. Siskiyou County Water Users Association's opening brief was filed on February 15, 2012.	This is not an environmental impact issue and is not specifically addressed as part of this EIS/EIR. It is not yet known how the results of this case may affect the overall project.

¹ CEQA requires disclosure of the controversial project issues raised by agencies and the public. Table ES-8 presents a summary of some of the controversial project issues identified during the scoping period, which are addressed in this EIS/EIR. These are opinions and issues raised by agencies and members of the public and do not necessarily represent the position of the Lead Agencies. Additionally, Table ES-8 is not a summary of findings or determinations from the analysis in this EIS/EIR.

Chapter 1

Introduction

On September 22, 2011, the U.S. Department of the Interior (DOI), acting as the National Environmental Policy Act (NEPA) Lead Agency and the California Department of Fish and Game (CDFG), acting as the California Environmental Quality Act (CEQA) Lead Agency, released the Klamath Facilities Removal Draft Environmental Impact Statement/Environmental Impact Report (Draft EIS/EIR) for public review and comment.

In compliance with NEPA, a Notice of Availability (NOA) was published by DOI's Office of Environmental Policy and Compliance in the Federal Register (Federal Register Vol. 76, No. 184, 58833) on Thursday September 22, 2011, and an associated NOA was published by the U.S. Environmental Protection Agency (USEPA) in the Federal Register (Federal Register Vol. 76, No. 190, 60822) on Friday September 30, 2011. A Notice of Completion (NOC) was also published in the State Clearinghouse (State Clearinghouse # 2010062060) on the same date, in accordance with CEQA.

The Lead Agencies conducted public involvement activities on the EIS/EIR during scoping and upon release of the Draft EIS/EIR. The scoping comment period and scoping meetings were held in June and July of 2010. Additionally the Lead Agencies held six public hearings during the comment period on the Draft EIS/EIR at the following locations in California and Oregon:

- Klamath County Fairgrounds, Klamath Falls, Oregon, October, 18, 2011;
- Chiloquin Community Center, Chiloquin, Oregon, October 19, 2011;
- Yreka Community Center, City of Yreka, California, October 20, 2011;
- Karuk Community Room, Orleans, California, October 25, 2011;
- Arcata Community Center, Arcata, California, October 26, 2011; and
- Yurok Tribal Administration Office, Klamath, California, October 27, 2011.

Written and verbal comments were accepted at meetings and written comments were accepted throughout the comment period. The comment period on the Draft EIS/EIR closed on December 30, 2011.

Since receipt of public comments revision of the Draft EIS/EIR has been underway to produce this Klamath Facilities Removal Final Environmental Impact Statement/Environmental Impact Report (Final EIS/EIR). This Final EIS/EIR consists of three volumes: the revised Volume I, revised Volume II, and new Volume III. Volumes I and II of the Final EIS/EIR have been revised in response to the comments.

Volume III of the Final EIS/EIR contains responses to all comments received during the comment period (see Chapter 10, Chapter 11, and Chapter 12), as well as all changes made to the public Draft EIS/EIR (see Appendix AB in Volume III).

During the process of addressing public comments, some notable content changes were made in the Final EIS/EIR from the prior Draft EIS/EIR. In this Final EIS/EIR, the Lead Agencies:

- Disclosed the Preferred Alternative as Alternative 2, Full Facilities Removal of Four Dams (Proposed Action) (see Executive Summary, ES.7.4 and Chapter 5, Section 5.9);
- Refined and more clearly articulated how stored sediment and suspended sediment volumes were calculated (see Section 2.4.3 “Sediment Weight and Volume in the Four Facilities and Erosion with Dam Removal”);
- More clearly identified the City of Yreka pipeline relocation discussion as being a programmatic level of analysis (see Section 2.4.3.9);
- Added a determination on critical habitat for eulachon with information from the recent listing (see Section 3.3.4.3);
- Expanded and refined information on flow modeling and flow requirements on the Klamath River (see Section 3.3.3.3.7);
- Expanded and refined the discussion in the Algae Section (see Section 3.4.4.3);
- Expanded the discussion on wetlands, riparian communities, and mitigation for possible effects to these resources (see Section 3.5.4.3);
- Expanded the discussion and added a determination on amphibians and reptiles (see Section 3.5.4.3);
- Expanded and refined the discussion on effects on groundwater from the On-Project plan (see Section 3.7.4.3);
- Expanded discussion and added a determination on water rights assurances related to tribal water rights (see Section 3.8.4.3);
- Expanded discussion of the Tribal Trust for several of the federally recognized tribes (see Section 3.12);
- Expanded the Cultural Resources sections to more comprehensively address National Historic Preservation Act (NHPA) compliance and more clearly articulated the mitigation measures for Cultural Resources (see Section 3.13.4.1);
- Refined the discussion on real estate effects (see Section 3.15.3.6); and
- Added a Scenic Quality mitigation measure SQ-1: Measures to Minimize Scenery Disturbances (See Section 3.19.4.4).

1.1 Purpose and Approach of this Document

This EIS/EIR evaluates the potential impacts of the removal of the four PacifiCorp¹ dams on the Klamath River as contemplated in the Klamath Hydroelectric Settlement Agreement (KHSA [2010]). The Klamath Basin Restoration Agreement (KBRA [2010]), as well as the transfer of Keno Dam are treated and analyzed as connected actions.² The KBRA includes programs that will undergo detailed development and analysis in the future. Therefore, it is anticipated that additional NEPA and CEQA analyses for the suite of actions contained in KBRA will be tiered as appropriate to this EIS/EIR. CDFG recognizes that additional environmental analysis may be required by any California public entity with an approval or permitting obligation if required by CEQA.

The EIS/EIR is being prepared in compliance with NEPA and CEQA and will inform a determination by the Secretary of the Interior (Secretary) (i.e., Secretarial Determination) on whether dam removal will advance salmonid restoration and is in the public interest, including but not limited to, consideration of potential impacts on affected local communities and Indian Tribes.

The KHSA establishes a process for the Secretarial Determination.³ This process includes additional studies, environmental review, and the decision by the Secretary. This process also includes decisions by the States of Oregon and California as to whether they concur with the Secretarial Determination.

The J.C. Boyle, Copco 1, Copco 2, and Iron Gate Dams and appurtenant facilities (herein referenced as the Four Facilities) are being evaluated for removal, and Keno Dam is being evaluated for transfer (not the removal of) from PacifiCorp to DOI as a connected action. These dams are affecting salmonid fisheries by blocking hundreds of miles of potential river habitat, by affecting downstream water quality (specifically, dissolved oxygen, water temperature, and algal toxins), and altering flows in sections of the mainstem of the river (Hamilton et al. 2011). If authorized through legislation, the Secretary will use the impacts analysis presented in this EIS/EIR to help determine whether and to what extent facilities removal should occur.

Conflicts over water and other natural resources in the Klamath Basin between conservationists, tribes, farmers, fishermen, and State and Federal agencies have existed for decades. In particular, several developments affecting the Klamath Basin have occurred in recent years:

¹ PacifiCorp refers to the current utility and all previous owners/names.

² NEPA defines a connected action as an action that (i) automatically triggers other actions that may require environmental impact statements (ii) cannot or will not proceed unless other actions are taken previously or simultaneously (iii) is an interdependent part of a larger action and depends on the larger action for its justification. Connected actions are closely related and therefore should be discussed in the same impact statement (40 CFR Part 1508.25 (a)1).

³ Secretarial Determination: Decision by the Secretary of the Interior based on a thorough scientific review of existing science, data and other information whether removal of the dams: (1) will advance restoration of the salmonid fisheries of the Klamath Basin; and (2) is in the public interest.

- In 2001, water deliveries to irrigation contractors in Reclamation’s Klamath Project (described below) were substantially reduced.
- In 2002, returning adult salmon suffered a major die-off.
- In 2006, the commercial salmon fishing season was closed along 700 miles of the West Coast to protect weak Klamath River and other major river salmon stocks.
- In 2010, due to drought conditions,⁴ Reclamation’s Klamath Project had a reduction in water deliveries resulting in short-term idling of farmland and increased groundwater pumping.

Historical conflicts over the Klamath Basin’s limited water resources stem in part from concerns over fish populations. The fish populations native to the Klamath River have decreased over time due to human activities in the basin. The Lost River and shortnose suckers have been affected by degradation and loss of habitat as a result of human activities in the Upper Klamath Basin over the last century (United States Fish and Wildlife Service [USFWS] 2008). Water resource development on the Klamath River and its tributaries (including the Shasta, Scott, and Trinity Rivers) has contributed to declines in salmonid fish populations that have harmed both in-river and coastal fishing for subsistence, commercial, and recreational fishing (Congressional Research Service 2005).

1.2 Physical and Biological Setting

The Klamath Basin geography, topography, hydrology, and biology are unique from other watersheds in the Pacific Northwest. Water in the Klamath River, unlike other watersheds in the Pacific Northwest, originates in relatively flat, open valleys before crossing the Trinity and Coast Ranges in a steep river canyon and intercepting cold water inputs from the Scott, Salmon, and Trinity Rivers. The flat topography, along with lower average precipitation in the Upper Klamath Basin than the Lower Klamath Basin, influences water flow and temperature in the river. Figure 1-1 illustrates many of the features of the Klamath Basin described in this section.

1.2.1 Geography and Topography

The Klamath River originates just downstream from Upper Klamath Lake in southern Oregon and flows 253 miles southwest through northern California to the Pacific Ocean. Along this course, the Klamath River crosses the Cascade Mountains; the Klamath is one of the only rivers to do so. The Upper Klamath Basin has five main lakes: Crater Lake, Upper Klamath Lake, Lower Klamath Lake, Clear Lake, and Tule Lake. The Lower Klamath Basin, with its border beginning at Iron Gate Dam, is almost 200 miles long and contains the four major Klamath River tributaries: the Shasta, Scott, Salmon, and Trinity Rivers. The basin is generally rural, with a total population of approximately 120,000. Its largest communities are Klamath Falls, Oregon, and City of Yreka, California.

⁴ As declared by the Governor of Oregon (State of Oregon 2010).

Figure 1-1. The Klamath Basin.

The Upper Klamath Basin has broad, extending valleys shaped by volcanoes and active faulting. The fault-bounded valleys contain all of the large, natural lakes and large wetlands of the Klamath Basin, with the exception of Crater Lake.

As described above, the Klamath River is unlike most river systems, in that the river is warmer and flatter in its headwaters, while downstream portions, beginning near the dams, tend to be colder and steeper. The Klamath River flows through mountainous terrain from the Oregon-California State line to the reaches downstream from Iron Gate Dam. Downstream from Iron Gate Dam, and for most of the river's length to the Pacific Ocean, the river maintains a relatively steep, high-energy channel. Here, the Klamath River forms a deep canyon surrounded by mountains of the Trinity and Coast Ranges. Lower Klamath Basin valleys include those of the Shasta and Scott Rivers (National Research Council [NRC] 2004).

1.2.2 Climate and Hydrology

The basin receives widely varying precipitation. The climate in the Upper Klamath Basin is dry, with an annual precipitation of approximately 13 inches at the river's origin near Klamath Falls, Oregon. In contrast, the Lower Klamath Basin is wet, with an annual precipitation of approximately 80 inches near the river's mouth at Requa, California. At its higher elevations (above 5,000 feet), the Upper Klamath Basin receives rain and snow during the late fall, winter and spring. Peak stream flows generally occur during snowmelt runoff in late spring/early summer. After the runoff period, flows drop in the late summer/early fall. Fall storms may increase flows compared with the lower summer flows in the Lower Klamath Basin.

1.2.3 Biology

The Klamath Basin has some of the richest biological and ecological habitats in the United States. The Klamath Basin is within the Klamath Bioregion (California) and the East and West Slope Cascades (Oregon) eco-regions. Below are overviews of the biological resources within this unique and biologically important basin and effects of natural resource development on these resources in the Upper and Lower Klamath Basins. Chapter 3 and the appendices of this document describe these resources in detail.

1.2.3.1 Vegetation

Vegetation communities in these eco-regions include drier pine and fir forests in the mountain ranges of Siskiyou County and wetter forests near the coast. Recognized for their biological diversity, the Klamath-Siskiyou mountain ranges contain more than 3,000 known plant species, including 30 temperate conifer tree species, more than any other ecosystem in the world (CDFG 2006). Land cover in the basin consists of a combination of upland forest habitat, aquatic habitat, and wetland habitat. Sagebrush and interior valley vegetation communities also exist within lower elevation areas.

The Klamath River Canyon itself is a mosaic of mixed conifer forest communities and riparian habitats (Federal Energy Regulatory Commission [FERC] 2007).

In addition to their ecological significance, many plants, especially wetland plants, in the Klamath Basin are culturally important to Indian Tribes in the Klamath River region for food, basketry, regalia, and medicine, and some have importance for ceremonial use as well (Larson and Brush 2010; FERC 2007).

1.2.3.2 Wildlife

The Klamath Basin is home to a large number of wildlife species, with great diversity. Surveys have identified more than 200 vertebrate species, including amphibians, reptiles, birds, and mammals (PacifiCorp 2004a).

The Upper Klamath Basin is along the Pacific Flyway, and it supports the largest concentration of migratory waterfowl in North America, with up to 2 million migratory birds during fall migration and about half that number in spring (Jarvis 2002). Large numbers of water-related birds also use the Upper Klamath Basin for breeding (Shuford et al. 2004). In addition, the Upper Klamath Basin supports the largest wintering population of bald eagles in the coterminous United States (Shuford et al. 2004).

1.2.3.3 National Wildlife Refuges

The Klamath Basin National Wildlife Refuge (NWR) System comprises six refuges (Bear Valley, Clear Lake, Klamath Marsh, Lower Klamath, Tule Lake, and Upper Klamath). The refuges maintain critical wetland habitat in the river basin and provide a stopover point for three-quarters of the migratory waterfowl on the Pacific Flyway (USFWS 2010). The refuges provide vital feeding, nesting, and resting habitat for one to two million birds during the spring and fall migrations, all of which are highly dependent on the water resources of the area.

1.2.3.4 Fish

The Klamath Basin is home to 19 native fish species. The Klamath Basin once produced large runs of steelhead, Chinook salmon, coho salmon, green sturgeon, eulachon, coastal cutthroat trout, and Pacific lamprey. Runs of these anadromous fish (fish that migrate from salt water to spawn in fresh water) contributed substantially to tribal, commercial, and recreational fisheries (USFWS 1986; DOI Klamath Basin Task Force 1991; Gresh et al. 2000).

Some of these fish species are listed under the Federal Endangered Species Act (ESA) and California Endangered Species Act (CESA). Federally listed species include coho salmon, bull trout, Lost River sucker, shortnose sucker, southern distinct population segment green sturgeon, and southern distinct population segment eulachon. California listed species include coho salmon, Lost River sucker, shortnose sucker and longfin smelt. In addition, both the Lost River sucker and the shortnose sucker are fully protected under the California Fish and Game Code Section 5515(a)(3)(b)(4) and (6), respectively.

Upper Klamath Lake and other waterways in the upper watershed provide habitat for the Lost River and shortnose suckers. Suckers are an important part of tribal culture and were an important part of tribal diet. The Lost River and shortnose sucker spawning runs still constitute ceremonial events for the Klamath Tribes. In 1988, these fish were listed as endangered under the ESA (USFWS 1988) and CESA, eliminating the ability to fish for suckers and thus eliminating them from tribal diet and traditional cultural practices.

Copco 1 Dam, completed in 1918, was the first mainstem dam to block fish passage to the majority of the Upper Klamath Basin. Iron Gate Dam, completed in 1962, is the downstream-most dam that blocks upstream fish passage. Flow releases from Iron Gate Dam, and the quality of the water being released, affect the quantity and quality of fish habitat for listed and non-listed species in the mainstem downstream from Iron Gate Dam (FERC 2007). The other hydroelectric dams, with the exception of J.C. Boyle Dam, which is equipped with a ladder that does not meet current standards (Administrative Law Judge 2006), also block upstream fish passage and isolate fish populations between these dams. The dams have eliminated access for anadromous fish, including salmon and steelhead, to hundreds of miles of potential habitat in at least 49 tributaries upstream of Iron Gate Dam.

The text boxes below describes the development and use of natural resources in the basin and some of the corresponding effects on water supplies and water quality as well as vegetation and wildlife communities in the Upper and Lower Klamath Basin.

Effects of Natural Resource Development

In the Upper Klamath Basin

- Logging, road-building, farming, and ranching above Upper Klamath Lake have removed riparian vegetation, warmed streams, and increased the loads of nutrients and sediment entering the rivers and Upper Klamath Lake, contributing to water-quality problems.
- Draining tens of thousands of acres of wetlands around Upper Klamath Lake for agriculture land increased nutrient loads to the lake and eliminated near-shore habitat for aquatic biota.
- Link River Dam operations to meet irrigation water demand cause wider water-level fluctuation in Upper Klamath Lake.
- Upper Klamath Lake has become more enriched with nutrients, leading to pH and dissolved oxygen problems that are stressful to aquatic biota and nuisance blooms of blue-green algae that produce toxins (primarily microcystin) .
- Shortnose and Lost River suckers went from a dominant species in Upper Klamath Lake, and a food source for tribal members, to an endangered species in 1988, a closed fishery, and a fish population that continues to decline.
- The Keno Reach and Keno Impoundment/Lake Ewauna receives large loads of decaying organic matter (blue-green algae) from Upper Klamath Lake, producing extremely low dissolved-oxygen levels that persist in the summer and fall.

Effects of Natural Resource Development

In the Upper Klamath Basin

- Draining and farming hundreds of thousands of acres of wetlands below Upper Klamath Lake (and the Lost River Valley) has decreased habitat for waterfowl on the Pacific Flyway and affects the amount and timing of water released downstream for fish.
- Klamath River is blocked at Iron Gate Dam for passage of fall and spring run Chinook salmon, coho salmon, and steelhead, limiting fish production in the basin and access to salmon by tribes in the Upper Klamath Basin.

In the Lower Klamath Basin

- The four dams create a “thermal lag” in both the spring and the fall. This means that the river warms more slowly in the spring and cools more slowly in the fall than it would without the dams. The result of these thermal effects is a delay in timing of runs for the migration of fall Chinook salmon.
- Severe water quality problems in the two larger reservoirs, Copco 1 and Iron Gate, including blue-green algal toxins (that can affect humans and fish), low dissolved oxygen, high temperatures, and high pH, create stressful biological conditions.
- Use of water in major Klamath River tributaries (e.g., Scott and Shasta Rivers) for farming and ranching has decreased habitat for coho salmon, which was federally listed in 1997.
- High nutrient concentrations leaving the Upper Klamath Basin result in the excessive growth of attached algae (periphyton) in the lower mainstem river, which causes stressful swings in pH and DO for aquatic biota.
- Reduced flows during extreme droughts have been identified as a factor in large fish die-offs, as occurred in the fall of 2002 when tens of thousands of pre-spawned salmon and steelhead died in the lower river.
- Weak Klamath salmon stocks in the ocean has required closure of fisheries and commercial and recreational fishing along 700 miles of the Oregon and California coasts, as occurred in 2006.

1.3 People and Historic Setting

1.3.1 Tribes

Six federally recognized Indian Tribes live, work, hunt, and fish within the basin, including the Klamath Tribes, Quartz Valley Indian Community, Karuk Tribe, Hoopa Valley Tribe, Yurok Tribe, and Resighini Rancheria. Historically, the tribes depended on the fish populations of the Klamath Basin for food as well as ceremonial traditions. Prior to European settlement, generations of Indians resided along the Klamath, , Shasta, Scott, and Trinity Rivers, as well as in the Upper Klamath Basin, and depended on the fisheries for cultural, ceremonial, subsistence, and commercial purposes.

The decline in the fisheries has caused economic hardship for all the tribes. The Klamath Tribes, in the Upper Klamath Basin, have not had salmon harvest opportunities since 1918, when Copco 1 Dam was built. By contrast, the salmon harvest continues to provide revenue for the Yurok and Hoopa Valley Tribes (who reside in the Lower Klamath Basin).

1.3.1.1 The Klamath Tribes

The Klamath Tribes, headquartered in Chiloquin, Oregon, in the Upper Klamath Basin near Upper Klamath Lake, are composed of three historically separate tribes: the Klamath Tribe, the Modoc Tribe, and the Yahooskin band of Snake Indians. The Klamath Tribes' ancestral territory covers approximately 580,000 acres. The current membership is about 3,400 and the current total land base is approximately 600 acres.

1.3.1.2 Quartz Valley Indian Community

The Quartz Valley Indian Community is a federally recognized Indian Tribe representing people of Upper Klamath Basin (Karuk) and Shasta Indian ancestry. The Quartz Valley Reservation is in Siskiyou County near the community of Fort Jones. The population is around 126, with a tribal enrollment of about 150. Total reservation size is 174 acres.

1.3.1.3 Karuk Tribe

The Karuk Tribe has been federally recognized since 1979 and occupies territory along the middle section of the Klamath River. The 2000 U.S. Census reported tribal membership to be 2,702 individuals. In 2004, the California Department of Housing and Community Development reported tribal membership to be 3,164 individuals. Currently, the Karuk have one of the largest Indian Tribes in California with approximately 4,800 members.

1.3.1.4 Hoopa Valley Tribe

The Hoopa Valley Indian Reservation is in the northeastern corner of Humboldt County in northern California, approximately 50 miles inland from the Pacific Ocean, and encompasses roughly 20 percent of Hupa aboriginal territory. The reservation has nearly 92,160 acres, and is the largest reservation in California. The northern portion of the reservation is in Yurok ancestral territory. The Trinity River bisects the reservation, and a small length of the northern border of the reservation includes about a quarter mile

reach of the Klamath River. The 2000 U.S. Census counted 2,633 people on the reservation, and the tribe listed an enrollment of 2,130 in 2004.

1.3.1.5 Yurok Tribe

With more than 5,000 members, the Yurok Tribe is the largest Indian Tribe in California. The tribe's ancestral territory covers approximately 350,000 acres and includes approximately 50 miles of Pacific coastline. Today, the tribe's reservation in Del Norte and Humboldt Counties in California encompasses approximately 57,000 acres, bordered on the west by the Pacific Ocean, and consists of a strip of land extending a mile along each side of the Klamath River from just upstream of the confluence of the Klamath and Trinity Rivers about 50 miles inland.

1.3.1.6 Resighini Rancheria

The Resighini Rancheria is in Del Norte County, California, and encompasses 239 acres. The Resighini Rancheria is several miles inland from the mouth of the Klamath River and rests on the southern banks of the river, completely surrounded by the Yurok Reservation. It is primarily settled by Yurok Indians affiliated with the Yurok Coast Indian Community. A population of 36 was reported on Rancheria lands in the 2000 U.S. Census.

1.3.2 Early Euroamerican Settlement and Hydroelectric History

Before the influx of Euroamericans that began in the 1840s, the basin was settled by American Indians. Euroamerican exploration of the Klamath Basin began in the early 19th Century. The discovery of gold in California in 1848 prompted a dramatic influx of European immigrants to California and other areas, including the Klamath Basin. Euroamerican settlement in the Klamath River watershed continued throughout the 19th Century. Sustained logging enterprises appeared in the 1880s, and the first hydroelectric development in the Klamath Basin was established in 1891 in the Shasta River Canyon below Yreka Creek.

Envisioned in 1911, the Klamath Hydroelectric Project was built in phases, beginning with Copco 1 (1918), followed by Copco 2 (1925), J.C. Boyle (1958) and the Iron Gate facilities in 1962. The development of the Klamath Hydroelectric Project played a significant role in the area's economic development, both as part of a regionally significant, locally owned and operated private utility and through the role that increased electrical capacity played in the expansion of the timber, agriculture, and recreation industries during the 20th century.

Other historical developments have also influenced human uses of Klamath Basin resources. In 1906 the Bureau of Reclamation began constructing the Klamath Project, which converted wetlands to agricultural development and encouraged settlement of farmers in the Klamath Basin. Farmers in the Basin include off-project as well as project irrigators. In 1908 President Theodore Roosevelt established the Klamath Lake Reservation, the nation's first waterfowl refuge. The refuge, which was later renamed the Lower Klamath National Wildlife Refuge, is now part of a complex of refuges that

attracts wildlife viewers and waterfowl hunters. The commercial salmon fishery, which originated with gillnetters on California rivers in the early 1850s, was superseded by ocean trollers when the river fisheries were closed (in 1933 for the Klamath River). The ocean salmon fishery, which originated with a few fishermen operating from sailboats in Monterey Bay in the 1880s, expanded to northern California ports by 1916 due to changes such as the replacement of sails with gasoline engines. Ocean recreational fishing became popular with the development of the commercial passenger fishing vessel industry after World War II. The redband trout fishery in the Klamath Basin had become a renowned trophy fishery by 1920, and steelhead fishing on the Klamath River dates back to the early 1930s.

Multiple generations of farmers, fishermen and recreationalists have been a part of Klamath Basin and nearby coastal communities over the past century.

The text box below (p. 1-13) summarizes more detail of early settlement in the Klamath Basin and some of the effects of historic and current land and water use in the basin.

1.3.3 Water Use and Management

1.3.3.1 Water Management

Figure 1-2 presents a timeline for activities within the Klamath Basin that have resulted in current conditions. The timeline follows the development of several major institutions, Reclamation's Klamath Project, Oregon's Klamath Basin Adjudication, and PacifiCorp's Klamath Basin Hydroelectric Project and relicensing. Today these institutions influence the major water management decisions in the Klamath Basin and played a key role in the negotiations that eventually became the KHSA and KBRA.

1.3.4 Reclamation's Klamath Project

In addition to the Klamath Basin's distinctive setting, biological resources, and cultural history, the basin is also the site of one of the first developments authorized under the 1902 Reclamation Act (Public Law 57-161, 32 Stat. 388). Development and construction of Reclamation's Klamath Project took place between 1905 and 1966, with major features of the project completed by the early 1940s. As the largest water management effort in the Upper Klamath Basin, Reclamation's Klamath Project features include a system of reservoirs, dams, canals, and pumps (Figure 1-3), and use of Gerber Reservoir and Clear Lake to reduce flooding of lands in the Tule Lake area. The authorization for Reclamation's Klamath Project stated its purpose:

For project works to drain and reclaim lake bed lands of the Lower Klamath and Tule Lakes, to store water of the Klamath and Lost Rivers, including storage of water in Lower Klamath and Tule Lakes, to divert irrigation supplies, and to control flooding of the reclaimed lands.

History of Land- and Water-Use Changes in the Klamath Basin

When settlers of European descent first arrived in the Klamath Basin in the 1800s, there was a vast complex of 350,000 acres of lakes and wetlands, interconnected by sloughs and river channels. Many of these wetlands were attractive for farming if drained and a reliable source of irrigation could be developed. Construction of Reclamation's Klamath Project began in the early 1900s to facilitate farming. The Klamath Project, the largest water delivery system in the basin, now includes 7 dams, 18 canals, 45 pumping facilities, and over 500 miles of ditches to supply irrigation water to over 224,000 acres of agricultural lands (DOI 2010b). Upper Klamath Lake's outlet was modified with the construction of Link River Dam (completed in 1921) to allow more active storage of irrigation water for the Klamath Project.

Farms and ranches above Upper Klamath Lake, and on tributaries in the lower Klamath River (e.g., Scott, Shasta, and Trinity Rivers) use surface water supplies that are not part of the Klamath Project. In total, about 80 percent of the wetlands in the Klamath Basin were converted to farming and ranching activities (Atkins 1970, Natural Resources Conservation Service 2007 as referenced in Larson and Brush 2010). However, some of these wetlands were retained, like the Lower Klamath National Wildlife Refuge, by President Roosevelt in 1908, creating the first waterfowl refuge in the United States and providing critical habitat along the Pacific Flyway.

Economic development of natural resources changed conditions in the Klamath Basin over the past 100 years, including extensive basin-wide logging, gold mining in the lower river basin, and construction of a railroad causeway in the early 1900s that isolated and dried Lower Klamath Lake. Construction of four main-stem hydroelectric facilities on the middle part of the Klamath Basin between 1918 (Copco 1 Dam) and 1962 (Iron Gate Dam) blocked the passage of migrating salmon and steelhead to the Upper Basin and represents that last major hydrologic modification in the basin.

The combination of these changes have contributed to significant loss of fish habitat, degradation of water quality, and declining fish populations -- especially for salmon and two endangered sucker species (shortnose and Lost River suckers). Hydrologic alterations, including water diversions, wetland losses, declining water quality, and dam construction are among the most significant land- and water-use changes in the Klamath Basin.

Land use patterns in the Klamath Basin will continue to reflect the value of natural resources in providing economic gain for local communities and the Nation. Returning to conditions seen in the 1800's is unrealistic; however, there are numerous opportunities to substantially improve fisheries, wildlife habitat, and water quality conditions in the Klamath Basin and reverse the pattern of environmental problems in the Klamath Basin.

Klamath Facilities Removal
Final EIS/EIR

Figure 1-2a. Klamath Basin Timeline Since 1905.

Figure 1-2b. Klamath Basin Timeline Since 1905.

Klamath Facilities Removal
Final EIS/EIR

Figure 1-3. Reclamation's Klamath Project.

Reclamation’s Klamath Project was originally authorized at a time when an increasing number of farmers were drawn to the fertile land in northern California and southern Oregon. Development of Reclamation’s Klamath Project converted much of the Tule Lake and Lower Klamath Lake wetland complexes into farmland.

The first dams constructed for Reclamation’s Klamath Project included Clear Lake Dam (1910), Lost River Diversion Dam (1912), and Lower Lost River Diversion Dam (1921). Also in 1921, the completion of Link River Dam, executed through a contract between PacifiCorp and the United States, allowed for additional water management in the Upper Klamath Basin. This included greater storage in Upper Klamath Lake, water releases reflecting natural conditions, and controlled releases from the lake to provide a source of irrigation water. The agreement between the power company and the government allowed for PacifiCorp to operate the dam for hydropower production, and in return, the company was to supply low-cost electricity to Reclamation and farmers in the region.

Today, Reclamation’s Klamath Project irrigates up to 224,000 acres of land on which farmers grow wheat, malt barley, potatoes, onions, alfalfa, and other crops (DOI 2010b). Reclamation’s Klamath Project also provides recreational opportunities for boating, water skiing, hunting, fishing, camping, and picnicking. In addition, the Klamath Basin National Wildlife Refuge System usually receives water from the operation of Reclamation’s Klamath Project for the benefit of waterfowl and other species.

Reclamation’s Klamath Project, with the exception of Clear Lake, does not include multi-year water storage facilities. Upper Klamath Lake represents most of its storage, but the lake is shallow, with an average depth of approximately 9 feet when full (Wood et al. 2006). Upper Klamath Lake can only provide small opportunities for carryover storage between years; therefore, Reclamation’s Klamath Project operations are dependent on the amount of annual precipitation. During wet years, Reclamation’s Klamath Project irrigators typically receive full contract deliveries of water. In the past few decades, however, Klamath Project irrigators and refuge managers have not always had their requests for water met during drought years because of the need to conserve water for fish in the Klamath River downstream from Iron Gate Dam and in Upper Klamath Lake.

Keno Dam (constructed in 1966 by PacifiCorp) also plays an important role in regulating water elevations in Keno Impoundment/Lake Ewauna for the gravity operation of irrigation canals. Keno Dam is owned by PacifiCorp and is not part of Reclamation’s Klamath Project.

1.3.5 Oregon Water Rights Adjudication

If an appropriation of water was initiated prior to the enactment of the Oregon Water Rights Adjudication 1909 water code and has not been forfeited or abandoned since then, a water user may have a “vested” water right. Federal reserved water rights vest no later than the date of the reservation, and as early as “time immemorial,” regardless of whether they have been used. A claim to a vested water right is quantified and made a matter of record through an adjudication proceeding. The Oregon Water Resources Department

(OWRD) is responsible for gathering information about the use of water and presenting its findings to the County Circuit Court. This circuit court is responsible for resolution and issues a decree that states who has the right to use water, the amount and location of water use, and the priority date. A water right certificate is issued for each decreed right (State of Oregon 2009).

The Klamath Basin Adjudication is the adjudication process for pre-1909 and Federal reserved water right claims for the use of surface water within the Klamath Basin. The Klamath Basin proceeding began in 1975. Claims of water use have been gathered and contests have been filed on most of those claims. Administrative law judges have been holding hearings and issuing proposed orders determining the claims and contests. The OWRD will review those proposed orders, and any proposed settlements of contests, and submit its Findings and Order of Determination to the Circuit Court in December 2012. Water right claims have been filed by private water users, The Klamath Tribes, Klamath allottees, and the United States (the Klamath Project and for Indian and other Federal reservations of land). Once OWRD's findings are submitted to court there will be an opportunity for parties to file exceptions to those findings. The Klamath Circuit Court will resolve the exceptions and issue a decree. As of July 2010, 97 percent of contests and 92 percent of the claims in the Klamath have reached a proposed resolution, either by issuance of an administrative law judge's proposed order or by a proposed settlement of contests (State of Oregon 2010).

1.3.6 Klamath Hydroelectric Project and Relicensing

1.3.6.1 Klamath Hydroelectric Project

Constructed between 1911 and 1962, the Klamath Hydroelectric Project includes eight facilities: Iron Gate, Copco 1, Copco 2, J.C. Boyle, Fall Creek, and Keno Dams, and the East and Westside developments. The portion of the Klamath River that includes the four most downstream dams is referred to as the Klamath Hydroelectric Reach. Keno Dam was originally constructed to produce power, but hydropower facilities were never developed (PacifiCorp 2004b) and it currently has no generating facilities. Its primary purpose is to maintain water levels in Keno Impoundment/Lake Ewauna for gravity delivery of water into irrigation canals. Link River Dam was constructed for Reclamation's Klamath Project. Link River Dam is operated under Reclamation direction for regulating flows, storing water in Upper Klamath Lake, and hydropower production through the PacifiCorp's East and Westside powerhouses.

The purpose of the PacifiCorp Klamath Hydroelectric Project is power generation. In addition, the Four Facilities provide mid to late summer whitewater boating on the Hells Corner Reach as a result of hydropower peaking operations and other recreation opportunities at the existing reservoirs and associated facilities. PacifiCorp's total annual generation from the Klamath Hydroelectric Project is 716,800 megawatt-hours of electricity (FERC 2007). These dams were not designed to provide downstream flood protection or to provide water storage for drought relief (FERC 2007). The J.C. Boyle,

Copco 1, and Copco 2 facilities are hydro peaking⁵ operations and Iron Gate Dam is operated as a re-regulating facility, so that on a daily basis roughly as much water enters the Hydroelectric Reach as leaves the Hydroelectric Reach. Chapter 2 presents additional information about the physical characteristics of the Four Facilities.

1.3.6.2 Federal Energy Regulatory Commission Relicensing

The Klamath Hydroelectric Project is regulated by FERC. The original 1956 license for these dams expired in 2006. The dams have been operating under annual licenses since the original license expired. The annual license specifies the same conditions as the original license. The 1956 PacifiCorp license pre-dated environmental laws, and did not include prescriptions (Section 18 of the Federal Power Act [16 USC 811]) for fish passage over or around the dams; only J.C. Boyle Dam has fish passage facilities, but these fishways do not meet current criteria (Administrative Law Judge 2006).

On February 24, 2004, PacifiCorp filed an application with FERC for a new operating license for the Klamath Hydroelectric Project. FERC prepared a Final EIS for relicensing the project, but no license has been issued. Currently, the relicensing proceeding remains active. Until a decision is made regarding its license application, PacifiCorp will continue to operate the dams under annual licenses from FERC.

As part of the process for the 2004 relicensing application, a variety of stakeholders (individuals, Indian Tribes, fishing interests, and conservation groups) expressed a strong desire that the four hydroelectric dams be decommissioned and removed to address declining fisheries in the lower Klamath River and reopen approximately 43 miles of blocked mainstem river habitat between Iron Gate and Keno Dams and hundreds of miles of stream habitat in Upper Klamath Basin tributaries. Fish considerations were a major subject during the relicensing process.

The National Oceanic and Atmospheric Administration (NOAA) Fisheries Service recommended to FERC under Federal Power Act Section 10(a) removal of the Four Facilities as the best alternative to contribute to restoration of all fish species of concern in the Klamath watershed. Concurrently under Section 18 authority of the Federal Power Act, NOAA Fisheries Service (the Secretary of Commerce's authority under the FPA has been delegated to the NOAA Fisheries Service) and DOI prescribed mandatory fishways and passage at each mainstem dam. Flows were conditioned from J. C. Boyle for riparian habitat, whitewater recreation, and attraction flows for fish passage by DOI under Section 4(e) authority. The fishway prescriptions by the NOAA Fisheries Service and the DOI were strongly supported by basin tribes, fishing interests, and conservation groups to address declining fisheries in the lower Klamath River and to reopen blocked habitat. The fishway prescriptions and the DOI's conditions were challenged by PacifiCorp and others under the Energy Policy Act of 2005, in a trial-type hearing that considered disputed issues of material fact relating to the prescriptions and conditions. The resulting Administrative Law Judge decision (*In the Matter of: Klamath Hydroelectric Project*, Docket Number 2006-NMFS-0001, September 27, 2006) found that PacifiCorp failed to

⁵ Peaking: operation of a hydropower projects to meet peak electrical demands.

meet its burden of proof regarding most of the factual issues in dispute. FERC conducted environmental analysis of the proposed project, including the mandatory terms and conditions and prescriptions in 2007. However, the FERC relicensing proceedings are still active; accordingly, the mandatory terms and conditions and fishway prescriptions, and the terms of Biological Opinions issued by the USFWS and NOAA Fisheries Service to FERC for the new license, have not been incorporated as terms of the Klamath Hydroelectric Project license.

Before FERC relicenses the Klamath Hydroelectric Project, the states of Oregon and California must also issue water quality certification under Section 401 of the Clean Water Act. The California State Water Resources Control Board (SWRCB) cannot issue certification until environmental documentation, consistent with the requirements of the CEQA, is completed. The certification proceedings are currently being held in abeyance as requested in Section 6.5 of the KHSA. The SWRCB held a hearing on July 7, 2012, on this matter. The SWRCB decided to continue holding the certification in abeyance, however, SWRCB then noted they could not continue to do so indefinitely. In a February 2009 letter addressing their CEQA Notice of Preparation, the agency noted that failing to process the water quality certification in a timely manner risks a FERC determination that the Board has waived of certification, and the State of California would have no regulatory authority to address water quality issues associated with the Klamath Hydroelectric Project during the FERC relicensing.

1.4 KHSA and KBRA

The KHSA was an outcome of the FERC's Alternative Dispute Resolution Procedures (18 CFR 385.601, et seq.) wherein the parties elected to set aside differences to reach resolution on a settlement that is in furtherance of the interests of all of the parties. As established in Section 1.2 of the KHSA, many of the parties to the settlement maintain that removal will help restore basin resources and all signatory parties agree that settlement is in the public interest. As also specified in the KHSA, and in compliance with applicable law, the Secretary is undertaking a scientific and environmental analysis of potential facilities removal, and connected actions under the KBRA. The Secretary acknowledges that full implementation of the KHSA will depend on factors not entirely within the control of the settling parties and that failure to implement the KHSA, like any proposed settlement, could lead to a resumption of the underlying new licensing proceeding for the Klamath Hydroelectric Project that is pending before the FERC. As a consequence, should the FERC proceeding resume for any reason, we want to remind the reader that the analysis in this EIS/EIR was undertaken pursuant to the KHSA for the purpose of implementation of this settlement and to inform the Secretary in his determination under the KHSA regarding dam removal. This analysis and its comparison of alternatives is being conducted pursuant to NEPA and CEQA and solely in support of the determination to be made by the Secretary pursuant to the KHSA, a negotiated settlement agreement. It is not prepared to inform any other determinations made or environmental documents prepared pursuant to NEPA or CEQA outside the KHSA framework, including FERC's determination in the Klamath Hydroelectric Project

licensing proceeding, which is to determine whether, and if so, under what conditions, to issue a new license for the Klamath Hydroelectric Project, or the States’ determinations including whether, and under what conditions, to issue a Section 401 water quality certification for the Klamath Hydroelectric Project and associated environmental documents.

Negotiations leading to the KBRA began in 2005 after the water-related farming and fisheries crises in 2001 and 2002. The negotiation process also coincided with PacifiCorp’s 2004 relicensing application. The proposed KBRA was released in January 2008. The KHSA and KBRA are negotiated agreements and reflect the cooperative effort by more than 40 parties in the basin, representing different interest groups. The agreements were negotiated and written to be executed together and are referred to herein as the Klamath Settlement. Representatives of Federal agencies, the states of California and Oregon, Indian Tribes, counties, farmers, and conservation and fishing groups agreed to the comprehensive solutions presented in the KHSA and KBRA.⁶

1.4.1 KHSA

The KHSA establishes the process for additional studies, including the development of a “Detailed Plan for Facilities Removal” (Detailed Plan) and environmental review to support the Secretary’s Determination as to whether removal of the four downstream-most dams on the Klamath River that are owned by PacifiCorp (1) will advance restoration of the salmonid fisheries of the basin, and (2) is

From the KHSA...

“By March 31, 2012, the Secretary shall use best efforts to (i) determine whether the costs of Facilities Removal as estimated in the Detailed Plan, including the cost of insurance, performance bond, or similar measures, will not exceed the State Cost Cap, and (ii) otherwise complete his determination whether to proceed with Facilities Removal as described in Section 3.3.1, provided that any such determination shall not be made until the following conditions have been satisfied:

- A. Federal legislation, which in the judgment of the Secretary is materially consistent with Appendix E, has been enacted;
- B. The Secretary and PacifiCorp have agreed upon acceptable terms of transfer of the Keno facility pursuant to Section 7.5.2;
- C. The States of Oregon and California have authorized funding for Facilities Removal as set forth in Section 4 of this Settlement;
- D. The Parties have developed a plan to address the excess costs, consistent with Section 4.10 of the Settlement, if the estimate of costs prepared as part of the Detailed Plan (including the cost of insurance, performance bond, or similar measures) shows that there is a reasonable likelihood such costs are likely to exceed the State Cost Cap; and
- E. The Secretary has identified a DRE¹-designate, and, if the DRE-designate is a non-Federal entity: (i) the Secretary has found that the DRE-designate is qualified; (ii) the States have concurred in such finding; the (iii) the DRE-designate has committed, if so designated, to perform Facilities Removal within the State Cost Cap (KHSA Section 3.3.4).”

¹ DRE: Dam Removal Entity

⁶ Although representatives of the Federal agencies participated in negotiations for both the KHSA and the KBRA, Federal agencies did not sign the KBRA.

in the public interest, which includes, but is not limited to, consideration of the potential impacts on affected local communities and Indian Tribes.

The KHSA also includes provisions for the interim operation of the Four Facilities by PacifiCorp and the process to transfer, decommission, and remove the dams.

1.4.1.1 Detailed Plan and Other Studies

The Parties⁷ to the KHSA agreed further studies were needed to determine if the actions specified under the KHSA were feasible. These studies include analysis of the regional impacts of both the KHSA and the KBRA on water quality, economics, real estate, recreation, and biology. The findings of these studies are summarized in the *Final Klamath Dam Removal Overview Report for the Secretary of the Interior – an Assessment of Science and Technical Information* (DOI and DOC [NOAA Fisheries Service] 2012).

In addition, the Secretary's Determination and concurrence from the states will also be based, in part, on a Detailed Plan that describes the following:

- Physical methods to remove the dams and achieve a free-flowing condition.
- As necessary and appropriate, plans for management, removal, and/or disposal of sediment, debris, and other materials.
- A plan for site remediation and restoration.
- A plan for measures to avoid or minimize adverse downstream impacts.
- A plan for compliance with all Applicable Laws, including anticipated permits and permit conditions.
- Estimated costs.
- A statement of measures to reduce risks of cost overruns, delays, or other impediments to Facilities Removal.
- The identification, qualifications, management, and oversight of a non-Federal Dam Removal Entity (DRE), if any, that the Secretary may designate.

The Overview Report, Detailed Plan, and other studies produced as part of the Secretarial Determination process are available online at: www.klamathrestoration.gov.

1.4.1.2 State Cost Cap

The KHSA sets a cost cap of \$450 million for removal of the Four Facilities. In addition, pending regulatory approval, the KHSA allows for PacifiCorp to recover the costs of the company's net investment in the facilities, the ongoing operating costs, and the costs of replacement power. The \$450 million would come from the State of California and PacifiCorp's ratepayers. Specifically, an amount not to exceed \$200 million would come from additional charges to PacifiCorp customers (residing in either state) and \$250 million from the sale of California bonds or other means at the discretion of California. The United States would not be responsible for the costs of facilities removal.

⁷ Parties: Signatories to the Klamath Hydroelectric Settlement Agreement.

1.4.1.3 Secretarial Determination

The KHSA establishes a process for the Secretarial Determination. This process also includes decisions by the States of Oregon and California as to whether they concur with the Secretarial Determination. Implementation of the KHSA requires both Federal legislation and for the Secretary to make a determination, in cooperation with the Secretary of Commerce and other Federal agencies as appropriate, regarding facilities removal, particularly whether, in his judgment, the conditions of the KHSA have been satisfied, and whether facilities removal should proceed. This process includes existing and additional studies, environmental review, and the decision by the Secretary.

1.4.1.3.1 Affirmative Determination

If the Secretary finds that the removal of the facilities would advance restoration of the salmonid fisheries and is in the public interest, an Affirmation Determination, as defined under Section 3 of the KHSA, can be made. Once the Secretary has made an Affirmation Determination, California and Oregon would also provide notice to the Secretary and other parties within 60 days on whether each State concurs with the Affirmative Determination. The KHSA provides for each State to consider two factors when deciding to concur or not: 1) whether significant impacts identified in its environmental review can be avoided or mitigated as provided under its State law, and 2) whether facilities removal will be completed within the State cost cap (defined as the collective maximum monetary contribution from the states of California and Oregon, described below and in Section 4.1.3 of the KHSA).

As part of an Affirmative Determination, the Secretary will also concurrently designate the entity that will serve as the DRE. The DRE, once identified, would develop a Definite Plan for Facilities Removal which would include all the information necessary to implement the Detailed Plan as well as the additional elements listed in KHSA Section 7.2.A. The Secretary must consult with the Parties to the KHSA prior to designating a non-Federal DRE and receive concurrence from the states with that selection.

In addition to the decommissioning and removal of the Four Facilities, actions associated with an Affirmative Determination would include the transfer of Keno Dam ownership from PacifiCorp to DOI, which is analyzed as a connected action in this EIS/EIR.

1.4.1.3.2 Negative Determination

If the Secretary determines not to proceed with facilities removal, the KHSA terminates unless the Parties can agree to a remedy for the issues leading to the Negative Determination.⁸ Prior to adopting or public release of such a determination, the Secretary would notify the Parties of the tentative determination and its basis. The Parties would consider whether to amend the KHSA in a manner that would permit the Secretary to make an Affirmative Determination.

⁸ Negative Determination: A determination by the Secretary of the Interior under Section 3 of the Klamath Hydroelectric Settlement Agreement that facilities removal should not proceed.

1.4.1.4 KHSA Implementation

If an Affirmative Determination is made, PacifiCorp would transfer ownership of each facility when the DRE provides notice that all necessary permits and approvals have been obtained for removal of a facility, all contracts necessary for facility removal have been finalized, and facility removal is ready to commence. After the transfer, the DRE would remove the facilities. The target date to begin deconstruction is January 1, 2020.

1.4.1.4.1 Local Power

Section 5 of the KHSA includes terms for collaborative efforts between PacifiCorp and the Parties to identify potential ways to reduce impacts of dam removal on local community power. However, the KHSA does not provide for specifics on this collaborative effort, and therefore is not included in the analysis presented in this EIS/EIR. For further information see Section 5 of the KHSA.

1.4.1.4.2 KHSA Interim Measures

The KHSA includes interim measures for the operation of the Klamath Hydroelectric Project by PacifiCorp from the effective date of the agreement (February 18, 2010) or as otherwise specified for each interim measure. If the Secretary makes an Affirmative Determination, PacifiCorp would continue to perform the interim measures until decommissioning. If there is a Negative Determination or the KHSA terminates for other reasons prior to decommissioning, then the interim measures may generally cease, except for the purposes of the Clean Water Act or the ESA. These measures include the implementation of measures included as part of PacifiCorp's Interim Conservation Plan (ICP).⁹ Measures from the ICP (see Appendix C of the KHSA) are included in the Habitat Conservation Plan (HCP). The HCP requires PacifiCorp to fund projects to enhance the survival and recovery of ESA-listed coho salmon, turbine venting to improve dissolved oxygen concentrations downstream from Iron Gate Dam, funding for the development and implementation of a Hatchery Genetics Management Plan for Iron Gate Hatchery, increased flow variability at Iron Gate Dam, and studies on fish disease. On March 13, 2012, NOAA Fisheries Service issued an Incidental Take Permit (ITP) that authorizes potential take associated with Klamath Hydroelectric Project operations and Interim Measure implementation. Under the ITP, PacifiCorp is required to implement a HCP that contains measures to minimize and mitigate Project effects on coho salmon. The HCP was developed by PacifiCorp over a period of several years with involvement from NOAA Fisheries Service, CDFG, and other stakeholders in the basin. The HCP, ITP, and supporting documents are available at <http://swr.nmfs.noaa.gov/nepa.htm>.

Appendix D of the KHSA provides additional measures to be implemented during the interim period. These measures include funding restoration activities, increasing monitoring activities, removing the J.C. Boyle bypass barrier, funding water quality research, funding to the Bureau of Land Management for the land management measures

⁹ As described in the KHSA, the Interim Conservation Plan was developed by PacifiCorp through technical discussions with the NOAA Fisheries Service and the USFWS describing measures for the enhancement of coho salmon and suckers listed under the ESA (see KHSA Appendix A). The Interim Conservation Plan was submitted to FERC on November 25, 2008 and can be found online through the FERC Web site (<http://ferc.gov>).

in Appendix C of the KHSA, possibly removing three diversions on Shovel and Negro Creeks, and funding for Iron Gate Hatchery operations and maintenance (including funding for an 8-year period after removal of Iron Gate Dam).

1.4.1.4.3 City of Yreka Water Supply

The City of Yreka has a municipal water supply intake on Fall Creek and a pipeline that crosses Iron Gate Reservoir; the pipeline would be affected if the Iron Gate Dam were removed. The KHSA addresses the possible impacts that facilities removal would have on the water supply pipeline for the City of Yreka and provides provisions for mitigation of impacts on this supply system. Signatories agree not to prevent use of the City of Yreka's Water Rights permit and will study the potential risks to the water supply system from facilities removal. Necessary actions for the continued use of the City of Yreka water supply infrastructure would be funded and implemented as part of implementation of the KHSA (Section 7.2.3).

1.4.1.4.4 Keno Facilities Transfer

The KHSA calls for transferring ownership and operation of Keno Dam from PacifiCorp to DOI. The Secretary and PacifiCorp are studying the proposed transfer of Keno facilities (the Keno Transfer). An Affirmative Determination by the Secretary depends on an agreement between the Secretary and PacifiCorp on terms for transfer of title of the Keno facility. Further, transfer of title shall be subject to completion of any necessary improvements to the facility to meet DOI directives and standards for dam safety identified by the DOI through its safety of dams inspection of the Keno facility. This EIS/EIR will analyze the impacts associated with the Keno Transfer as a connected action.

1.4.1.4.5 East and Westside Powerhouse Decommissioning

PacifiCorp's East and Westside facilities were proposed for decommissioning in PacifiCorp's 2004 relicensing application, and their decommissioning through the FERC process is described in the KHSA (KHSA 6.4.1(B)). Removing the two facilities would result in the loss of 3.8 megawatts of generating capacity and the removal of the generating infrastructure. The dams and associated infrastructure were built in 1921, and would require upgrading and maintenance to remain in compliance with DOI and FERC standards. This would include the installation of fish screens, which would require major construction changes and associated maintenance. The Link River Dam, which is the point of diversion for the two generating facilities, is already owned by Reclamation.

As noted above, the East and Westside facilities decommissioning would be carried out through application to the FERC. FERC will conduct any necessary environmental analysis and make a FERC determination. This EIS/EIR uses a programmatic analysis to evaluate the impacts associated with the East and Westside facilities decommissioning as a connected action.

1.4.2 KBRA

As a result of the Klamath Basin issues surrounding the limited availability of water to support agricultural, tribal, environmental, and fishery needs in many years, the United States;¹⁰ the States of California and Oregon; the Klamath, Karuk, and Yurok Tribes; Reclamation's Klamath Project Water Users; and other Klamath Basin stakeholders (collectively the Parties) negotiated the KBRA to resolve the water conflicts among the many users, restore stressed fisheries, and identify reliable power supplies. The KBRA is intended to result in effective and durable solutions. The goals of the KBRA are to (1) restore and sustain natural fish production and provide for full participation in ocean and river harvest opportunities of fish species throughout the Klamath Basin; (2) establish more reliable water and power supplies which sustain agricultural uses, communities, and NWRs; and (3) contribute to the public welfare and the sustainability of all Klamath Basin communities. The Parties view these agreements as an important part of the resolution of long-standing, complex, and difficult-to-resolve concerns over resources in the Klamath Basin.

Negotiations leading to the KBRA began in 2005 after the water-related farming and fisheries crises occurred in 2001 and 2002. The negotiation process also coincided with PacifiCorp's 2004 relicensing application. The proposed KBRA was released in January 2008. The KBRA includes plans and programs that interrelate with each other and with facilities removal as contemplated by the KHSAs, and is intended to benefit fish throughout the basin, water users in the Upper Klamath Basin, and the community overall. The KBRA brings many parties together, including Federal and State agencies, Indian Tribes, Reclamation's Klamath Project irrigators, and on- and off-Project water users to support one another's efforts to restore fish populations in the Klamath Basin and provide for sustainable communities with a strong agricultural base. The KBRA has required each party to make some concessions in order to secure assurances on other important interests. These compromises include:

- Through the agreement, the Klamath, Karuk, and Yurok Tribes, the signatory Indian Tribes, have agreed to water rights assurances as defined in KBRA Section 15.3. Under the KBRA, the tribes would benefit from a suite of fisheries restoration and reintroduction measures that would complement dam removal pursuant to the KHSAs, improvements in water quantity and quality in the lakes and rivers of the basin, and other habitat improvements that would support a sustainable fishery throughout the basin.
- Representative organizations of water users and irrigators, both on-Project and off-Project, agreed to limit their water diversions in exchange for increased Representative organizations of water users and irrigators, both on-Project and off-Project, agreed to limit their water diversions in exchange for increased

¹⁰ Agencies involved in KBRA negotiations include: NOAA Fisheries Service, U.S. Forest Service, U.S. Department of the Interior (including, the Bureau of Indian Affairs, Bureau of Land Management, Bureau of Reclamation, and Fish and Wildlife Service).

predictability about seasonal water deliveries and affordable power supplies.¹¹ Increased predictability allows individual landowners to more efficiently plan annual operations and avoid the economic impacts that result from uncertainty. The economic impacts felt at the individual level ripple up through the whole community, so this increased certainty benefits everyone. As reintroductions of currently threatened and endangered fish species are successfully implemented, the KBRA envisions that landowners will benefit from regulatory assurances (under the ESA¹²) that their operations would not be additionally burdened by new regulatory restrictions to the extent legally possible.

Under this system of compromises, the question of who “goes first” becomes critical. Some of the provisions in the agreement may take over 10 years to be implemented and many of the proposed actions need to be started in good faith. The KBRA establishes a framework for interim actions and planning efforts that would involve the broader community and protect the Parties’ interests during the interim period. The interim period is the time between the signing of the KBRA and full implementation of the limits on water diversions to Reclamation’s Klamath Project. The plans and programs described in the KBRA lead through a series of milestones that culminate in the formal relinquishment of claims for damages, permanent assurances related to tribal water rights, and limitations on water diversions to Reclamation’s Klamath Project.

An Affirmative Determination and Federal authorizing legislation are two early key milestones towards full implementation of the KBRA. Following an Affirmative Determination, the key milestones leading to the publication of a Secretarial Notice, which make Federal water assurances permanent and is a prerequisite to other water rights assurances and diversion limitations, are described below:

- 1) “The application deadline under Section 15.3.8.A for full implementation of the On-Project Plan has passed.
- 2) The required environmental analysis regarding the proposed project to reconnect the Wood River Wetlands to Upper Klamath Lake as described in Section 18.2.3 is completed, and any necessary funding to implement the preferred alternative of the required environmental analysis is authorized by Congress or that funding is otherwise committed by State, local, tribal, or private sources.
- 3) The required environmental analysis regarding the proposed project to reconnect Agency Lake and Barnes Ranches to Upper Klamath Lake as described in Section 18.2.2.C is completed, and any necessary funding to implement the preferred alternative of the required environmental analysis is authorized by Congress or that funding is otherwise committed by state, local, tribal or private sources.

¹¹ Off-project water users may also be eligible for affordable power benefits without reducing their surface water diversions, if other criteria are met (See KBRA § 17.3.2.C).

¹² These regulatory assurances do not apply to the Clean Water Act, the Porter-Cologne Water Quality Control Act, or to any other authorities beyond the Endangered Species Act.

- 4) Funding has been authorized for the Water Use Retirement Program described in Section 16.2.2.
- 5) The physical removal of all or part of each of the Hydroelectric Facilities has occurred and achieved a free-flowing condition and volitional fish passage.” (KBRA Section 15.3.4.A).

Once the Federal and tribal water rights assurances have been made permanent, the diversion limits on Reclamation’s Klamath Project, including a Refuge Allocation, would become permanent.

The Federal Lead Agency is analyzing the KBRA as a connected action. NEPA defines connected actions as those actions that are closely related or cannot or will not proceed unless other actions are taken previously or simultaneously (40 Code of Federal Regulations (CFR) 1508.25(a)(1)(ii)).¹³ Some actions or component elements of the KBRA are independent obligations and thus have independent utility from the KHSA, but the implementation of several significant elements of the KBRA package would be different, if the determination under the KHSA is not to pursue full dam removal (see Table 1-1). Recognizing that implementation of many elements of the KBRA is unknown and not reasonably foreseeable at this time, the connected action analysis is being undertaken at a programmatic level. Consequently, appropriate NEPA compliance will be completed for the KBRA in the future. The KBRA and KHSA are available in their entirety from the Web site <http://klamathrestoration.gov/>. The updated table of KBRA programs (since February 2010) is available at: <http://216.119.96.156/Klamath/2011/06/RevisedCostEstimates.pdf>.

Table 1-1. Linkage of KBRA Programs, Plans, Commitments to Dam Removal¹

Program, Plan, or Commitment	Linked to Dam Removal and Secretarial Determination	KBRA Programs Included in this analysis as a Connected Actions under NEPA
Fisheries Programs:		
Fish Habitat Restoration Activities	T	
Fisheries Restoration Phase I Plan	T

Fisheries Monitoring Plan	T	
Additional Water Storage Projects:		X
Williamson River Delta Project		X

¹³ We acknowledge, however, that the actions that constitute KBRA could also be analyzed as cumulative or similar actions under 40 CFR 1508.25(a)(2) and (3). We note that all three definitions (connected action, cumulative actions, and similar actions) are within the section that provides parameters for the “scope” of the action, which determines both the range of alternatives and the impacts to be considered in an EIS. Ultimately, however, we believe the important point is not the labeling but the analysis and whether the decision (in this case, whether to remove four dams) is informed by an EIS that is proper in scope.

Notes

T means timing is related to dam removal or Secretarial Determination

O means other relationship to dam removal or Secretarial Determination through funding or other key milestones described in the KBRA

X means this Program, Plan, or Commitment is considered a connected action under NEPA for this analysis

1 As explained above, for purposes of this EIS/EIR, we have determined that the KBRA should be evaluated in its entirety as a connected action. The purpose of this table is to show those individual activities under the KBRA that are not linked to the removal of the Four Facilities in order to provide an understanding of the potential effect to the KBRA in the absence of facilities removal. It shows those individual KBRA activities that are expressly linked to removal of the Four Facilities and those individual activities under the KBRA that are not linked to facilities removal. In the absence of facilities removal these activities may still proceed independently but the KBRA will not include all of the components present in its current form and some activities could be substantially altered or even avoided by parties who seek dam removal as a primary pre-condition for the commencement of their obligations. While we have decided to analyze the KBRA in its entirety as a connected action, we believe it also appropriate to show the relationship to dam removal of each of its component parts.

1.5 NEPA/CEQA

1.5.1 NEPA/CEQA Requirements

This document is a joint EIS/EIR, developed to satisfy the requirements of both NEPA and CEQA by disclosing to decisionmakers and the public, significant environmental impacts of the Proposed Action, identifying feasible mitigation measures, and describing a reasonable range of alternatives prior to rendering any final decisions or issuing any permits, agreements, or authorizations on the Proposed Action or alternative. For the purposes of NEPA/CEQA analysis, the Proposed Action is to remove the four lower PacifiCorp dams on the Klamath River. As explained in Section 1.3.2, the KBRA and other actions are being discussed programmatically as actions connected to the Proposed Action. CDFG recognizes that additional environmental analysis may be required by any California public entity with an approval or permitting obligation if required by CEQA.

In general the period of analysis for this EIS/EIR extends, where possible, for 50 years through 2061. Certain contractual commitments in the KBRA extend beyond 50 years or are perpetual. Certain effects of actions as well as contract commitments in the KBRA and KHSAs are expected to extend beyond 50 years. (See, for example, KBRA §§ 15.3.10).

This EIS/EIR has been prepared by the DOI, as lead NEPA agency, and the CDFG, as lead CEQA agency (collectively referred to herein as the Lead Agencies). Recognizing that elements of the Proposed Action would occur in California and Oregon, CDFG collaborated with DOI, with input from the State of Oregon, to make a reasonable, good faith effort in disclosing all significant environmental effects of the Proposed Action and the alternatives. Absent certain circumstances, CEQA does not apply to any project or portion thereof located outside of California which will be subject to environmental review pursuant to NEPA (Public Resources Code § 21080(b)(14); CEQA Guidelines § 15277).

NEPA requires the lead Federal agency to request the participation of other government agencies or Indian Tribes with jurisdiction by law or special expertise, collectively referred to as Cooperating Agencies. Table 1-2 lists the governmental entities and Indian Tribes that have agreed to be Cooperating Agencies in the preparation of the EIS/EIR.

CEQA requires a Lead Agency to identify a list of agencies that are expected to use the EIR in their decisionmaking. For the Proposed Action, CDFG anticipates that the California Coastal Commission, The SWRCB and the California North Coast Regional Water Quality Control Board (CNCRWQCB) will use this EIS/EIR in their decisionmaking.

Table 1-2. Cooperating Agencies

Agency/Entity
National Oceanic and Atmospheric Administration Fisheries Service
U.S. Forest Service
U.S. Environmental Protection Agency
Karuk Tribe
The Klamath Tribes
Quartz Valley Indian Community
Resighini Rancheria
Yurok Tribe
Hoopla Valley Tribe
Humboldt County
Trinity County
California State Water Resources Control Board
California North Coast Regional Water Quality Control Board
Oregon Department of Environmental Quality
Oregon Department of State Lands
Oregon Department of Fish and Wildlife
Oregon Water Resources Division
Klamath River Compact Commission
Klamath Water and Power Authority

Note: DOI is the Lead Agency under NEPA for this EIS/EIR, and although several agencies under the DOI have assisted with EIS/EIR development, including BLM, BIA, BOR, USGS, and USFWS, these agencies have not been included as separate Cooperating Agencies under NEPA. For the list of preparers of this EIS/EIR, please see Chapter 8.

1.5.2 Purpose and Need/Project Objectives

1.5.2.1 Purpose and Need

The stated Purpose and Need statement below has changed since the publication of the Notice of Intent in order to provide further clarification. These changes are not substantive and do not change any alternatives.

The Proposed Action is to remove the four lower PacifiCorp dams on the Klamath River. The need for the Proposed Action is to advance restoration of the salmonid fisheries in the Klamath Basin consistent with the KHSA and the connected KBRA. The purpose is to achieve a free flowing river condition and full volitional fish passage as well as other goals expressed in the KHSA and KBRA. By the terms of the KHSA, the Secretary will determine whether the Proposed Action is appropriate and should proceed. In making this determination, the Secretary will consider whether removal of the Four Facilities will advance the restoration of the salmonid fisheries of the Klamath Basin, and is in the public interest, which includes but is not limited to consideration of potential impacts on affected local communities and Tribes.

1.5.2.2 Project Objectives

This EIR is prepared in accordance with the CEQA, Public Resources Code Section 21000 et seq., to evaluate the potential environmental impacts associated with the implementation of the KHSA and KBRA to inform decisionmakers, including the Governor of the State of California, representatives of affected and responsible agencies, the public, and other interested parties of the potential environmental effects that may result from implementation of the Agreements as proposed. This EIR describes potential impacts relating to a wide variety of environmental issues and methods by which these impacts can be mitigated or avoided.

As required by CEQA, a Lead Agency must identify the objectives sought by the proposed project. For this project, CDFG as Lead Agency has identified the following objectives:

1. Advance restoration of the salmonid fisheries in the Klamath Basin.
2. Restore and sustain natural production of fish species throughout the Klamath Basin in part by restoring access to habitat currently upstream of impassable dams.
3. Provide for full participation in harvest opportunities for sport, commercial, and tribal fisheries.
4. Establish reliable water and power supplies, which sustain agricultural uses and communities and NWRs.
5. Improve long-term water quality conditions consistent with designated beneficial uses.
6. Contribute to the public welfare and the sustainability of Klamath Basin communities.
7. To be consistent with the goals and objectives of KHSA and KBRA.

1.5.3 Oregon Concurrence

The State of Oregon, and more specifically the “Klamath Team” consisting of OWRD, Oregon Department of Fish and Wildlife, and Oregon Department of Environmental Quality, will follow a distinct process for determining concurrence with an Affirmative Determination by the Secretary of Interior (as defined pursuant to Executive Order No. 10-10 by the Governor of Oregon) should such a determination be made.

The Klamath Team will evaluate two questions in order to determine concurrence:

1. Whether significant impacts identified in its environmental review can be avoided or mitigated as provided under State law.

2. Whether the facilities removal will be completed within the State Cost Cap.

The Klamath Team will provide the results of its evaluation in a recommendation to the Governor, for transmittal to the Secretary of Interior as a concurrence, if appropriate.

Chapter 2

Proposed Action and Description of the Alternatives

This chapter includes an overview of the National Environmental Policy Act (NEPA) and the California Environmental Quality Act (CEQA) requirements for a project description. It also includes a description of the alternatives formulation process to select a reasonable range of alternatives and a description of the Proposed Action and alternatives to the Proposed Action.

2.1 NEPA Requirements

Federal law outlines the required components of the “alternatives” section of an Environmental Impact Statement (EIS) (40 CFR Part 1502.14), which include the following:

- (a) Rigorous exploration and objective evaluation of all reasonable alternatives, and for alternatives which were eliminated from study, a brief discussion of the reasons for their having been eliminated.
- (b) Substantial treatment of each alternative considered in detail, including the proposed action, so that reviewers may evaluate their comparative merits.
- (c) Inclusion of reasonable alternatives that are not within the jurisdiction of the lead agency.
- (d) Inclusion of the alternative of no action.
- (e) Identification of the agency’s preferred alternative or alternatives, if one or more exists, in the draft statement and identification of such alternative in the final statement unless another law prohibits the expression of such a preference.
- (f) Inclusion of appropriate mitigation measures that are not already included in the proposed action or alternatives.

2.2 CEQA Requirements

The CEQA Guidelines¹ developed by the California Natural Resources Agency include prescriptive requirements for the components of the “project description” section of an Environmental Impact Report (EIR). The required components from Section 15124 of the CEQA Guidelines are listed below. Table 2-1 indicates the chapter and section in which each component is included in this EIS/EIR.

**Table 2-1. Location of CEQA Guidelines
Section 15124 Project Description Components**

Component	Location
(a) Map of project location and Boundaries	Section 1.1
(b) Project objectives	Section 1.4.2
(c) General description of the project's characteristics	Section 2.4.3
(d) Statement of the intended uses of the EIR	Section 1.4.1
(d)(1)(B) A list of permits and other approvals required to implement the project	Chapters 6 and 7

- (a) The precise location and boundaries of the proposed project shall be shown on a detailed map, preferably topographic. The location of the project shall also appear on a regional map.
- (b) The document will include a statement of objectives sought by the proposed project. A clearly written statement of objectives will help the lead agency develop a reasonable range of alternatives to evaluate in the EIR and will aid the decisionmakers in preparing findings or a statement of overriding considerations, if necessary. The statement of objectives should include the underlying purpose of the project.
- (c) A general description of the project's technical, economic, and environmental characteristics, considering the principal engineering proposals, if any, and supporting public service facilities.
- (d) A statement briefly describing the intended uses of the EIR.
 - (1) This statement shall include the following, to the extent that the information is known to the lead agency:
 - (A) A list of the agencies that are expected to use the EIR in their decisionmaking.

¹ Title 14, California Code of Regulations, §§ 15000–15387.

- (B) A list of permits and other approvals required to implement the project.
 - (C) A list of related environmental review and consultation requirements required by Federal, State, or local laws, regulations, or policies. To the fullest extent possible, the lead agency should integrate CEQA review with these related environmental review and consultation requirements.
- (2) If a public agency must make more than one decision on a project, all its decisions subject to CEQA should be listed, preferably in the order in which they occur.

2.3 Alternatives Development

Both NEPA and CEQA require EIS/EIRs to identify a reasonable range of alternatives and provide guidance on the identification and screening of such alternatives. For this EIS/EIR, the Lead Agencies followed a structured, documented process to identify and screen alternatives for inclusion in the EIS/EIR. Figure 2-1 illustrates the process that the Lead Agencies conducted to identify and screen alternatives.

Figure 2-1. Alternatives Development and Screening Process.

During public scoping, the public provided input regarding potential alternatives to the Proposed Action. The Lead Agencies reviewed the purpose and need/project objectives statement, public scoping comments, and previous studies in their initial effort to develop conceptual alternatives. This resulted in an initial list of action alternatives described in Appendix A, Alternatives Formulation Report. The initial list included more than 18 alternatives; however, some were determined to have limited functionality as full alternatives because they focused on techniques for improving natural resources conditions that are already a part of the Klamath Basin Restoration Agreement (KBRA). These alternatives were screened out. The Lead Agencies then developed and applied a set of screening considerations to determine which of the remaining alternatives should move forward for further analysis. Some alternatives were evaluated based on preliminary analysis conducted during the EIS/EIR development, as discussed in Appendix A.

Alternatives may have moved forward for detailed analysis in the EIS/EIR if they do not fully meet the purpose and need/project objectives but may be able to reduce environmental effects or help create a reasonable range of alternatives.

Both NEPA and CEQA include provisions that alternatives meet (or meet most of) the purpose and need/project objectives, and be potentially feasible. Under CEQA, alternatives do not need to meet all of the project objectives; alternatives should be included if they can meet most of the objectives and avoid or substantially lessen significant environmental impacts of the project. The alternatives that moved forward for more detailed analysis in this EIS/EIR are those that best meet the NEPA purpose and need and CEQA objectives, minimize negative effects, are feasible, and represent a range of reasonable alternatives. Some alternatives do not fully meet the purpose and need/project objectives, but they have potential to minimize some types of environmental effects or help create a reasonable range of alternatives for consideration by decisionmakers. Table 2-2 presents the screening results for the 18 initial alternatives. A full description of the alternatives and the rationale for screening the alternatives is presented in Appendix A, the Alternatives Formulation Report.

The Klamath Hydroelectric Settlement Agreement (KHSA) Section 3.2.1(iii), signed by Secretary of the Interior Ken Salazar on February 18, 2010, directs the Secretary to undertake environmental review in support of the Secretarial Determination. All alternatives carried forward for further analysis in the EIS/EIR were analyzed using existing studies and other appropriate data as suggested in KHSA Section 3.2.1 (i), where such analysis met criteria in 40 CFR 1502.22 and 43 CFR 46.125 to incorporate available information. As part of developing the basis for the Secretarial Determination, the KHSA requires in Section 3.3.2 that the Secretary prepare a Detailed Plan, including the identification, qualifications, management, and oversight of a non-Federal DRE, if any, that the Secretary may designate. KHSA Section 3.3.4.D requires that an estimate of costs be prepared as part of the Detailed Plan. The Detailed Plan analysis provides most of the information for the project description for Alternatives 2 and 3, and this information was used to analyze these two action alternatives. As described in KHSA Section 3.2.1(i), the Federal Energy Regulatory Commission (FERC) record is used to form the project description for Alternatives 4 and 5. Alternatives 4 and 5 were analyzed to ensure that the review of reasonable fish passage alternatives was comprehensive. In addition, at the time of developing a reasonable range of alternatives, the Lead Agencies recognized that the inclusion of Alternatives 4 and 5 would provide an assessment of the short- and long-term effects from a broader range of reasonable alternatives, as defined under CEQA. Alternatives 4 and 5 are outside the authority of the Department of the Interior, the Four Facilities proposed for removal are privately owned structures, and there was no provision in the KHSA to include them in the Detailed Plan. The result is differing levels of available information for alternatives carried forward in the EIS/EIR consistent with the elements of each action alternative.

Table 2-2. Initial Alternatives

Alternative Number	Alternative Name	Description	Screening Result
Alternative 1	No Action/ No Project	Implement none of the action alternatives; Klamath Hydroelectric Project would continue current operations.	Alternative 1 moved forward to the EIS/EIR for further review because it is required under NEPA and CEQA.
Alternative 2	Full Facilities Removal of Four Dams (Proposed Action)	Remove four dams and related facilities.	Alternative 2 moved forward to the EIS/EIR for further review because it fully meets the purpose and need/project objectives.
Alternative 3	Partial Facilities Removal of Four Dams	Remove main areas of four dams to allow a free-flowing river and volitional fish passage; related facilities and/or abutments may remain.	Alternative 3 moved forward to the EIS/EIR for further review because it fully meets the purpose and need/project objectives.
Alternative 4	Fish Passage at Four Dams	Construct fish passage facilities to provide upstream and downstream passage at four dams.	Alternative 4 has been retained for further analysis because the No Action alternative, per the requirements of NEPA, may not presume the types of conditions that FERC might require should it re-issue a license under the Federal Power Act. Consequently, without this alternative, there would be no analysis in this document on fish passage. The Lead Agencies believe it is appropriate to include in the alternatives for further consideration our best assessment of probable fish passage. By bringing the fish passage alternative forward, the public will be better informed, which will in turn help foster better decisionmaking by the Secretary, all of which being consistent with the goals of NEPA.
Alternative 5	Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate	Remove Copco 1 and Iron Gate Dams, construct fish passage at J.C. Boyle and Copco 2 Dams.	While Alternative 5 does not fully meet the purpose and need/project objectives, it moved forward to the EIS/EIR for further review because it could lessen potential construction-related environmental and power generation effects of the Proposed Action. Additionally, it would lessen water quality effects of the two larger reservoirs. Consideration of this alternative would give the Secretary a reasonable range of alternatives to inform decisionmaking.
Alternative 6	Fish Passage at J.C. Boyle, Remove Copco 1, Copco 2, and Iron Gate	Remove Copco 1, Copco 2, and Iron Gate Dams, construct upgraded fish passage at J.C. Boyle.	The EIS/EIR will fully analyze effects of removing all dams, constructing fish passage facilities at all dams, and a combination of these measures as a part of Alternatives 2, 4, and 5. Potential effects of Alternative 6 will be fully analyzed through these other alternatives. Alternative 6 will not move forward for further analysis.

Table 2-2. Initial Alternatives

Alternative Number	Alternative Name	Description	Screening Result
Alternative 7	Sequenced Removal of Four Dams	Sequence dam removal over three to five years.	Alternative 7 will not be carried forward for more detailed analysis in the EIS/EIR because it would not reduce environmental effects of the Proposed Action, and may increase effects to fish associated with sediment release from the reservoirs over multiple years.
Alternative 8	Full Facilities removal of Four Dams without KBRA	Remove four dams and related facilities but do not implement KBRA elements.	Alternative 8 will not be carried forward for more detailed analysis in the EIS/EIR because it does not meet most of the purpose and need/project objectives and would not reduce environmental effects of the Proposed Action. The effects of removing the four dams and related facilities will be fully analyzed under Alternative 2.
Alternative 9	Trap and Haul Fish	Capture fish at Iron Gate Dam and transport them upstream of J.C. Boyle Dam.	Alternative 9 will not move forward for further analysis because it does not meet the purpose and need under NEPA or most of the project objectives under CEQA.
Alternative 10	Fish Bypass: Bogus Creek Bypass	Create fish bypass using Bogus Creek, Cold Creek, Little Deer Creek, and a constructed canal to connect to Copco 1 Reservoir.	Alternative 10 will not move forward for more detailed analysis in the EIS/EIR because it does not meet any elements of the purpose and need under NEPA or project objectives under CEQA.
Alternative 11	Fish Bypass: Alternative Tunnel Route	Create fish bypass using Bogus Creek and a 5-mile tunnel to connect to Copco Reservoir.	Alternative 11 will not move forward for more detailed analysis in the EIS/EIR because it does not meet any elements of the purpose and need under NEPA or project objectives under CEQA.
Alternative 12	Notching Four Dams	Notch four dams to create a free-flowing river.	Alternative 12 is very similar to Alternative 3, and would result in the same type of impacts. Therefore, this alternative will not move forward for more detailed analysis in the EIS/EIR as a separate alternative.
Alternative 13	Federal Takeover of Project	Use authority of the Federal Power Act for government to take over dams and initiate removal.	Alternative 13 will not move forward for more detailed analysis in the EIS/EIR because the environmental impacts would be generally the same (and have generally the same timeframe) as the dam removal impacts under Alternative 2.
Alternative 14	Full Removal of Five Dams	Remove Keno Dam in addition to four downstream dams.	Alternative 14 will not be carried forward for more detailed analysis in the EIS/EIR because it does not fully meet the purpose and need/project objectives (because it is not consistent with the KHSA) and it would not avoid or lessen potential adverse environmental effects of the Proposed Action.

Table 2-2. Initial Alternatives

Alternative Number	Alternative Name	Description	Screening Result
Alternative 15	Full Removal of Six Dams	Remove Keno and Link River Dams in addition to four downstream dams.	Alternative 15 will not be carried forward for more detailed analysis in the EIS/EIR because it does not fully meet the purpose and need/project objectives (because it is not consistent with the KHSA) and it would not avoid or lessen potential environmental effects of the Proposed Action. Implementation of Alternative 15 would also not be likely to meet Endangered Species Act requirements or tribal trust water rights within Upper Klamath Lake.
Alternative 16	Dredge Upper Klamath Lake	Remove sediments in Upper Klamath Lake to remove phosphorus and increase storage capacity.	Alternative 16 will not move forward for more detailed analysis in the EIS/EIR because it does not meet the purpose and need under NEPA or most of the project objectives under CEQA.
Alternative 17	Predator Control	Control seal, sea lion, and cormorant populations that are salmonid predators.	Alternative 17 will not move forward for more detailed analysis in the EIS/EIR because it does not meet the purpose and need under NEPA or project objectives under CEQA. Moreover, it would be difficult to permit because of biological concerns.
Alternative 18	Partition Upper Klamath Lake	Create an “inner lake” that may improve water quality.	Alternative 18 will not move forward for more detailed analysis in the EIS/EIR because it does not meet the purpose and need under NEPA or project objectives under CEQA.

Key:
 CEQA: California Environmental Quality Act
 EIS/EIR: Environmental Impact Statement/Environmental Impact Report
 FEIS: Federal Energy Regulatory Commission Environmental Impact Statement
 FERC: Federal Energy Regulatory Commission
 KBRA: Klamath Basin Restoration Agreement
 KHSA: Klamath Hydroelectric Settlement
 NEPA: National Environmental Policy Act

As a result of the initial alternative screening, four action alternatives and the No Action/No Project alternative were selected to move forward for analysis in the EIS/EIR. Table 2-3 presents the alternatives carried forward for analysis in the EIS/EIR. These alternatives represent a reasonable range of alternatives for analysis to provide context for decisionmakers. Analysis of these alternatives will provide the Secretary with information needed to make a decision, and potentially to mix and match elements of the alternatives, if needed, to create an alternative that would reduce environmental impacts and increase environmental benefits.

Table 2-3. Alternatives Selected for Analysis in the EIS/EIR

Alternative Number	Alternative Name	Description
Alternative 1	No Action/No Project	Implement none of the action alternatives; Klamath Hydroelectric Project would continue current operations.
Alternative 2	Full Facilities Removal of Four Dams (Proposed Action)	Remove four dams and related facilities.
Alternative 3	Partial Facilities Removal of Four Dams	Remove main areas of four dams to allow a free-flowing river and volitional fish passage; related facilities and/or abutments may remain.
Alternative 4	Fish Passage at Four Dams	Construct fish passage facilities to provide upstream and downstream passage at four dams.
Alternative 5	Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate	Remove Copco 1 and Iron Gate Dams, construct fish passage at J.C. Boyle and Copco 2 Dams.

2.4 Proposed Action and Alternatives

The following sections describe the alternatives under evaluation in this EIS/EIR. Appendix A includes more detailed descriptions of these alternatives.

2.4.1 Facilities Common to All Alternatives

All of the alternatives, except for the No Action/No Project Alternative, include actions at the Four Facilities of the Klamath Hydroelectric Project: the J.C. Boyle, Copco 1, Copco 2, and Iron Gate dam sites. Table 2-4 outlines characteristics of the Four Facilities.

Table 2-4. Dam and Powerhouse Components

	J.C. Boyle	Copco 1	Copco 2	Iron Gate
Dam type	Concrete and earthfill embankment	Concrete	Concrete	Earthfill embankment
Dam maximum height	68 feet	135 feet	33 feet	189 feet
Dam crest length	692 feet	410 feet	335 feet	740 feet
Reservoir surface area	420 acres	1,000 acres	N/A	944 acres
Reservoir storage volume	2,629 acre-feet	40,000 acre-feet	73 acre-feet	53,800 acre-feet
Type of facility to allow water to flow past dam	Overflow spillway with control gates and diversion culvert	Overflow spillway with control gates and diversion tunnel	Overflow spillway with control gates	Uncontrolled overflow spillway and diversion tunnel

Source: FERC 2007; Reclamation 2012a

Each of the facilities generates power using various methods for water delivery to the power generation facility as summarized in Table 2-5.

Table 2-5. Power Generation Facilities

	J.C. Boyle	Copco 1	Copco 2	Iron Gate
Type of facility to divert water for power generation	Concrete tower with screened water intake	Intakes at upstream end of dam	Diversion intake with gate	Concrete tower with water intake
Water conveyance system to power generation facility	638 feet of steel pipe (14-foot diameter), 2 mile concrete flume, 1,660 foot tunnel, and into two 10.5 foot penstock pipes 956 feet long	Two 10-foot and one 14-foot diameter penstock pipes	2,440 feet of concrete-lined tunnel, 1,313 feet of wood-stave pipeline, 1,110 feet of additional concrete-lined tunnel, and into two penstock pipes (16-foot diameter)	One 12-foot diameter penstock pipe
Power generation mechanism	2 turbines	2 turbines	2 turbines	1 turbine
Powerhouse Type	Concrete foundations with concrete pads for access, no building	Enclosed building	Enclosed building	Concrete foundations with concrete pads for access, no building
Power Capacity	98 MW	20 MW	27 MW	18 MW

MW: megawatt

2.4.1.1 J.C. Boyle Dam and Powerhouse

The J.C. Boyle facilities consist of a reservoir, embankment dam, concrete spillway, fish ladder, water intake structure, water conveyance system, and powerhouse. The narrow reservoir is created by an embankment dam with a concrete spillway as shown in Figure 2-2. The concrete spillway has flow control gates on the crest along with a fish ladder and water intake structure for diverting water to power generation facilities. The water conveyance system transmits diverted water several miles downstream to the powerhouse on the Klamath River.

At J.C. Boyle Dam, a portion of Klamath River flow is diverted into the power generation system and the non-diverted water is used to maintain flow in the fish ladder with the excess flow going over the spillway as necessary. The fish ladder discharge and spillway discharge combine and flow through the section of river referred to as the “Bypass Reach,” which contains less flow than other sections of the river. Water diverted at the dam for power generation is conveyed through a steel pipe, concrete canal, tunnel, and penstock pipe to the powerhouse. The powerhouse is approximately four river miles downstream from the dam. After water runs through the power generation facilities, it rejoins the Klamath River.

Figure 2-2. J.C. Boyle Dam and Powerhouse.

J.C. Boyle powerhouse is generally operated as a peaking facility when river flows are too low to allow for continuous operations, such as the summer low flow period. Power demand peaks during weekday afternoons in the summer. Peaking power generation occurs in the late afternoons and early evenings to meet this demand, which allows the reservoir to refill during the night when power demand is minimal. Figure 2-3 shows early summer flows in 2011 as an example of how peaking operations affect flow downstream from the powerhouse. The reach between the powerhouse and the upstream end of Copco 1 Reservoir is referred to as the “Peaking Reach.” Historically, flows in this reach fluctuated rapidly to meet demand and peaking operations for power generation.

Figure 2-3. Example Flows in Peaking Reach downstream from J.C. Boyle Powerplant (United States Geological Survey [USGS] station 11510700).

Source: USGS 2011

2.4.1.2 Copco 1 Dam and Powerhouse

The Copco 1 facilities consist of a reservoir, concrete dam, concrete spillway, water intake structure, and powerhouse. Copco 1 Dam (Figure 2-4) is in a bedrock canyon on the Klamath River at River Mile (RM) 198.6. Construction records show that the concrete dam includes 465 tons of 30-pound steel rails for reinforcement.

Water is routed past the dam, through the power generation facilities, and/or over the concrete spillway. Water diversion for power generation is via two intake structures on the right dam abutment (these descriptions refer to river right and river left when looking downstream). Water flows into the intakes and down to the powerhouse, located at the base of the dam, through steel penstock pipes. Excess water not diverted for power generation is allowed to flow over the concrete spillway and down the face of the dam. The entire width of the dam creates the spillway, which is controlled by gates that run across the top of the spillway. Water that flows over the spillway rejoins water diverted for power generation near the base of the dam at the powerhouse. Copco 1 had been built with the intention that a fishway passage would be constructed as a mitigation measure for salmon. However, by the completion of Copco 1, the idea of fishway passage had been abandoned due to its impracticality, and a hatchery was planned in lieu of fish passage (Lane and Lane 1981).

Figure 2-4. Copco 1 Dam and Powerhouse.

2.4.1.3 Copco 2 Dam and Powerhouse

The Copco 2 facilities consist of a concrete dam, water diversion intake, water conveyance system for power generation, penstock pipes, powerhouse, and switchyard. The dam is at the bottom of a confined canyon on the Klamath River at RM 198.3. Copco 2 Dam is a concrete dam that spans the river with an earthen embankment section that fully spans the bottom of the canyon (see Figure 2-5).

At Copco 2 Dam, flow is diverted on river left through a water intake structure and conveyed through the power generation system. River flow in excess of diverted water is allowed to flow over the concrete spillway. An existing metal pipe through the dam provides an additional 5 cubic feet per second (cfs) to the Bypass Reach below the dam.

Copco 2 Powerhouse is 1.5 miles downstream from Copco 2 Dam. Diverted river water flows from the dam through 2,440 feet of concrete-lined tunnel, 1,313 feet of pipeline, an additional 1,110 feet of concrete-lined tunnel, and two steel penstocks.

Figure 2-5. Copco 2 Powerhouse (left photo) and Dam.

2.4.1.4 Iron Gate Dam and Powerhouse

The Iron Gate facilities consist of a reservoir, earthfill embankment dam, concrete spillway, water intake structure, penstock pipes, and power generation facility (see Figure 2-6). The embankment dam is in a bedrock canyon at RM 190.1.

Water for power generation is drawn from the reservoir using a concrete water intake tower on the left side of the reservoir.² Water is transported down the face of the dam through penstock pipes and into the powerhouse immediately downstream from the dam on the left bank of the river. The powerhouse consists of one turbine with concrete structural slabs and no overhead building structure.

Water not diverted for power generation is allowed to flow freely over the concrete spillway on the right side of the dam. There are no gates or flow controls for the spillway and flow is directed to the base of the dam where it converges with power

² Unlike other dams in the region including Shasta Dam, there is no low level intake to tap cold water in the hypolimnium at Iron Gate Dam.

Figure 2-6. Iron Gate Dam, Reservoir, and Power Generating Facilities.

generation return flows to resume flow down the Klamath River. The Iron Gate Dam has the original bypass tunnel used during construction of the dam that allows water in the reservoir to be drawn down over 125 feet.

The Iron Gate Fish Hatchery, located immediately below Iron Gate Dam, was constructed to mitigate for the loss of 16 miles of fish habitat between Iron Gate Dam and Copco 2 Dam.

2.4.2 Alternative 1: No Action/No Project Alternative

NEPA requires an EIS to “include the alternative of no action” (40 CFR Part 1502.14(d)). CEQA requires an EIR to include a No Project Alternative. CEQA Guidelines Section 15126.6(e)(2) states that “The ‘no project’ analysis shall discuss the existing conditions at the time the notice of preparation is published, or if no notice of preparation is published, at the time environmental analysis is commenced, as well as what would be reasonably expected to occur in the foreseeable future if the project were not approved, based on current plans and consistent with available infrastructure and community

services.” For the Klamath Facilities Removal EIS/EIR, NEPA’s No Action Alternative and CEQA’s No Project Alternative describe the same conditions, and this alternative is referred to as the No Action/No Project Alternative.

The No Action/No Project Alternative represents the state of the environment without the Proposed Action or any of the alternatives. In this instance, the No Action/No Project Alternative would be no change from current management conditions, other than as noted below, with the dams remaining in place. The No Action/No Project Alternative would only include the portions of the KBRA that are ongoing resource management activities. These resource management actions could receive additional funding and could be expanded or accelerated through the KBRA; however, they were started or under consideration before the KBRA was developed and would move forward even without the KBRA. Therefore, the No Action/No Project Alternative includes the following resource management actions:

- **Williamson River Delta Project** – As part of this project, levees were breached on Williamson River in November 2008 to restore historic wetlands, benefit water quality, and provide habitat for threatened and endangered fish. This project also provides 28,800 acre-feet of additional storage in Upper Klamath Lake.
- **Agency Lake and Barnes Ranches Project** – The diked and drained portion of the ranches are currently used by Reclamation as pumped storage. The lands have been transferred from Reclamation to the United States Fish and Wildlife Service (USFWS) and incorporated into the National Wildlife Refuge (NWR) system so that the dikes can be breached to reconnect wetlands to Upper Klamath Lake and add 63,770 acre feet of storage Upper Klamath Lake. USFWS is studying options to breach the dikes.
- **Fish Habitat Restoration** – restoration activities are ongoing throughout the basin under current authorities and funding levels. These restoration activities include, but are not limited to, restoration and permanent protection of riparian vegetation, water quality improvements, restoration of stream channel functions, measures to prevent and control excessive sediment inputs, remediation of fish passage problems, and prevention of entrainment into diversions. Specific types of activities include floodplain rehabilitation, large woody debris placement, fish passage correction, cattle exclusion, riparian vegetation planting, mechanical thinning to promote conifers, fire treatment, purchase of conservation easements/land, road decommissioning, gravel augmentation (main stem), and treatment of fine sediment sources. The fish habitat restoration program that would be implemented under the KBRA would include these same types of activities but is described under the Proposed Action.
- **Climate Change Assessment** – this assessment is intended to ensure that long-term climate change in the Klamath Basin is assessed early and continuously, allowing the Parties to collaboratively respond in a manner that protects basin

interests from the adverse effects of climate change for as long as practicable, and to manage the resources of the basin on the basis of the best available science.

The KHSA outlines 20 Interim Measures (IMs) for the Klamath Hydroelectric Project that would be implemented until construction begins (if the Secretary makes an Affirmative Determination). Under the No Action/No Project Alternative, the KHSA would not move forward. However, several of these IMs have already been implemented, or would likely be implemented with a Negative Determination. Table 2-6 includes the IMs that are part of the No Action/No Project Alternative because:

- IMs are included in PacifiCorp's Habitat Conservation Plan (PacifiCorp 2012) (IMs 2, 4, 5, and 6);
- IMs are included in an Environmental Assessment from BLM and are scheduled to move forward before the Secretary makes a determination (IMs 7 and 8); or
- IMs represent a continuation of existing operations (IMs 13, 14, and 17).

IM 7 (J.C. Boyle Gravel Placement) would start before the Secretary makes a determination, but it would end with a Negative Determination. Gravel placement would occur for approximately one year under the No Action/No Project Alternative before a determination is made; therefore, only one year of implementation of IM 7 is included in the No Action/No Project Alternative. IMs 3 (Iron Gate Turbine Venting) and 12 (J.C. Boyle Bypass Reach and Spencer Creek Gaging) have already been implemented and are therefore part of existing conditions. The remaining IMs would end with a Negative Determination and are not included in the No Action/No Project Alternative.

PacifiCorp included IMs 2, 4, 5, and 6 in a Habitat Conservation Plan (HCP) and National Oceanic and Atmospheric Administration (NOAA) Fisheries Service has analyzed them in accompanying NEPA environmental documents, biological opinions, and findings documents. NOAA Fisheries Service has completed an Environmental Assessment (NOAA Fisheries Service 2012a) and a Finding of No Significant Impact (NOAA Fisheries Service 2012b) for incidental take and implementation of IMs and related project operations for a 10-year period. BLM has completed an Environmental Assessment and Finding of No Significant Impact related to IMs 7 and 8 (BLM 2011).

PacifiCorp would need to obtain a long-term operating license from the FERC to replace the existing annual license. PacifiCorp would continue seeking a new license from FERC.

Table 2-6. Interim Measures included in the No Action/No Project Alternative

Interim Measure	Description
IM2 – California Klamath Restoration Fund/Coho Enhancement	PacifiCorp would fund actions to enhance survival and recovery of coho salmon, including habitat restoration and acquisition.
IM4 – Hatchery and Genetics Management Plan	PacifiCorp would fund the development and implementation of a Hatchery and Genetics Management Plan for the Iron Gate Hatchery.
IM5 – Iron Gate Flow Variability	PacifiCorp and Reclamation would annually evaluate the feasibility of enhancing fall and early winter flow variability to benefit salmonids downstream from Iron Gate Dams. In the event that fall and early winter flow variability can feasibly be accomplished, PacifiCorp would develop and implement flow variability plans. This IM would not adversely affect the volume of water available for Reclamation’s Klamath Project or wildlife refuges.
IM6 – Fish Disease Relationship and Control Studies	PacifiCorp has established a fund to study fish disease relationships downstream from Iron Gate Dam. PacifiCorp would consult with the Klamath River Fish Health Workgroup regarding selection, prioritization, and implementation of such studies.
IM7 – J.C. Boyle Gravel Placement and/or Habitat Enhancement (one year only)	PacifiCorp would provide funding for the planning, permitting, and implementation of gravel placement or habitat enhancement projects, including related monitoring, in the Klamath River above Copco Reservoir within 90 days of the effective date.
IM8 – J.C. Boyle Bypass Barrier Removal	PacifiCorp would remove the sidecast rock barrier approximately 3 miles upstream of the J.C. Boyle Powerhouse in the Bypass Reach. This IM would help with safe, timely, and effective upstream passage of Chinook and coho salmon, steelhead trout, Pacific lamprey, and redband trout.
IM13 – Flow Releases and Ramp Rates	PacifiCorp would maintain current operations including instream flow releases of 100 cfs from J.C. Boyle Dam to the J.C. Boyle Bypass Reach and a 9-inch per hour ramp rate below the J.C. Boyle powerhouse prior to transfer of the J.C. Boyle facility.
IM14 – 3,000 cfs Power Generation	Upon approval by OWRD, PacifiCorp would continue maximum diversions of 3,000 cfs at J.C. Boyle Dam for power generation prior to decommissioning of the facility.
IM17 – Fall Creek Flow Releases	PacifiCorp would continue to provide a continuous flow release to the Fall Creek Bypass Reach targeted at 5 cfs.

Key:
IM: Interim Measure
OWRD: Oregon Water Resources Department

For the purposes of this analysis, the No Action/No Project Alternative would continue current operations with the dams remaining in place and PacifiCorp operating under the current annual license. The existing license has no requirements for additional fish passage or implementation of the prescriptions that are currently before FERC in the relicensing process. PacifiCorp would continue to operate the Iron Gate Hatchery under its current operations. Flows would remain similar to current flows, which are released from Reclamation’s Klamath Project and passed through the Klamath Hydroelectric Project. Figure 2-7 shows modeled future flows in dry conditions (represented by the flows exceeded 90 percent of the time, or 90 percent exceedence), average conditions (flows exceeded 50 percent of the time), and wet conditions (flows exceeded 10 percent of the time). These exceedence plots do not represent a flow pattern in any specific year. A 90 percent exceedence flow is a flow that would be exceeded 90 percent of the time;

therefore, it is generally representative of a dry year because most years have greater flows. The biological opinions on Reclamation's Klamath Project operations, and a biological opinion on FERC's licensing of the Klamath Hydroelectric Project may change in the future as understanding of species or their populations change; however, these changes are unknown at this time and not included in the hydrologic assumptions.

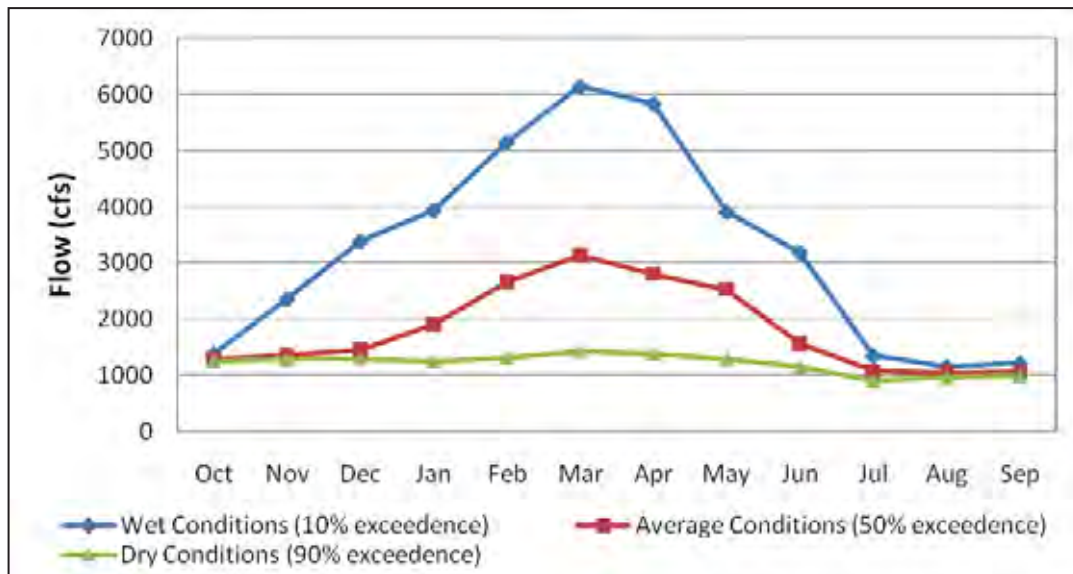

Figure 2-7. No Action/No Project Flows below Iron Gate Dam in Wet, Average, and Dry Conditions.

The USFWS issued a biological opinion to Reclamation on the operation and maintenance of Reclamation's Klamath Project (USFWS 2008). This biological opinion outlines measures to improve the habitat for the Lost River sucker and shortnose sucker affected by Reclamation's Klamath Project operations. Among other measures to protect the suckers, the biological opinion requires that specific surface elevations of Upper Klamath Lake be maintained to meet certain criteria.

The National Oceanic and Atmospheric Administration Fisheries Service (NOAA Fisheries Service) also issued a biological opinion to Reclamation requiring releases from Reclamation's Klamath Project to produce specified rates of flow for the Klamath River downstream from Iron Gate Dam, based on the habitat needs of coho salmon (NOAA Fisheries Service 2010). Target flow rates in the Klamath River downstream from Iron Gate Dam vary by month, and are dependent in part on the amount of water entering Upper Klamath Lake.

PacifiCorp would continue to coordinate operations with Reclamation and operate the Klamath Hydroelectric Project in compliance with existing NOAA Fisheries Service and USFWS biological opinions issued for Reclamation's Klamath Project. Under the No Action/No Project Alternative, the Four Facilities would continue to be subject to requirements in PacifiCorp's current annual FERC permit:

- Operating the peaking facility at J.C. Boyle such that the river does not rise or fall more quickly than 9 inches per hour and that minimum flows immediately downstream from the dam are maintained at 100 cfs.
- Maintaining minimum flows downstream from Iron Gate Dam.
- Limiting the change in the rate of the release of water from Iron Gate Dam to no more than 250 cfs per hour or a three-inch change in river stage (FERC 2007).

PacifiCorp also currently coordinates with Reclamation to meet ramp rates in the NOAA Fisheries Service biological opinion on Reclamation's Klamath Project:

- When flows at Iron Gate Dam are 3000 cfs or above, Iron Gate Dam ramp down rates will follow the rate of decline to inflows to Upper Klamath Lake combined with accretions between Keno Dam and Iron Gate Dam.
- When flows at Iron Gate Dam are between 1,750 cfs and 3,000 cfs, Iron Gate Dam ramp down rates will be 300 cfs or less per 24 hour period and no more than 125 cfs per 4 hour period.
- When flows at Iron Gate Dam are 1,750 cfs or less, Iron Gate ramp down rates will be 150 cfs or less per 24 hour period and no more than 50 cfs per two hour period (NOAA Fisheries Service 2010).

The No Action/No Project Alternative would include other regulatory conditions that would affect conditions in the Klamath Basin. To improve water quality, the Oregon Department of Environmental Quality (ODEQ) and California North Coast Regional Water Quality Control Board (NCRWQCB) cooperated to develop Total Maximum Daily Loads (TMDLs) for impaired water bodies within the basin. TMDLs are pollution control plans that identify the pollutant load reductions that are necessary from point and nonpoint sources to meet water quality standards. Table 2-7 shows the status of the TMDLs in the Klamath Basin. The California and Oregon Klamath River TMDLs focus on reducing high water temperatures, increasing dissolved oxygen levels, and reducing nutrient concentrations in the mainstem Klamath River (NCRWQCB 2010a, ODEQ 2010). Major tributaries in the Lower Klamath Basin, such as the Scott, Shasta, and Trinity Rivers, are not included in the technical analyses (i.e., modeling efforts) for the California Klamath TMDLs but the entire Klamath Basin is included in the associated Implementation Plan (NCRWQCB 2010b).

The TMDLs within the basin are expected to result in improvements to water quality conditions over time, but the pace of achieving improvements and the implementation mechanisms are unknown. Section 3.2, Water Quality, describes these TMDLs in detail.

Table 2-7. Status of TMDLs in the Klamath Basin

Water Body	Pollutant/Stressor	Agency	Original Listing Date	TMDL Completion Date ¹
Oregon				
Upper Klamath Lake Drainage	Temperature, dissolved oxygen, and pH	ODEQ	1998	2002
Upper Klamath and Lost Rivers	Temperature, dissolved oxygen, pH, ammonia toxicity, and chlorophyll-a	ODEQ	1998	2011
California				
Lower Lost River (Tule Lake, Lower Klamath Lake National Wildlife Refuge, and Mt Dome) ²	pH and nutrients	USEPA	1992 (Nutrients), 2002 (pH)	2008
Klamath River	Temperature, organic enrichment/low dissolved oxygen ³ , nutrient, and microcystin ⁴	NCRWQCB	1992 (Temperature and nutrients), 1998 (Dissolved oxygen), 2006 and 2010 (Microcystin)	2010
Shasta River	Temperature and dissolved oxygen	NCRWQCB	1992 (Dissolved oxygen), 1994 (Temperature)	2007
Scott River	Temperature and sediment	NCRWQCB	1992 (Sediment), 1996 (Temperature)	2006
Salmon River	Temperature	NCRWQCB	1992	2005
Trinity	Sediment	USEPA	1992	2001
South Fork Trinity	Sediment	USEPA	1992	1998

Notes:

¹ The TMDL completion date is the year the USEPA approved or is expected to approve the TMDL.

² The Upper Lost River upstream of the Oregon border, Clear Lake Reservoir, and tributaries were listed for water temperature and nutrients. In 2004, North Coast Regional Board staff completed an analysis of beneficial uses and water quality conditions in the Upper Lost River watershed and concluded that the listing was not warranted.

³ Listing applies only to the mainstem Klamath River.

⁴ Listings occurred in 2006 for the mainstem Klamath River from the Oregon-California State line to Iron Gate Dam (including Copco and Iron Gate Reservoirs), and in 2010 for the mainstem Klamath River from Iron Gate Dam to the Trinity River.

Key:

TMDL = Total Maximum Daily Load
 ODEQ = Oregon Department of Environmental Quality
 USEPA = U.S. Environmental Protection Agency
 NCRWQCB = North Coast Regional Water Quality Control Board

2.4.3 Alternative 2: Full Facilities Removal of Four Dams (Proposed Action)

The Full Facilities Removal of Four Dams Alternative (the Proposed Action) includes the removal of the Four Facilities as described in the KHSA. This alternative would include the complete removal of dams, power generation facilities, water intake structures, canals, pipelines, and ancillary buildings. During deconstruction the reservoirs would be closed to recreation. This alternative would include the transfer of Keno Dam to the Department of the Interior (DOI), decommissioning of PacifiCorp’s East Side/West Side facilities, and the implementation of the KBRA as connected actions as defined under NEPA. For purposes of CEQA, the proposed project is Alternative 2.

The result of the Proposed Action would be that the Klamath River would have no dams downstream from Keno Dam. Operation of Reclamation’s Klamath Project and the related river flows, measured at the United States Geological Survey gauge downstream from Iron Gate Dam, would be according to the hydrologic model outputs in modeled KBRA hydrology (Reclamation 2012b). Figure 2-8 shows simulated future flows at the Iron Gate Gauge during dry conditions (represented by the flows exceeded 90 percent of the time, or 90 percent exceedence), average conditions (flows exceeded 50 percent of the time), and wet conditions (flows exceeded 10 percent of the time).³

Figure 2-8. Proposed Action Flows at the Iron Gate Gauge in Wet, Average, and Dry Conditions.

³ Minimum flows may change in the future. Hydrologic modeling assumed that the Drought Plan would include a minimum flow of 800 cfs (Reclamation 2011). The final Drought Plan or future ESA actions could change the minimum flows; however, these assumptions reflect the best available information at the time of the modeling.

Removing the Four Facilities would release some of the sediment currently stored behind the dams into the downstream river system. The call-out box on the next pages, “Sediment Weight and Volume in the Four Facilities and Erosion with Dam Removal,” provides information on the quantity and type of sediment in the Four Facilities.

Reservoir drawdown schedules were selected to minimize release of sediment during critical times for sensitive species. The Lead Agencies studied multiple drawdown timing scenarios to avoid or minimize impacts to aquatic species, especially anadromous fishes. The challenge in selecting a drawdown period was to avoid impacts to migrating adult fish (salmonids, sturgeon, and lamprey), migrating juvenile smolts, and rearing of juveniles. During summer, there are juveniles rearing, green sturgeon adults, and spring-run Chinook salmon migrating. During fall, there are adult coho salmon, steelhead, and fall-run Chinook salmon migrating, and smolts outmigrating. During spring, there are smolts outmigrating, adult green sturgeon, and steelhead and spring-run Chinook adults migrating. Drawdown would primarily occur during winter because it would be the least harmful season; however, there are still species and life stages that may be affected, such as adult migrating steelhead and lamprey.

Prior to construction, IMs as described in the KHSA (KHSA Section 1.2.4) would be implemented and would control operations of the hydroelectric facilities. Some of these IMs would be implemented in the No Action/No Project Alternative, but the remaining would be included in the Proposed Action. Some of the IMs propose studies, planning efforts, or the continued funding of existing facilities that do not constitute new actions with the potential to affect the environment and are therefore not analyzed in this EIS/EIR. Table 2-10 presents these IMs included in the Proposed Action that would not result in environmental effects.

The remaining IMs are also included in the Proposed Action and will be analyzed in Chapter 3 of this EIS/EIR (see Table 2-11). As discussed under the No Action/No Project Alternative, one year of IM7 would be implemented before the Secretary makes a determination. The remaining seven years, however, would only occur in the case of an Affirmative Determination and are therefore included in the Proposed Action.

Sediment Weight and Volume in the Four Facilities and Erosion with Dam Removal

Sediment in the reservoirs is primarily composed of silt and clay (fine sediment) with lesser amounts of cobble and gravel (Reclamation 2012b). Distribution of sediment varies within each of the reservoirs. In J.C. Boyle Reservoir, sediment primarily resides in the area nearest to the dam, with thicknesses up to 20 feet. Both Copco 1 and Iron Gate Reservoirs have generally even distributions of sediment with thicknesses increasing towards the dams. The maximum thickness of the Copco 1 Reservoir sediment is approximately 10 ft. The maximum deposition within the main stem of Iron Gate Reservoir is around 5 ft, with deposition thickness of near 10 ft in the Jenny Creek arm of Iron Gate Reservoir. Copco 2 Reservoir does not retain appreciable amounts of sediment. The current volume and weight of sediment for each reservoir is given in Table 2-8.

There is uncertainty associated with the reservoir computations because the volume estimates are based upon the drill hole sediment thicknesses (Reclamation 2012a, 2012b). There were between 28 to 31 drill holes in each reservoir used to develop maps of reservoir sediment thickness and it was necessary to interpolate the sediment thicknesses between the holes. This introduces some uncertainty in the volume estimates as reported in Table 2-8. While the uncertainty in the volume estimate is noticeable, the sediment analysis is not sensitive to the degree of uncertainty in the volume estimates. If the reservoir sediment volumes were on the higher end of the uncertainty estimate or the lower end of the uncertainty estimate, the dam removal plan would remain the same.

Table 2-8. Stored Sediment in the Klamath Hydroelectric Project, Fall 2009

	Volume (yd ³)	Uncertainty ¹ (+/- yd ³)	Dry Weight (tons)	% Fine Sediment by mass	Fine Sediment ² (tons)	Sand Sediment ³ (tons)
J.C. Boyle	1,000,000	+/- 300,000	290,000	66%	190,000	100,000
Copco 1	7,440,000	+/-1,500,000	1,880,000	87%	1,630,000	260,000
Iron Gate	4,710,000	+/-1,300,000	1,430,000	85%	1,210,000	230,000
Total⁴	13,150,000	+/-2,000,000	3,600,000	85%	3,020,000	590,000
Total Copco 1 and Iron Gate⁴	12,150,000	+/-2,000,000	3,320,000	85%	2,830,000	490,000

Source: *Reclamation 2012b*

¹ Uncertainty resulted from interpolation between drill holes and is calculated as a +/- amount shown (Reclamation 2012b).

² Fine Sediment is sediment with a diameter less than 0.063 millimeters

³ Sand Sediment is sediment with a diameter between 0.063 and 2 millimeters

⁴ Amounts of sediment (volumes and weights) from individual reservoirs may not equal the total amounts indicated because all volumes and weights taken from Reclamation (2012b) were rounded to the nearest 10,000th unit. Copco 2 Reservoir does not retain measureable amounts of sediment and therefore is not included in the estimates of total stored sediment.

⁵ Average dry densities vary between reservoirs and within the reservoir depending upon compaction and grain size distribution. The dry unit weight varies between 44.4 and 16.3 lb/ft³ (Reclamation 2012b). See Table 3.11-2 for more information.

Table 2-9. Estimated Amount of Sediment in the Reservoirs in 2020 and Erodible Sediment¹ with Dam Removal

Reservoir	Estimated 2020 Total			
	Total Volume (yd ³)	Total Sediment (tons)	Fine Sediment ² (tons)	Sand Sediment ³ (tons)
J.C. Boyle	1,190,000	340,000	220,000	120,000
Copco 1	8,250,000	2,090,000	1,800,000	290,000
Iron Gate	5,690,000	1,730,000	1,460,000	280,000
Total⁴	15,130,000	4,160,000	3,480,000	680,000
Total Copco 1 and Iron Gate⁴	13,940,000	3,820,000	3,260,000	560,000

Reservoir	Percent Erosion		Fine Sediment ¹ Erosion		Sand Sediment ² Erosion	
	Minimum Erosion (%)	Maximum Erosion (%)	Minimum (tons)	Maximum (tons)	Minimum (tons)	Maximum (tons)
J.C. Boyle	27%	51%	60,000	110,000	30,000	60,000
Copco 1	45%	76%	820,000	1,370,000	130,000	220,000
Iron Gate	24%	32%	350,000	460,000	70,000	90,000
Total⁴	36%	57%	1,230,000	1,950,000	230,000	370,000
Total Copco 1 and Iron Gate⁴	36%	56%	1,170,000	1,830,000	200,000	300,000

Source: Reclamation 2012b

¹ Erosion will primarily occur during the drawdown period in the winter and spring of 2020. The erosion rates were based on the hydrologic conditions recorded for the March to June flow volume at Keno gage on the Klamath River from water year 2001 (90% exceedance) and 1984 (10% exceedance). Additional erosion and sediment transport could occur in the following year that would be indistinguishable from background sediment regime.

² Fine Sediment is sediment with a diameter less than 0.063 millimeters

³ Sand Sediment is sediment with a diameter between 0.063 and 2 millimeters

⁴ Amounts of sediment (volumes and weights) from individual reservoirs may not equal the total amounts indicated because all volumes and weights taken from Reclamation (2011) were rounded to the nearest 10,000th unit. Copco 2 Reservoir does not retain measureable amounts of sediment and therefore is not included in the estimates of total stored sediment.

By 2020, an approximately 15.1 million yd³ (4.16 million tons) of sediment would be deposited behind the dams. During drawdown, approximately 36 to 57 percent of the 2020 volume or an estimated 5.4 and 8.6 million yd³ (1.2 to 2.3 million tons) of reservoir sediment will be eroded (see Table 2-9). The range in erosion volume is primarily dependent upon whether it is a dry year or wet year, respectively. The vast majority of the erosion will occur during the drawdown process and be a combination of direct erosion of the sediment by moving water and slumping of the fine sediment toward the river. The remaining sediment will erode more slowly because it will harden and dry following drawdown. With the return to riverine conditions, erosion and sediment transport will occur but will be indistinguishable from the background sediment regime.

Table 2-10. KHSA Interim Measures that would not produce Environmental Effects

Interim Measure	Description
IM1 – Interim Measures Implementation Committee	PacifiCorp would work with a committee to monitor IM implementation
IM9 – J.C. Boyle Powerhouse Gage	PacifiCorp would fund the continued operation of the existing gage below J.C. Boyle Powerhouse.
IM10 – Water Quality Conference	PacifiCorp would fund a basin-wide technical conference on water quality.
IM15 – Water Quality Monitoring	PacifiCorp would fund long-term baseline water quality monitoring to support dam removal, nutrient removal, and permitting studies, and would also fund blue-green algae (i.e., periphyton) and toxin monitoring.
IM 18 – Hatchery Funding	PacifiCorp would fund Iron Gate Hatchery operations and maintenance.
IM21 - BLM Land Management Provisions	PacifiCorp would fund BLM's continued land management activities including road maintenance, invasive weed management, cultural resource management, and recreation.

Key:
IM: Interim Measure
BLM: Bureau of Land Management

The ongoing resource management activities, TMDLs, biological opinions, and other regulatory conditions described under the No Action/No Project Alternative would also occur under this alternative.

2.4.3.1 Deconstruction Actions

2.4.3.1.1 J.C. Boyle Dam and Powerhouse

Full removal of the J.C. Boyle Dam and Powerhouse would include removal of the dam, spillway and gates, powerhouse, powerhouse equipment, and concrete fish ladder. This alternative would also include removal of ancillary facilities, such as the canal and pipeline that convey water to the powerhouse. The extensive headcut downstream from the forebay overflow discharge canal would be filled and stabilized with a portion of the material removed from the dam structure. Further, the dam removal entity (DRE) would fill the tailrace (where the powerhouse discharges water) to restore natural river conditions in this area. In order to access the dam for deconstruction, the DRE would perform a controlled reservoir drawdown using the spillway gates, conveyance pipeline and canal, and diversion conduit.

The deconstruction process would begin by gradually drawing down the reservoir. Reservoir drawdown would release water into the concrete canal (the power generation intake), the spillway, and the bypass conduit through the dam depending on the water surface elevation in the reservoir. Water would flow through the Bypass Reach throughout reservoir drawdown. As the reservoir was drawn down, the DRE would remove facilities from the top down. The DRE would start by removing the spillway gates, the spillway bridge, and the upstream concrete intake structure for the powerhouse canal. The DRE would use cranes and excavators for removal, and might also need blasting to remove concrete facilities.

Table 2-11. KHSA Interim Measures Analyzed in the Proposed Action

Interim Measure	Description
IM7- J.C. Boyle Gravel Placement and/or Habitat Enhancement (final 7 years)	PacifiCorp would provide funding for the planning, permitting, and implementation of gravel placement or habitat enhancement projects, including related monitoring, in the Klamath River above Copco Reservoir within 90 days of the effective date.
IM11- Interim Water Quality Improvements	<p>PacifiCorp would fund studies or pilot projects developed in consultation with the Implementation Committee regarding the following:</p> <ul style="list-style-type: none"> • Development of a Water Quality Accounting Framework • Constructed Treatment Wetlands Pilot Evaluation • Assessment of In-Reservoir Water Quality Control Techniques • Improvement of J.C. Boyle Reservoir Dissolved Oxygen <p>PacifiCorp would provide funding for implementation of projects approved by the ODEQ and the State and Regional Water Boards, and to cover project operation and maintenance expenses related to those projects.</p>
IM16 - Water Diversions	PacifiCorp would seek to eliminate three screened diversions from Shovel and Negro Creeks and would seek to modify its water rights as listed above to move the points of diversion from Shovel and Negro Creeks to the mainstem Klamath River.
IM19 - Hatchery Production Continuity	PacifiCorp would evaluate hatchery production options that do not rely on the current Iron Gate Hatchery water supply. The study will assess groundwater and surface water supply options, water reuse technologies or operational changes that could support hatchery production in the absence of Iron Gate Dam. Based on the study results, PacifiCorp would propose a post-Iron Gate Dam Mitigation Hatchery Plan to provide continued hatchery production for eight years after the removal of Iron Gate Dam. ¹
IM20 - Hatchery Funding After Removal of Iron Gate Dam	After removal of Iron Gate Dam and for a period of eight years, PacifiCorp would fund 100 percent of hatchery operations and maintenance costs necessary to fulfill annual mitigation objectives developed by the CDFG in consultation with the NOAA Fisheries Service. ¹

Key:

CDFG: California Department of Fish and Game

IM: Interim Measure

KBRA: Klamath Basin Restoration Agreement

NOAA Fisheries Service: National Oceanic and Atmospheric Administration

ODEQ: Oregon Department of Environmental Quality

Notes:

1. Implementation of IMs 19 and 20 would support the Fish Reintroduction Plans under the KBRA (see Section 2.4.3.10).

The DRE would install a temporary cofferdam to isolate the work area near the spillway to continue deconstruction activities. To the extent possible, the DRE would use debris from deconstruction for the cofferdam. The cofferdams would likely be constructed using a combination of concrete rubble, rock, and earthen materials that would come from the dams. The cofferdam would isolate the left side of the dam to allow the DRE to deconstruct the concrete portion of the spillway using a hoe-ram (an excavator with a hydraulic hammering attachment) or by drilling and blasting. The DRE would also remove other concrete facilities (including the fish ladder, intake structure, power canal, forebay structures, and powerhouse) using a hoe-ram or drilling and blasting.

After reservoir drawdown, the DRE would remove the embankment dam, working from the top down with standard excavation equipment. The DRE would place portions of the excavated rockfill on the upstream embankment to create an isolation cofferdam. After removing the embankment, the DRE would breach the cofferdam and allow materials to naturally erode. For a full description of the deconstruction activities at the Four Facilities see the Detailed Plan which can be found on KlamathRestoration.gov (Reclamation 2012a).

Estimated waste quantities for Full Facilities Removal at the J.C. Boyle facility include 40,000 cubic yards (yd³) of concrete, 140,000 yd³ of earthfill, and 3,000 tons of mechanical and electrical items at the dam. The DRE would fill the original borrow pits on the right abutment of J.C. Boyle Dam with waste concrete and earthfill. The DRE would haul materials on existing unpaved roads to the disposal sites along the cleared transmission line corridor, and place some material within ravines below the transmission lines (see Figure 2-9). The existing haul roads would require some initial clearing and minor improvements. The DRE would grade disposal sites for drainage and revegetate to prevent erosion.

The DRE would use surplus waste concrete and earth materials to fill the eroded scour hole on the hillside below the spillway structure to restore the area to near pre-dam conditions. For the remaining waste that would not be disposed on-site, the DRE would separate reinforcing steel from the concrete and haul the steel to a recycling facility in Klamath Falls, Oregon. The DRE would also haul mechanical and electrical equipment to Klamath Falls to be transferred to a suitable recycling facility outside the project boundaries.

Trapped sediments within the reservoir consist primarily of silts and clays that would be easily eroded and flushed out of the reservoir into the river. Modeling studies indicate that drawdown would erode and flush approximately 27 to 51 percent of the stored sediment from J.C. Boyle Reservoir downstream during the drawdown period (see above call-out box for more information on sediments and erosion). Once eroded from the reservoir, the fine sediment would continue to be suspended in the river water downstream to the ocean. Large quantities of sediment would remain in place after dam removal, primarily on areas above the active channel. The remaining sediments would consolidate (dry out and decrease in thickness) and would decrease the depth of the

Figure 2-9. J.C. Boyle Haul Roads and Disposal Sites.

remaining sediment. Modeling studies show a change in sediment depth of up to 61 percent of original depth (Reclamation 2012b). Similar shrinkage of sediment layers would be expected for Copco 1 and Iron Gate Reservoirs.

2.4.3.1.2 Copco 1 Dam and Powerhouse

Under the Proposed Action, the DRE would remove the entire Copco 1 Dam from canyon wall to canyon wall and five feet below the existing streambed (a total of 130 feet from the top of the dam). Removing all facilities would include removal of the concrete water intake structure, concrete gate houses, penstock pipes and supports, powerhouse, power generation support facilities, switchyard, and unused transmission lines.

The deconstruction process would begin by gradually drawing down the reservoir. Reservoir drawdown would release water through three primary locations: over the spillway, through the penstock pipes, and through the diversion tunnel. Use of the diversion tunnel would require removal of three gates, three valves, and a concrete plug to make it operable. Three new gates would be placed on the diversion tunnel; these could be remotely operated. The concrete dam could safely allow flows that overtop the dam crest during dam removal without dam safety or flood concerns. The DRE would construct multiple “notches” in the dam to allow the reservoir to drain; the notches would be 20-foot wide openings that would be a minimum of 16 feet deep.

As the reservoir was drawn down, the DRE would remove facilities from the top down. The DRE would start by removing the spillway gates and the spillway deck bridge, using cranes and excavators. The DRE would then remove the concrete dam in 8-foot-high sections using drilling and blasting. Dam removal would be challenging because the dam has large boulders embedded in the concrete and is reinforced with steel rails.

After removal of the concrete dam down to the water level, the DRE would construct a cofferdam to isolate one side of the dam and remove water from the working area. The DRE would remove the dry portion of the dam to 5 feet below the existing riverbed and then divert the river through the new opening. The DRE would then isolate the other side of the dam and remove it. The DRE would use mechanical means (such as hydraulic shears that break concrete by shearing it like scissors or an excavator with a hoe-ram attachment) to excavate the reinforced concrete in deck, wall, and floor slabs for remaining features (including powerhouse and diversion intake structure).

The estimated waste quantity for Full Facilities Removal at Copco 1 Dam is 62,000 yd³ of concrete and 1,200 tons of mechanical and electrical items at the dam and powerhouse. The DRE would remove debris from the dam deconstruction, including concrete rubble and reinforcing steel, using a large tower crane on the right side of the river or by hauling from the downstream toe of the dam using trucks. The DRE would bury concrete rubble on the right abutment within an on-site disposal area (see Figure 2-10). After disposal was complete, the DRE would grade the areas for drainage and revegetate to prevent erosion.

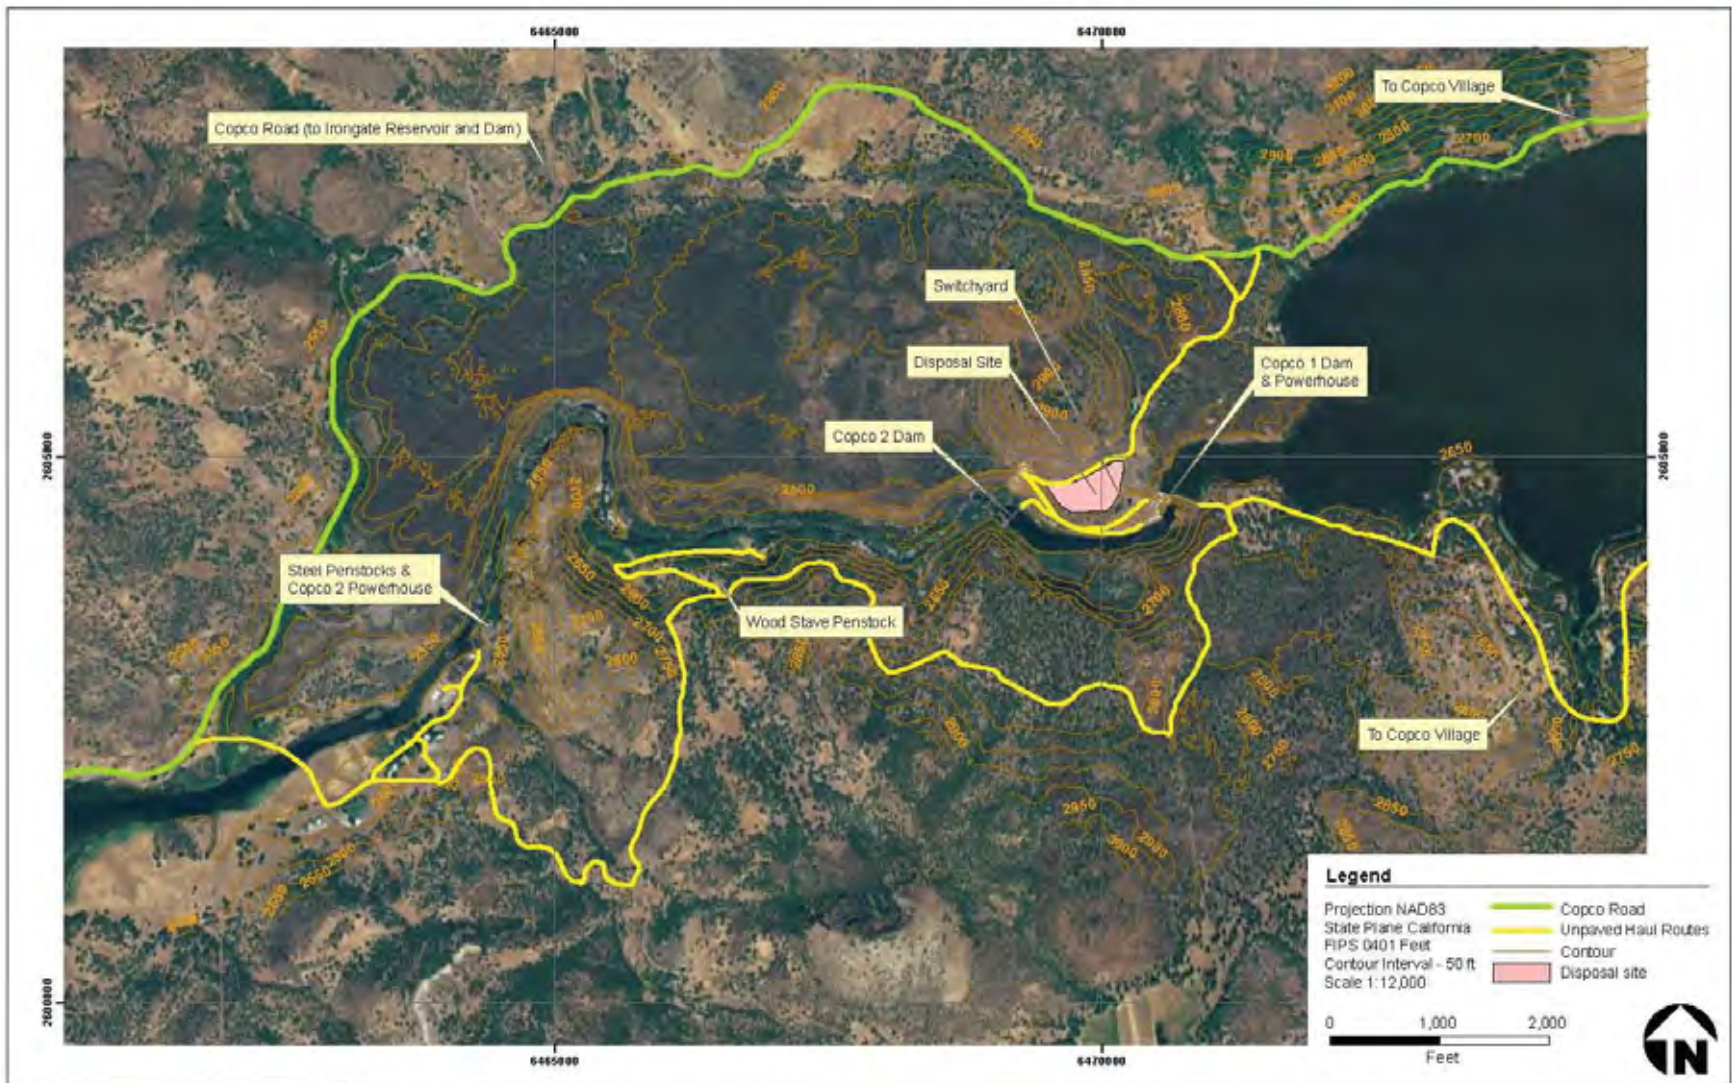

Figure 2-10. Copco 1 and Copco 2 Haul Roads and Disposal Sites.

The DRE would separate reinforcing steel from the concrete and haul it to a local recycling facility in the City of Yreka, California. The DRE would haul mechanical and electrical equipment to the City of Yreka, California for transfer to a salvage company or disposal outside the project boundaries.

The concrete dam and powerhouse are in a steep, narrow canyon. The existing access roads would require substantial upgrades to handle the hauling of excavated concrete and provide access for a large, crawler-mounted crane. Crane access may also be available from the left abutment using existing unpaved roads.

Modeling studies indicate that the initial drawdown would flush approximately 45-76 percent of the 8 million yd³ of the fine sediments (silts and clays) stored behind the dam when the dams are removed (see above call-out box for more information on sediments and erosion). Once eroded from the reservoir, the fine sediment would continue to be suspended in the river water downstream to the ocean. After drawdown, the remaining sediments would consolidate (dry out and decrease in thickness). Copco 1 Reservoir sediments would likely consolidate substantially, which would decrease the depth of the remaining sediment.

2.4.3.1.3 Copco 2 Dam and Powerhouse

The Proposed Action would include removal of the dam, spillway and gates, water intake structure, pipelines, penstock, power generation equipment, and unused transmission lines. The DRE would also reshape the embankment on river right to create a stable slope that blends into the natural hillslopes and river channel. Restoration would include filling in the tailrace channel between the powerhouse and the river to restore natural river conditions. The Copco 2 substation at the powerhouse and a switchyard on a bluff north of the river would remain in service following dam removal.

Because of the small reservoir size, a river diversion and work area isolation plan would be sufficient for dam removal. The DRE would start by removing the spillway gates and the spillway bridge using cranes and excavators. Next, the river flow would be lowered and routed through the spillway gates while a cofferdam would be constructed to isolate the left half of the dam. The river flow would be routed through the right two spillway gates as the left two spillway gates and spillway would be removed using mechanical techniques. The techniques would include use of hydraulic shears or hoe-ram attached to a track-hoe. The shears would be able to cut, or shear through the concrete like scissors while the hoe-ram is able to jackhammer the concrete into small pieces that can be removed. After the left spillway was removed, the river would be diverted through the vacated structure and the right portion of the dam would be removed using similar mechanical techniques. The remaining reinforced concrete walls and water intake structure on the side of the river would be removed after the dam is removed. The power generation water conveyance pipes and powerhouse would be removed using conventional track-hoes and off-road dump trucks.

Copco 2 Dam is a concrete dam in a confined canyon with poor access. The existing access roads would require substantial upgrades to handle the hauling of the excavated

concrete and provide access for a large, crawler-mounted crane. The access bridge across the Klamath River downstream from the powerhouse could require improvements to handle the construction equipment loads.

Estimated waste quantities for Full Facilities Removal at Copco 2 Dam and Powerhouse include more than 12,000 yd³ of concrete, 1,500 yd³ of earthfill, and 2,000 tons of mechanical and electrical items at the dam. The DRE would bury concrete rubble on the right abutment within an on-site disposal area (see Figure 2-10). The DRE would handle and dispose of reinforcing steel, concrete, and mechanical and electrical equipment in the same manner as removal of the Copco 1 facilities. Approximately 550 tons of creosote treated wood from the wood-stave conveyance pipe would have to be transported to an off-site disposal facility 120 miles from the site.

2.4.3.1.4 Iron Gate Dam and Powerhouse

The Proposed Action would include removal of the earthen dam, diversion tunnel gate structure, concrete water intake structure, powerhouse generation facility, penstock and its concrete supports, unused transmission lines, and the switchyard. The DRE would bury the concrete spillway to restore the pre-dam appearance of the right abutment bedrock canyon. Further, the DRE would fill the tailrace (where the powerhouse discharges water) to restore natural river conditions in this area.

The Proposed Action would include removal of the fish handling facilities at the base of the dam, but the Iron Gate Fish Hatchery would remain in place. PacifiCorp would need to identify and secure an alternate water source for the fish hatchery to remain operational because the water supply pipe from the penstock intake structure to the fish hatchery would be removed with the dam. PacifiCorp would fund eight years of hatchery operations after decommissioning of Iron Gate Dam, after which the parties will be responsible for identifying funding for continued operation if necessary.

The DRE would draw down the reservoir by releasing water through the diversion tunnel and into the power generation facilities. The DRE would begin excavation of the embankment on the very narrow top section, which would be a slow process because of the confined work area. As the excavation worked down from the top, the width of the excavation footprint would be wider and additional equipment could be used. The DRE would remove the riprap during embankment excavation. The DRE would then remove reinforced concrete from remaining structures (including intake structures, fish handling facilities, and powerhouse) using mechanical methods if possible (or drilling and blasting if necessary). The construction of temporary cofferdams would be necessary to divert water when removing the base of the dam and create isolated work areas. These cofferdams would be built using materials from the dam removal process and removed upon completion of the work.

Estimated waste quantities for full removal of Iron Gate Dam and powerhouse include 12,000 yd³ of concrete, 1.1 million yd³ of earthfill, and 1,000 tons of mechanical and electrical items at the dam and powerhouse. Removal would also generate waste from four buildings with a combined area of 2,300 square feet.

An original borrow site approximately 0.75 miles upstream of the dam on the left abutment would serve as a disposal site for earth and concrete waste (see Figure 2-11). Another disposal site would be the existing concrete-lined side-channel spillway, chute, and terminal structure, which could accept up to 300,000 yd³ of excavated material. As the excavation descended, the DRE would need to construct ramps out of the canyon. The DRE would stockpile some rockfill for later use as slope protection for the upstream cofferdam. The DRE would dispose of reinforcing steel, concrete, and mechanical and electrical equipment in the same manner as for the Copco 1 and Copco 2 sites.

Existing haul roads would require improvements to handle two-way traffic of large construction equipment between the dam and the disposal site. The access bridge across the Klamath River downstream from the dam could also require improvements to handle the construction equipment loads.

Modeling studies indicate that this drawdown would flush 24 to 32 percent of the trapped sediments in the reservoir (primarily silts and clays) (see above call-out box for more information on sediments and erosion). Once eroded from the reservoir, the fine sediment would continue in suspension all the way to the ocean. The remaining sediments would consolidate after drawdown, and restoration efforts would stabilize the remaining sediment.

2.4.3.2 Schedule

The DRE would begin preparatory work in May 2019. The initial schedule for this alternative would stop power generation at the Iron Gate and J.C. Boyle facilities on December 31, 2019. Power generation would stop at Copco 2 Powerhouse in April 2020 and would cease at Copco 1 in October 2019. Table 2-12 shows the schedule to draw down J.C. Boyle, Copco 1, and Iron Gate Reservoirs. (Copco 2 has no drawdown limitations or sediment stored in the reservoir.) The Lead Agencies designed drawdown rates to protect slope stability, public safety, and structures near the reservoirs. The drawdown periods were scheduled to avoid sediment release into downstream areas during critical times for sensitive aquatic species. The end dates in Table 2-9 may vary depending on year type; these dates reflect an average water year, but the draw down might be longer in wet years or shorter in dry years.

Table 2-12. Drawdown Plans for J.C. Boyle, Copco 1, and Iron Gate Reservoirs

	J.C. Boyle	Copco 1			Copco 2	Iron Gate
		Phase 1	Phase 2	Phase 3		
Start Date	1/1/2020	11/1/2019	1/1/2020	2/15/2020	6/1/2020	1/1/2020
Starting Elevation (feet)	3,793	2,606	2,590	2,529	2,484	2,328
End Date	2/1/2020	11/17/2019	2/11/2020	3/15/2020	6/30/2020	2/11/2020
Ending Elevation (feet)	3,762	2,590	2,529	2,484	2,460	2,202
Average Drawdown (feet/day)	1	1	1.5	1.5	0.8	3

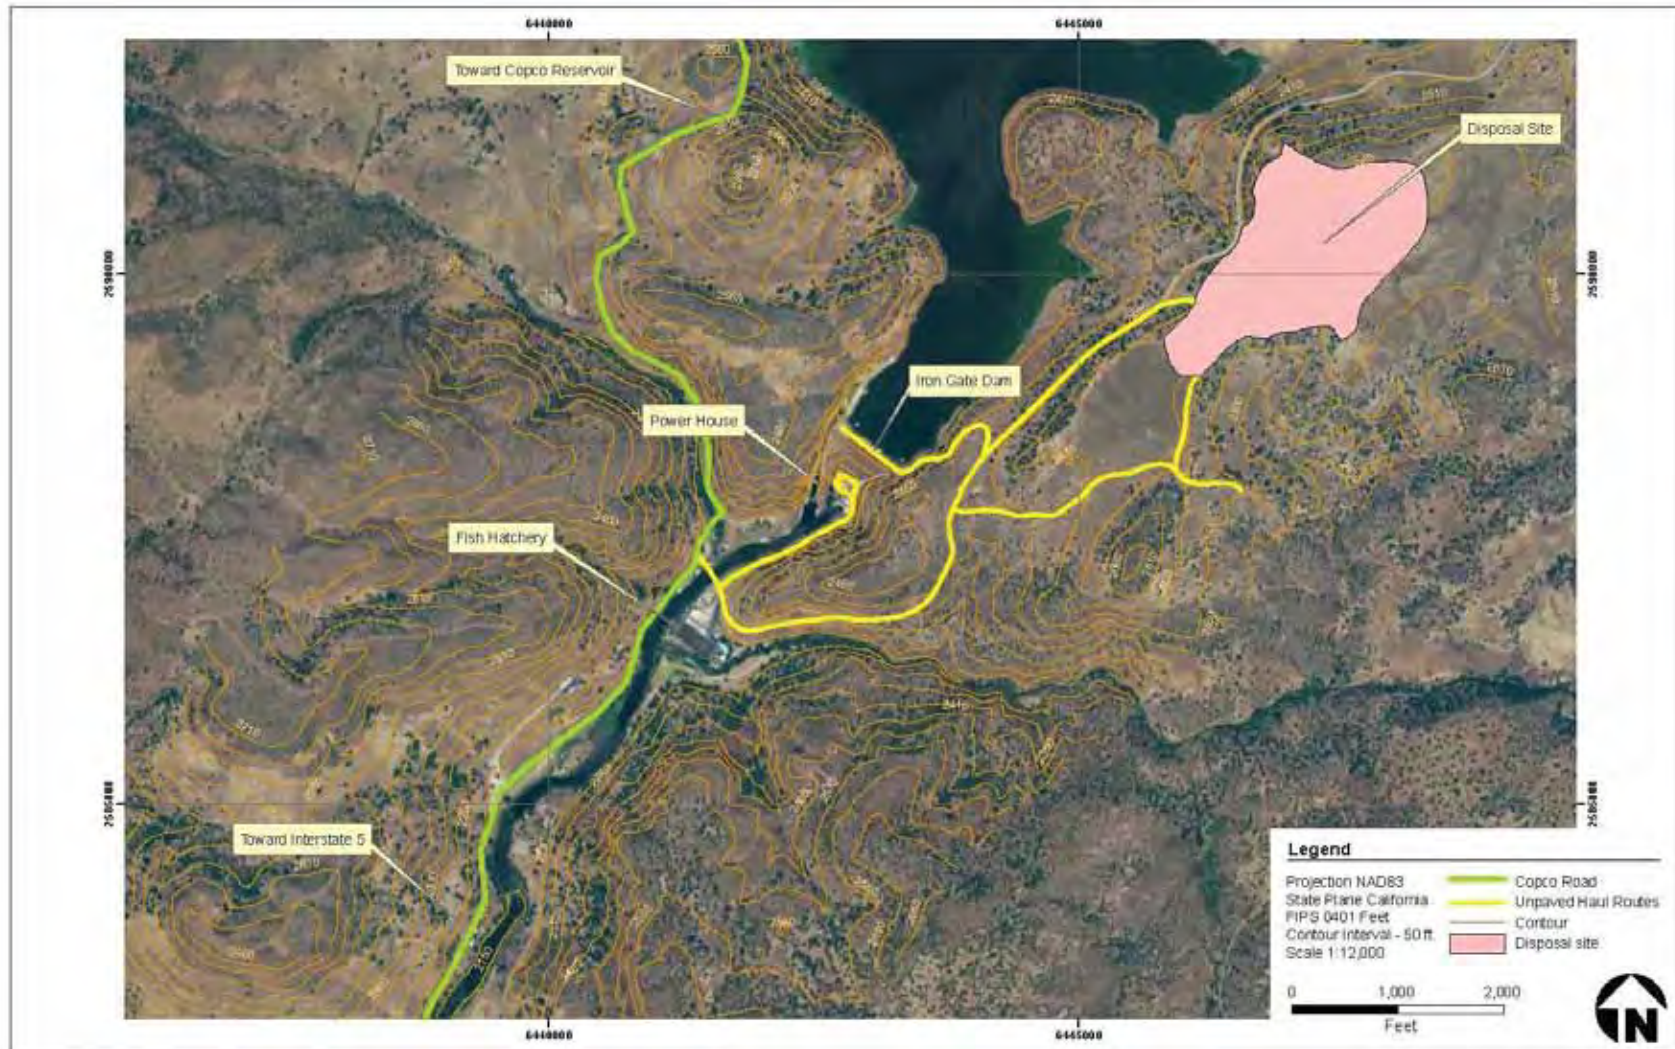

Figure 2-11. Iron Gate Haul Roads and Disposal Sites.

Figure 2-12 provides a schedule for the Proposed Action based on construction requirements for removal.

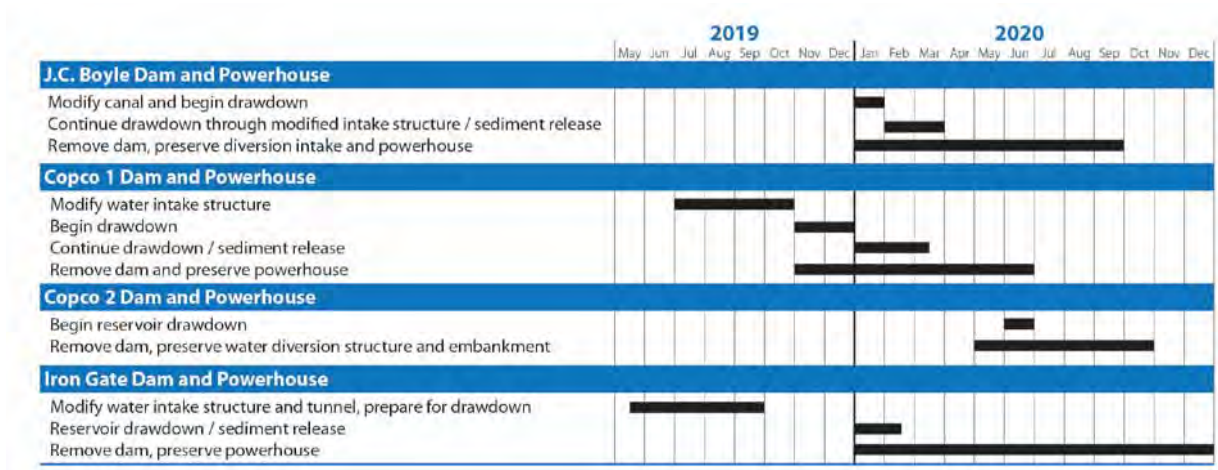

Figure 2-12. Anticipated Schedule for Full Facilities Removal.

2.4.3.3 Workforce

The size of the construction workforce at each site would vary, and the peak times for construction would be staggered. Table 2-13 shows the construction workforce needed for the Proposed Action.

Table 2-13. Workforce Projections for the Proposed Action

Facility	Estimated Average Construction Workforce	Duration	Estimated Peak Workforce	Peak Period
J.C. Boyle	25 to 30 people	10 months	40 - 45	Jul 2020 - Sep 2020
Copco 1	30 to 35 people	12 months	50 - 55	Nov 2019 - Apr 2020
Copco 2	25 to 30 people	7 months	35 - 40	May 2020 - Aug 2020
Iron Gate	35 to 40 people	18 months	75 - 80	Jun 2020 - Sep 2020

2.4.3.4 Environmental Measures

The Lead Agencies have several standard procedures and management practices that they incorporate into projects to avoid adverse effects to the environment. Key elements of these measures are summarized below, and a more complete description is presented in Appendix B. All the procedures and practices identified in this EIS/EIR are incorporated into each action alternative analyzed in this EIS/EIR.

2.4.3.4.1 Best Management Practices

For all deconstruction and/or construction activities, the DRE would implement standard pollution prevention measures as part of project design specifications and standard construction practices. These measures would include the following:

- (1) Storm water erosion and sediment control measures for all deconstruction and/or construction activities;
- (2) Proper control of non-stormwater discharges;
- (3) Water application to exposed soil surfaces in active construction areas at least three times per day when needed for dust abatement; and
- (4) Hazardous spill prevention and response measures.

The Proposed Action would include the transfer of PacifiCorp land surrounding the Four Facilities (Parcel B lands) to a State agency. This agency would install fencing around these lands for the purposes of land management. It would prevent cattle access but would allow wildlife to pass.

2.4.3.4.2 Terrestrial Resource Avoidance

The DRE would take actions to avoid impacts that could include fencing wetlands, training employees about species present, excluding workers and construction activities on areas with sensitive species, and filling trenches and holes quickly to avoid trapping wildlife. Measures would be implemented during construction to avoid or reduce impacts to special-status birds and migratory birds in compliance with the Endangered Species Act, Bald and Golden Eagle Protection Act, and the Migratory Bird Treaty Act. Specific avoidance measures would be developed in consultation with California Department of Fish and Game (CDFG), Oregon Department of Fish and Wildlife (ODFW), and USFWS.

2.4.3.4.3 Repair Road Damage

The DRE would repair any construction-related damage to surrounding roads.

2.4.3.4.4 Health and Safety Plan

The DRE would prepare and implement a worker Health and Safety Plan prior to the start of construction activities.

2.4.3.4.5 Hazardous Materials Disposal

If hazardous materials are encountered during construction or deconstruction activities, the DRE would use protocols for proper handling, transport, and disposal of the materials.

2.4.3.4.6 Traffic Signs

The DRE would install signs to route construction traffic and warn other motorists about construction activities.

2.4.3.4.7 Work Area Isolation for Dam Removal

The DRE would need to control water and isolate the work area from flowing water and aquatic organisms throughout the duration of construction. The DRE could control water in most areas using gravity diversions; however, pumps could be required to dewater

isolated ponding. Pumps would be screened to prevent entrainment of fish. Prior to pumping, the DRE would conduct a fish rescue, as described below, within the screened area isolating the pump.

The DRE would work in wet conditions in areas that cannot be dried. For in-water work, physical barriers would isolate the work area. Barriers would consist of bulk bags, which are fabric bags filled with sand or gravel that can be stacked as “bricks” to temporarily isolate work areas. Alternately, the DRE could use steel sheets, concrete blocks, gravel berms, inflatable berms or plastic sheeting as physical barriers to isolate work areas. All barriers would be temporary, and would be removed after completing work.

A fish rescue would be conducted in all areas that cannot be drained in a manner that allows fish to volitionally depart the area. Fish rescue activities would follow each State’s regulations, rules, and policies and would be in accordance with the NOAA Fisheries Service and USFWS biological opinions on the Proposed Action.

2.4.3.5 Reservoir Restoration

Under the Proposed Action, there would be substantial erosion of the reservoir sediment while the reservoirs were being drawn down. The eroded sediment would then be transported downstream. Following drawdown of the reservoirs, the DRE would complete restoration actions including revegetation, recreation area maintenance, and recreation area decommissioning, described in this section.

Following drawdown of the reservoirs, revegetation efforts would be initiated to support establishment of native wetland and riparian species on newly exposed reservoir sediment. Access for ground application equipment is expected to be limited immediately following drawdown due to terrain, slope, and sediment instability. Upper areas would be reseeded from a barge until the reservoir levels become too low to operate and access the barge. As the reservoirs are drawn down trucks will be used to apply hydroseed to all accessible areas. Aerial application would be necessary for precision applications of material near the sensitive areas and the newly established river channel, as well as in the remaining areas inaccessible by barge or truck.

Additional fall seeding might be necessary to supplement areas where spring hydroseeding was unsuccessful. In cases where mulch moved/degraded or otherwise exposed bare soil, aerial hydroseeding would be used again for the fall re-seeding. In other cases, where establishment failed, yet the mulch remained intact, new seed material applications might need to be incorporated in order to re-establish seed/soil contact sufficient for germination.

2.4.3.5.1 J.C. Boyle

Sediment in J.C. Boyle Reservoir is concentrated in the historical active channel and most of the sediment is near the dam. During drawdown, most of the sediment near the dam would be eroded from the reservoir area given the steep slopes on the reservoir floor. After drawdown, there would be minor amounts of sediment consolidation on the

floodplain areas. Herbaceous species would be planted or would naturally recruit in the spring following drawdown. Woody species would gradually establish on the river terraces as they propagated from the outer edges of the reservoir.

2.4.3.5.2 Copco 1

Among the reservoirs that would be removed, Copco 1 Reservoir contains the majority of the sediment and is the widest of the reservoirs. Most of the erosion would be focused in the main channel of the Reservoir where the thickness of the remaining sediment would be the greatest. Significant alluvial surface (the benches) would be exposed with drawdown of Copco 1. However, it is possible that reservoir sediment would remain in some of the side channels, particularly if dam removal occurred in a dry year.

After drawdown, the remaining sediments would begin to consolidate and decrease in thickness. Sediment erosion analysis indicates that allowing one high flow event (greater than 7,000 cfs) to pass through the reservoir area would minimize the need for sediment excavation after reservoir drawdown as part of the restoration effort. The erosion processes would be expected to occur during the winter season during the drawdown effort when the sediment would be the most erodible. Reestablishment of herbaceous species would occur soon after the revegetation in the spring. Woody species would be planted along the river banks and would establish over a period of years.

2.4.3.5.3 Iron Gate

The reservoir sediment at Iron Gate Reservoir is relatively thin and the only thicknesses over 5 feet were found in the Jenny Creek delta. The river corridor is relatively narrow throughout the Iron Gate reach and the side slopes of the reservoir area are mostly steeper than 20 percent, with a substantial area steeper than 40 percent. Most of the sediment remaining after dam removal would be less than 3 feet thick.

There are far fewer alluvial surfaces in Iron Gate Reservoir than there are in Copco 1 Reservoir, and the resulting riparian corridor would be much narrower at Iron Gate Reservoir than at Copco 1 Reservoir. The tributaries are heavily vegetated with woody species upstream of Iron Gate Reservoir (Philip Williams & Associates 2009) and the tributaries are expected to reestablish a similar riparian and geomorphic condition in the exposed reservoir areas.

2.4.3.6 Recreation Facilities

The Proposed Action would change recreational opportunities from lake-based recreation to river-based recreation. Table 2-14 shows the change to existing facilities under the Proposed Action.

2.4.3.7 Keno Transfer

As a connected action to removal of the Four Facilities, PacifiCorp would transfer ownership and operational responsibility of the Keno facility to the DOI. Reclamation is working with PacifiCorp on an Agreement in Principle for the transfer. They have a draft agreement, which will be further developed in preparation for a possible Affirmative Determination.

Table 2-14. Recreation Facilities under the Proposed Action

Site Name	Existing Facilities	Facilities Following Dam Removal
<i>Sites at J.C. Boyle Reservoir (Oregon)</i>		
Pioneer Park	Two day-use areas with picnic tables, fire rings, and portable toilets	All facilities would be removed
Topsy Campground	Campground, day-use area, boat launch	Site would be converted to river access facility. Boat ramp would either be extended to the river channel or removed. Other facilities would remain.
<i>Sites at Copco 1 Reservoir (California)</i>		
Mallard Cove	Day-use picnic area and boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted.
Copco Cove	Picnic area and boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted.
<i>Sites at Iron Gate Reservoir (California)</i>		
Fall Creek Trail	Day-use area and trail	This site would remain. There would be no improvements or changes.
Jenny Creek	Day-use area and campground	This site would remain. There would be no improvements or changes.
Wanaka Springs	Day-use area, campground, boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Camp Creek	Day-use area, campground, boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Juniper Point	Primitive campground and boat dock	All facilities would be removed. Parking area would be regraded, seeded, and planted
Mirror Cove	Campground and boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Overlook Point	Day-use area	All facilities would be removed. Parking area would be regraded, seeded, and planted
Long Gulch	Picnic area and boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Dutch Creek	Day-use area	All facilities would be removed. Parking area would be regraded, seeded, and planted
Iron Gate Fish Hatchery Public use Area	Day-use area and boat launch	This site would remain. There would be no improvements or changes.

Source: Reclamation 2011

Prior to the transfer, any necessary improvements to the facility in order to meet DOI Directives and Standards for dam safety would be completed. Prior to the transfer, the facility would be operated under the terms of the existing contract signed in 1968 between PacifiCorp and Reclamation. Following the transfer, DOI would continue to operate the facility consistent with the terms of the same contract and with historic practices (KHSAs Sections 7.5.3 and 7.5.4). Thus, operations under DOI would be consistent with the historic operations of the facility in place since the existing contract was signed on January 4, 1968; therefore, there would be no changes to operations or the surrounding areas as a result of the transfer. Future upgrades at the Keno facility by DOI

(such as a new fishway) would be subject to additional NEPA compliance. Potential seasonal trap and haul operations around Keno Dam would be part of the KBRA, as described in Section 2.4.3.10.

2.4.3.8 East and Westside Facilities – Programmatic Measure

In the event of an Affirmative Secretarial Determination and as a connected action to removal of the Four Facilities, PacifiCorp would apply to FERC for a partial surrender of its license of the East and Westside facilities in order to decommission the generating facilities (KHSA section 6.4.1(A)). Under a plan outlined in the KHSA, PacifiCorp would be responsible for the decommissioning and for recovering its costs through “standard ratemaking procedures” (KHSA 6.4.1(B)). Once the decommissioning is completed, the lands associated with the East and Westside facilities would be disposed of in accordance with the KHSA.

The two facilities were proposed for decommissioning in PacifiCorp’s 2004 relicensing application. Removing the two facilities would result in the loss of 3.8 megawatts (MW) of generating capacity and the removal of the generating infrastructure. The dams and associated infrastructure were built in 1921, and would require upgrading and maintenance to remain in compliance with DOI and FERC standards. The Link River Dam, which is the point of diversion for the two generating facilities, is already owned by Reclamation. There would be no diversions at Link River Dam after decommissioning.

2.4.3.9 City of Yreka Water Supply Pipeline Relocation – Programmatic Measure

The City of Yreka’s Water Supply Pipeline passes under the upstream end of the Iron Gate Reservoir and would become exposed to high-velocity river flows after dam removal that would damage the pipeline and require its relocation. The exact details of the pipeline relocation have not yet been determined at the same level of detail as the rest of the Proposed Action; therefore, this measure is analyzed at a programmatic level of detail. Reconstructing the pipe further under ground would likely require digging in bedrock, which would be complicated and expensive. For the purposes of this analysis, the EIS/EIR assumes the DRE would construct a new, elevated pipeline and steel pipeline bridge to support the pipe above the river. The prefabricated steel pipe bridge would be wide enough to accommodate the pipeline and walkway on the deck. The pipeline bridge would likely be three spans with a center span of 200 feet and two end spans of 100 feet. The spans would be supported on concrete piers. The new pipeline would be connected to the existing buried pipeline at each end of the bridge. In order to avoid a disruption to the City of Yreka’s water supply, the permissible outage period would be limited to 12 hours and would need to occur during the winter. The permissible outage period would be based on the available storage tank capacity for the City of Yreka Pipeline, which should be able to meet supplies for up to 72 hours in the winter (Taylor 2010). Subsequent detailed evaluation and continued consultation with the City of Yreka could change the configuration of the pipeline; additional environmental compliance will be completed as necessary.

2.4.3.10 KBRA – Programmatic Measures

As described in Chapter 1, the Federal lead agency is analyzing the KBRA as a connected action. The Klamath Basin Restoration Agreement (KBRA) is also a negotiated agreement that reflects a basin-wide approach to addressing the current resources challenges. The KBRA was negotiated concurrently with the KHSA and has been signed by most of the parties to the KHSA, but the Federal agencies are not yet parties to the KBRA. The KBRA will be signed by Federal agencies when Congress authorizes them to do so.⁴ The complete KBRA package entails various commitments and actions that have been or will be proposed and/or undertaken in the basin by Federal, State, local, tribal, and private interests. Some of the KBRA actions could have effects (whether adverse or beneficial) on the same environmental resources that would be affected by dam removal. Some KBRA actions are expressly preconditioned by and therefore hinge upon dam removal, and an Affirmative Secretarial Determination. Some KBRA actions are Federal but are not expressly linked to dam removal, and some actions involve only non-Federal parties.

2.4.3.10.1 NEPA-Specific Analysis

The Federal Lead Agency, the DOI, is analyzing the KBRA as a connected action to the proposed Secretarial Determination under the KHSA. NEPA defines connected actions as those actions that are closely related to or cannot or would not proceed unless other actions are taken previously or simultaneously (40 CFR 1508.25(a)(1)(ii)).⁵ Some actions or component elements of the KBRA are independent obligations and thus have independent utility from the KHSA, but the implementation of several significant elements of the KBRA would be different, if the Secretarial Determination under the KHSA is not to pursue full dam removal. Recognizing that implementation of many elements of the KBRA are unknown and not reasonably foreseeable at this time, the connected

NHPA Section 106 Process

DOI elected to utilize the NEPA process to meet the Federal requirements of Section 106 of the National Historic Preservation Act (NHPA) as allowed under 36 CFR Section 800.8(c). DOI defines the undertaking, for purposes of Section 106 of the NHPA, as the removal of the four PacifiCorp dams which may be a result of the Secretarial Determination. The proposed undertaking has the potential to affect historic properties triggering compliance with Section 106 of the NHPA. The analysis and consultations concerning any effects of the Proposed Action and alternatives on historic properties are integrated into the NEPA review and documentation pursuant to the criteria identified in 36 CFR Section 800.8(c)(1)-(4).

⁴ Under the KHSA and KBRA (Agreements) certain agencies of the United States (“Federal Agency Parties”) shall become parties to the KBRA upon enactment of authorizing legislation that authorizes and directs them to become parties (KBRA Section 1.2.2).

⁵ We acknowledge, however, that the KBRA could also be analyzed as a cumulative or similar action under 40 CFR 1508.25(a)(2) and (3). We note that all three definitions (connected action, cumulative actions, and similar actions) are within the section that provides parameters for the “scope” of the action, which determines both the range of alternatives and the impacts to be considered in an EIS. Ultimately, however, we believe the important point is not the labeling but the analysis and whether the decision (in this case whether to remove four dams) is informed by a EIS that is proper in scope.

action analysis under NEPA is being undertaken at a programmatic level. Consequently, appropriate future project-level analysis under NEPA would be completed for the KBRA in the future as project-specific proposals are developed and no Federal action regarding KBRA implementation would be made pursuant to the analysis in this document.

For purposes of this analysis, the KBRA, a connected action, is viewed as a whole program even though some of its component parts are currently being implemented (those without a Federal nexus or not subject to environmental review) or could be implemented on an individual basis without dam removal. One of the reasons why the KBRA is treated as a whole for purposes of this EIS/EIR is that the individual activities under the KBRA would be implemented, through adaptive management and in close coordination with committees comprised of stakeholders, in a manner that seeks to attain synergy and optimize benefits through a coordinated, holistic approach to restoration and water management. Implementing those KBRA activities that are not connected to facilities removal on an individual basis without the benefit of adaptive management and stakeholder input would likely not optimize benefits.

2.4.3.10.2 CEQA-Specific Analysis

CDFG, as Lead Agency under CEQA, is also analyzing relevant parts of the KBRA in a programmatic fashion, as described in Section 15168 of the CEQA Guidelines. This decision was made because many of KBRA's component elements have not been specified to a degree where the associated impacts would be reasonably foreseeable for purposes of this environmental analysis. The parties recognize that future project-specific analysis may be required for various components of the KBRA as they become more clearly defined and when a public entity, as defined by CEQA Guidelines Section 15379, identifies a discretionary approval pursuant to CEQA Guidelines Section 15378, which would obligate subsequent review. A program-level document is appropriate when a project consists of a series of smaller projects or phases that may be implemented separately. Under the programmatic EIR approach, future projects or phases may require additional, project-specific environmental analysis. It should also be noted that this EIR makes certain assumptions about the foreseeable effects of KBRA based on existing information, including, among other things, how the fishery and water resources programs may be designed and implemented. CDFG recognizes that subsequent environmental analysis may be required by any California public entity with an approval or permitting obligation if the circumstances specified by CEQA Guidelines Section 15162(a) are triggered.

Importantly, CDFG could have analyzed the associated impacts of the KBRA relative to the KHSAs in the indirect and cumulative impacts analysis portion of the KHSAs EIR as it is not affirmatively approving or carrying out any one aspect of the KBRA that would be subject to environmental review. CDFG recognizes it is not “approving” any discretionary portion of the KBRA that could alter the physical environment and that by signing the KBRA it has already executed and committed to the agreement itself. Thus, similarly to the EIS, there are no alternatives that consider what a new or revised KBRA might look in the event dams are not removed. Rather, to avoid confusion, duplication, and wasted resources, CDFG has determined that the concurrent and connected nature of

the KBRA to the KHSA warrants a clear understanding of its potentially significant impacts and that the approach of programmatic analysis is equally, if not more, sufficient for providing that information to decisionmakers.

Thus, out of an abundance of caution, and to ensure full transparency, CDFG has agreed to consider significance determinations for the KBRA in a programmatic fashion. Recognizing that elements of the Proposed Action would occur in California and Oregon, CDFG collaborated with DOI, with input from the State of Oregon, to make a reasonable, good faith effort in disclosing all significant environmental effects of the Proposed Action. Absent certain circumstances, CEQA does not apply to any project or portion thereof located outside of California which will be subject to environmental review pursuant to NEPA. (Public Resources Code § 21080(b)(14); CEQA Guidelines § 15277). CDFG considers the Proposed Actions by California to be implementation of the KHSA and thus has crafted alternatives only for dam removal itself, assuming that absent full or partial facilities removal the relevant elements of the KBRA will no longer be ascertainable. CDFG recognizes that in the event subsequent analysis is deemed appropriate, it will be required to consider any feasible alternatives, mitigation measures, and any other elements required by CEQA as the basis for any approval of such KBRA project or phase in accordance with existing law.

2.4.3.10.3 Implementation

Non-Federal parties who have signed the KBRA include states, tribes, counties, irrigators, and other organizations (Table 2-15). Prior to the enactment of Federal authorizing legislation, Federal agencies are not parties to the KBRA. However, DOI, NOAA Fisheries Service, and the United States Department of Agriculture have each expressed their intent to take actions consistent with the KBRA to the extent that such actions are consistent with the agency's existing legal authorities and appropriations available for such purposes. These Federal agencies have each sent separate letters to the non-Federal parties expressing this intent. Upon the enactment of authorizing legislation, NOAA Fisheries Service, United States Forest Service (USFS), Bureau of Indian Affairs, Bureau of Land Management, Reclamation, and the USFWS would become parties to the KBRA. Additional appropriations would likely be necessary for these agencies to fully implement their responsibilities under the agreement.

The “interim period” is the time between the signing of the KBRA and full implementation of the limits on water diversions to Reclamation's Klamath Project. The events that must occur to allow the full implementation of water diversion limits include the removal of the Four Facilities under the KHSA as well as other conditions listed in KBRA Sections 15.3.4 and 15.3.1.A.

While the water diversions to Reclamation's Klamath Project users are not enforceable during the interim period, water diversions would conform to the limits described below in the Diversion Limitations section as closely as possible. Until the On-Project Plan is fully implemented, it might not be possible for water to be managed consistent with the diversion limitations in all years because there are an insufficient number and amount of water measuring devices and control structures.

Table 2-15. Non-Federal Parties to the KBRA

Karuk Tribe	Malin Irrigation District
Klamath Tribes	Midland District Improvement Company
Yurok Tribe	Pioneer District Improvement Company
California Department of Fish and Game	Plevna District Improvement Company
California Natural Resources Agency	Reames Golf and Country Club
Oregon Department of Environmental Quality	Shasta View Irrigation District
Oregon Department of Fish and Wildlife	Sunnyside Irrigation District
Oregon Water Resources Department	Tulelake Irrigation District
Humboldt County, California	Van Brimmer Ditch Company
Klamath County, Oregon	Randolph and Jane Walthall 1995 Trust
Ady District Improvement Company	Westside Improvement District #4
Collins Products, LLC	Winema Hunting Lodge, Inc.
Enterprise Irrigation District	Upper Klamath Water Users Association
Don Johnston & Son	American Rivers
Inter-County Properties Company	California Trout
Klamath Irrigation District	Institute for Fisheries Resources
Klamath Drainage District	Northern California/Nevada Council Federation of Fly Fishers
Klamath Basin Improvement District	Pacific Coast Federation of Fisherman's Associations
Klamath Water Users Association	Salmon River Restoration Council
Klamath Water and Power Agency	Trout Unlimited
Bradley S. Luscombe	

Programs or activities that are scheduled to occur prior to the enactment of authorizing legislation would be conducted under existing authorities. However, implementation of most interim period activities would be dependent on approval by Congress of appropriate authorizing legislation and/or funding.

With enactment of authorizing legislation there would be the potential for additional funding to enhance some of the ongoing programs. In Table 2-16, programs that are ongoing and could be potentially increased in magnitude or would be accelerated in schedule with implementation of the KBRA are noted.

The plans and programs described in the KBRA lead through a series of milestones that culminate in the formal relinquishment of claims for damages, permanent assurances related to tribal water rights, and limitations on water diversions to

Reclamation’s Klamath Project. Long-term implementation would occur after the full implementation of the water diversion limitations.

The KBRA does not supersede existing Federal laws such as NEPA and ESA. Programs to be developed and implemented under the KBRA would still be subject to review and analysis and would need to comply with local, state, and Federal statutory authorities.

The programs proposed by the KBRA and shown in Table 2-16 are considered to be connected to the Proposed Action (except as noted). This list includes plans and programs that would only be implemented through enactment of authorizing legislation and/or approval of funding at the Federal and State levels, as well as, ongoing programs that would be enhanced by additional funding resulting from authorizing legislation. The portion of ongoing actions that would be amplified following enactment of authorizing legislation are considered a part of the Proposed Action and the portion that would be implemented regardless is considered under the No Action/No Project Alternative as noted above in Section 2.4.2.

Notes

1. This table is being provided for purposes of this analysis only and is not a determination of which programs may or may not be implemented or funded under existing authorities. Additionally, implementation under existing authorities may not fully provide the negotiated benefits for certain entities, and therefore new authority is needed to fully implement the program in the manner anticipated by the KBRA.
2. "Plans" include both the development of the plan and/or the implementation of the plan.
3. Ongoing fish habitat restoration activities and monitoring are part of the No Action/No Project because they are currently being conducted under current authorities and funding. The scope of these activities would be increased in magnitude and accelerated through implementation of the KBRA. Habitat restoration and monitoring under the Proposed Action would be guided by the Fisheries Restoration Plan and Fisheries Monitoring Plan to be developed under the KBRA.
4. Action is considered part of the No Action/No Project Alternative.
5. Development of additional storage would occur with implementation of KBRA and associated funding.
6. During the interim period, water diversion limitations to Reclamation's Klamath Project users would conform to the limits described in the Diversion Limitations section as closely as possible. However, before full implementation of the On-Project Plan, it might not be possible to fully comply with the diversion limitations in all years.
7. Groundwater Technical Investigations and Climate Change Assessment are on-going and could be increased in magnitude and accelerated through implementation of KBRA. However these KBRA Programs propose studies or planning efforts that do not constitute new actions with the potential to affect the environment and therefore receive only limited treatment in this EIS/EIR.

2.4.3.10.4 Fisheries Program

The Fisheries Program of the KBRA has three main goals:

- A. Restore and maintain ecological functionality and connectivity to historic habitat.
- B. Re-establish and maintain naturally sustainable and viable populations of fish to the full capacity of the restored habitats.
- C. Provide for full participation in harvest opportunities.

To meet these goals, the parties to the KBRA agreed to prepare and implement fisheries restoration, reintroduction and monitoring plans and to provide additional sources of instream water to support fish.

Fisheries Restoration Plans

The Phase I Fisheries Restoration Plan is intended to establish restoration priorities and criteria for restoration project selection for the immediate future through 2020 (KBRA Section 10.1). The plan is to be prepared by basin Fish Managers who are defined in the KBRA as Federal, State, or tribal agencies that have responsibility under applicable laws to manage one or more fish species or their habitat in the Klamath Basin. USFWS and NOAA Fisheries Service are to be the co-leads for administrative tasks related to the preparation of both the Phase I and Phase II Restoration Plans. Under the schedule anticipated in the KBRA, the Phase I Plan would be completed in March 2012.

The effectiveness of Phase I restoration activities would be monitored under the Fisheries Monitoring Plan. Monitoring results would be used in the development of the Phase II Restoration Plan to adjust the recommended mix of restoration activities, priorities, and/or project locations to more effectively restore aquatic habitats. The Phase II Fisheries Restoration Plan would establish long-term restoration priorities and an adaptive management process to maintain fish restoration through 2060. The Draft Phase II Restoration Plan is to be prepared within 7 years of the finalization of the Phase I plan, and a final plan is to be completed by March 31, 2022 (KBRA Section 10.2).

Implementation of the Phase I plan could include actions for restoration of existing fisheries in the upper basin, as well as actions necessary to prepare for reintroduction of anadromous fish upstream of Iron Gate Dam. Specific elements could include restoration and protection of riparian vegetation, water quality improvements, restoration of stream channel functions, measures to prevent excessive sediment inputs, remediation of fish passage blockages, and prevention of entrainment into diversions (KBRA Section 10.1.2). See Table 2-17 for a geographic breakdown of when and where restoration activities would occur.

Restoration activities similar to the general classes of actions described in the KBRA currently occur throughout the basin as funding is available. It is also expected that the Phase I Restoration Plan would build upon existing activities and identified restoration needs and that implementation would include the same types of restoration activities that are currently conducted within the basin. Activities would be prioritized under the Plan and additional funding that may become available under the KBRA would allow greater improvements to be realized than would occur without the KBRA.

Restoration activities are being conducted downstream from Iron Gate Dam on the mainstem and tributaries as well as in the upper basin subject to funding availability. The same types of activities would be expected to be conducted under the KBRA fish restoration program and would include the following types of work:

- Floodplain rehabilitation work includes activities to improve or restore connections between channels and floodplains to create and maintain off-channel habitat accessible to overwintering juvenile salmonids. Floodplain rehabilitation could include activities such as riparian planting and understory thinning, to facilitate the development of mature riparian stands that would provide shading and large and small wood to stream channels and floodplains; wetland restoration; and levee setback or dike removal to reconnect floodplain hydrology.

Table 2-17. KBRA Fisheries Restoration Projects

KBRA Project	Anticipated Schedule
Preparation Phase I Restoration Plan	2012–2013
Preparation Phase II Restoration Plan	2018–2019
Williamson River Aquatic Habitat Restoration	2012–2021
Sprague River Aquatic Habitat Restoration	2012–2021
Wood River Aquatic Habitat Restoration	2012–2021
Williamson Sprague Wood Screening Diversion	2012–2014
Williamson and Sprague USFS Uplands	2012–2021
Upper Klamath Lake Aquatic Habitat Restoration	2012–2021
Screening of Upper Klamath Lake Pumps	2012–2014
Upper Klamath Lake Watershed USFS Uplands	2013–2016
Keno Impoundment/Lake Ewauna Water Quantity Studies and Remediation Actions	2012–2021
Keno Impoundment/Lake Ewauna Wetlands Restoration	2013–2017
Keno to Iron Gate Upland Private and Bureau of Land Management	2012–2021
Keno to Iron Gate Upland USFS (Goosenest)	2012–2021
Keno to Iron Gate Mainstem Restoration	2012–2021
Keno to Iron Gate Tributaries – Diversions and Riparian	2016–2018
Shasta River Aquatic Habitat Restoration	2012–2021
Shasta River USFS Uplands	2012–2021
Scott River Aquatic Habitat Restoration	2012–2021
Scott River USFS Uplands	2012–2021
Scott River Private Uplands	2013–2019
Mid-Klamath River and Tributaries (Iron Gate to Weitchpec) Aquatic Habitat Restoration	2012–2021
Mid-Klamath Tributaries USFS Upland	2012–2021
Mid-Klamath Tributaries Private Upland	2012–2021
Lower Klamath River and Tributaries (Weitchpec to Mouth) Aquatic Habitat Restoration	2012–2021
Lower Klamath Private Uplands	2012–2021
Salmon River Aquatic Habitat Restoration	2013–2018
Salmon River USFS Upland	2012–2021

Source: KBRA Appendix C-2

Key:

USFS: United States Forest Service

- Large woody debris placement could include both mobile wood and complex structures and could be used to create off-channel habitat or provide cover in pools.
- Correction of fish passage issues could include culvert upgrades or replacement to meet current fish passage standards and correction of other fish blockages to provide access to new or historic habitats.
- Cattle exclusion typically includes the construction of fencing to prevent cattle from trampling stream banks, which allows riparian vegetation to grow. Cattle exclusion is often conducted in conjunction with riparian planting. Cattle exclusion fencing would only be implemented in accordance with applicable Federal, State, and county regulation and guidance.
- Mechanical thinning and prescribed burning are used to mimic some of the functions and characteristics historically provided by a natural fire regime. Thinning and prescribed burning reduce the potential for more catastrophic fires and the erosion that often follows.
- Purchases of conservation easements and land from willing sellers allow for more direct land management for habitat enhancement purposes.
- Decommissioning of roads could reduce road densities in areas with a high potential for failure and could stabilize slopes. Routine road operation and road failures can be a major source of chronic sediment inputs into stream systems.
- Gravel augmentation involves the direct placement of spawning-size gravel into the stream channel. Gravel augmentation could increase spawning habitat in systems by increasing the amount of area with suitable substrate. Currently, suitable spawning gravel substrate is limited due to capture of gravels behind dams or armoring of channel banks, or it could be covered with fines from sedimentation.
- Treatment of fine sediment sources could include a broad array of actions including management of stormwater runoff from roads and other developed areas, agricultural and forestry management practices, and other specific actions depending on the sources of fine sediments.
- Screening of diversion structures on the Williamson, Sprague and Wood Rivers and Upper Klamath Lake pumps. (This activity is separate from the fish entrainment reduction activities proposed on Reclamation's Klamath Project facilities as described under the Regulatory Assurances Program.)
- Above Upper Klamath Lake, activities may include restoration easements and grassbanks that facilitate habitat improvement and landowner economic stability.

2.4.3.10.5 Fisheries Reintroduction Plans

Under the KBRA, the States of California and Oregon would each prepare separate Fisheries Reintroduction Plans that identify the facilities and actions that would be necessary to start reintroduction of anadromous fish upstream of Iron Gate Dam (KBRA Section 11). The Phase I reintroduction plans would be prepared if there is an Affirmative Determination and each State concurs with that Determination. Reintroduction activities specifically exclude the Trinity River watershed upstream of the confluence with the Klamath River; Lost River and its tributaries; and Tule Lake Basin.

The Oregon Phase I Reintroduction Plan, to be prepared by the ODFW and the Klamath Tribes, would identify the facilities and actions necessary to start reintroduction and would be adaptable in order to incorporate information gained from the monitoring program. ODFW, the Klamath Tribes, and other Fish Managers would be responsible for implementation of the Phase I Reintroduction Plan.

Phase I reintroduction upstream of Upper Klamath Lake may include active intervention and movement of Chinook salmon into suitable habitats (KBRA Section 11.3). Following dam removal seasonal trap and haul operations, primarily for fall-run Chinook salmon may occur around Keno Dam until water quality conditions are sufficiently improved. A variety of release and rearing strategies would be utilized to optimize success; however, the KBRA does not contain specifics on what those strategies might include.

The California Phase I Reintroduction Plan, to be developed by the CDFG, would adopt a passive approach including development of reintroduction goals, monitoring protocols, habitat assessments, and strategies for adapting the plan as additional information is developed (KBRA Section 11.4). The Phase I Reintroduction Plan would also include development of guidelines for the use of a conservation hatchery at Iron Gate Dam or on Fall Creek to more quickly establish naturally producing populations in the wild if deemed necessary.

Once self-sustaining populations were established, Phase II Reintroduction Plans would be developed to integrate anadromous fisheries into each State's harvest management plans. Fisheries management, including the setting of harvest levels, would be in accordance with the goal of maintaining a sustainable fishery throughout the basin. A schedule for Phase II Reintroduction Plans cannot be established at this time as it is dependent on the success of the establishment of anadromous fisheries in the Upper Klamath Basin.

See Table 2-18 for the general classes of actions that could occur under the Fisheries Reintroduction program during the interim period.

Table 2-18. KBRA Fisheries Reintroduction Projects

KBRA Project	Anticipated Schedule
Reintroduction Plan	2012–2021
Collection Facility	2012–2021
Production Facility	2012–2021
Acclimation Facility	2012–2021
Transport	2015–2021
Monitoring and Evaluation	2012–2021
Hatchery Facilities (at Iron Gate Dam or Fall Creek)	2012–2021

Source: KBRA Appendix C-2

Fisheries Monitoring Plan

The Fisheries Monitoring Plan is intended to direct a cohesive effort to monitor the status and population trends of Chinook and coho salmon, steelhead trout, resident rainbow/redband trout, lamprey, suckers, bull trout, sturgeon, and eulachon (KBRA Section 12.2). Monitoring programs would also collect data on water quantity (e.g., instream flows and Upper Klamath Lake level elevations), water quality (e.g., temperature, nutrient loading, sediment, and algae), the effectiveness of restoration activities, and factors that may limit recovery of fish populations (KBRA Section 12.2).

The Monitoring Plan, to be prepared by the Fish Managers, is scheduled in the KBRA to be completed by March 2012. The results of the monitoring program are to be reviewed in 2020 and 2030 at a minimum. Adjustments in proposed restoration activities would be made on the basis of the results of the monitoring program.

Table 2-19 lists the general classes of actions that may occur under the Fisheries Monitoring program.

Additional Water for Fish

Many of the components of the KBRA are intended to result in additional instream flows and to retain water in Upper Klamath Lake in order to support fisheries restoration. Most of these actions are intended to benefit both anadromous and sucker populations regardless of the effects of dam removal. A cornerstone of the KBRA is the agreement to limit diversions to Reclamation’s Klamath Project in exchange for certain assurances among the parties in the Oregon water rights adjudication process and with respect to the exercise of certain tribal water rights.

Table 2-19. KBRA Fisheries Monitoring Projects

KBRA Project	Anticipated Schedule
Adult Salmonids	2013 start
Juvenile Salmonids	2013 start
Genetics Otololith	2013 start
Hatchery Tagging	2013 start
Disease	2013 start
Green Sturgeon	2013 start
Lamprey	2013 start
Geomorphology	2013 start
Habitat Monitoring	2013 start
Water Quality	2013 start
Upper Klamath Lake Bloom Dynamics	2014 start
Upper Klamath Lake Water Quality/Phytoplankton/Zooplankton	2012–2021
Upper Klamath Lake Internal Load/Bloom Dynamics	2014 start
Upper Klamath Lake External Nutrient Loading	2012–2021
Upper Klamath Lake Analysis of Long-term Data Sets	2014 and 2019 only
Upper Klamath Lake Listed Suckers	2012–2021
Tributaries Water Quality/Nutrients/Sediment	2012–2021
Tributaries Geomorphology/Riparian Vegetation	2012–2021
Tributaries Physical Habitat	2012–2021
Tributaries Listed Suckers	2013 start

Remote Sensing Acquisition and Analysis	2013, 2016, and 2019 only

Source: KBRA Appendix C-2

Most of the programs that provide additional water for fish are organized under the Water Programs section of the KBRA and are described in greater detail below. These programs include the following:

- Limit on diversions to Reclamation’s Klamath Project.
- Interim program of water lease and purchase to reduce diversions from the Klamath River and from tributaries upstream of Upper Klamath Lake.
- Voluntary Water Use Retirement Program (WURP) in Upper Klamath Basin to add up to 30,000 acre-feet of instream water per year to the Upper Klamath Basin including Wood River, Sprague River, Sycan River (except Sycan Marsh), and Williamson River.
- Increased water storage and conservation through specific projects including the following:

- Breach levees on Williamson River Delta (Completed) - added 28,000 acre-feet of storage.
- Reconnect Barnes and Agency Lake Ranches to Agency Lake (under study) - would shift 63,700 acre-feet of active (pumped) storage to passive storage.
- The Wood River Wetlands would add 16,000 acre-feet of storage (under study).
- Monitor groundwater use to ensure that specified springs or the river are not adversely affected (KBRA Sec. 15.2.4. E.ii, p. 76).
- Assess effects of climate change for adaptive management of water resources.
- Provide at least an additional 10,000 acre-feet of storage in the Upper Klamath Basin to allow increased diversions in some years, to mitigate effects of drought, and/or to further fish restoration goals.

Additional Water Storage Projects

Section 18 of the KBRA includes three restoration projects intended to increase the amount of water storage in the Upper Klamath Basin. Full implementation of the KBRA is linked to the completion of specific milestones in these projects.

Wood River Wetland Restoration Project

Bureau of Land Management presently manages the Wood River Wetlands for the purpose of restoring wetlands adjacent to Agency Lake. Under the KBRA, Bureau of Land Management would conduct a study, with input from other KBRA parties, to consider options for managing the Wood River Wetland area that would include operating it as a pumped storage within existing dikes or fully reconnecting the area to Agency Lake by breaching the dikes (KBRA Section 18.2.3). The intent is to provide additional water storage for a total of 16,000 acre-feet of potential water storage capacity between elevations 4,143.3 and 4,136.0 feet. Once the study is completed and a proposed action selected, the appropriate level of NEPA analysis and associated Endangered Species Act (ESA) consultation would need to be conducted. The anticipated schedule for the Wood River Wetland Restoration Project is 2013–2015 (KBRA Appendix C-2). Full implementation of the diversion limitations and associated assurances under the KBRA is linked to completion of the study, NEPA analysis, and ESA compliance and to funding for implementation of the selected alternative.

Agency Lake Ranch and Barnes Ranch Project

In 2007, the Agency Lake/Barnes Ranches were transferred to USFWS to be managed as part of the Upper Klamath NWR. Under the KBRA, USFWS would conduct a study with input from other KBRA parties, to consider options for managing the Agency Lake/Barnes Ranches area to enhance water management flexibility in providing benefits for water storage, fish, wildlife, and wetland habitats (KBRA Section 18.2.2). Potential options would include continuing to operate the area as a pumped storage facility or breaching lakeshore levees and reconnecting the land to Agency Lake. The restoration of diked and drained portions of the ranches could add 63,770 acre-feet of potential storage

capacity to Upper Klamath Lake between elevations 4,143.3 and 4,136.0 feet. Once the study is completed and a proposed action is selected, the appropriate level of NEPA analysis and associated ESA compliance would need to be conducted. The anticipated schedule for the Agency Lake/Barnes Ranches Project is between 2013 and 2015 (KBRA Appendix C-2). Full implementation of the diversion limitations and associated assurances under the KBRA is linked to completion of the study, NEPA analysis, and ESA compliance and to funding for implementation of the selected alternative.

Additional Water Storage

The KBRA includes provisions for further investigation and acquisition of at least an additional 10,000 acre-feet of storage (KBRA Section 18.3 and 15.1.1). This additional storage capacity would be in addition to the instream water and Upper Klamath Lake water storage benefits expected from the WURP and the water storage projects described above. Any project identified in the future that could provide this additional storage may need to comply with separate NEPA evaluations prior to implementation. The first 10,000 acre-feet of additional storage capacity is one of the identified milestones that would allow for increased diversion to Reclamation's Klamath Project users during the irrigation season in some years (KBRA Section 15.1.1).

Water and Power Programs

The Water and Power Programs in the KBRA address water supply reliability and power affordability for on- and off-Project agricultural users, and for moving water through the area of Reclamation's Klamath Project (Figure 2-13). These plans are intended to help all water users in the basin to be better prepared for reasonably foreseeable events and unexpected conditions.

Plans and programs to be developed and implemented under the Water and Power Program of the KBRA are described in the following sections and include:

- On-Project Plan
- Winter Shortage Plan
- WURP
- Off-Project Water Settlement
- Off-Project Reliance Program Plan
- Power for Water Management Plan
- Drought Plan
- Emergency Response Plan
- Climate Change Evaluation
- Interim Flow and Lake Level Protection Plan
- Environmental Water Program

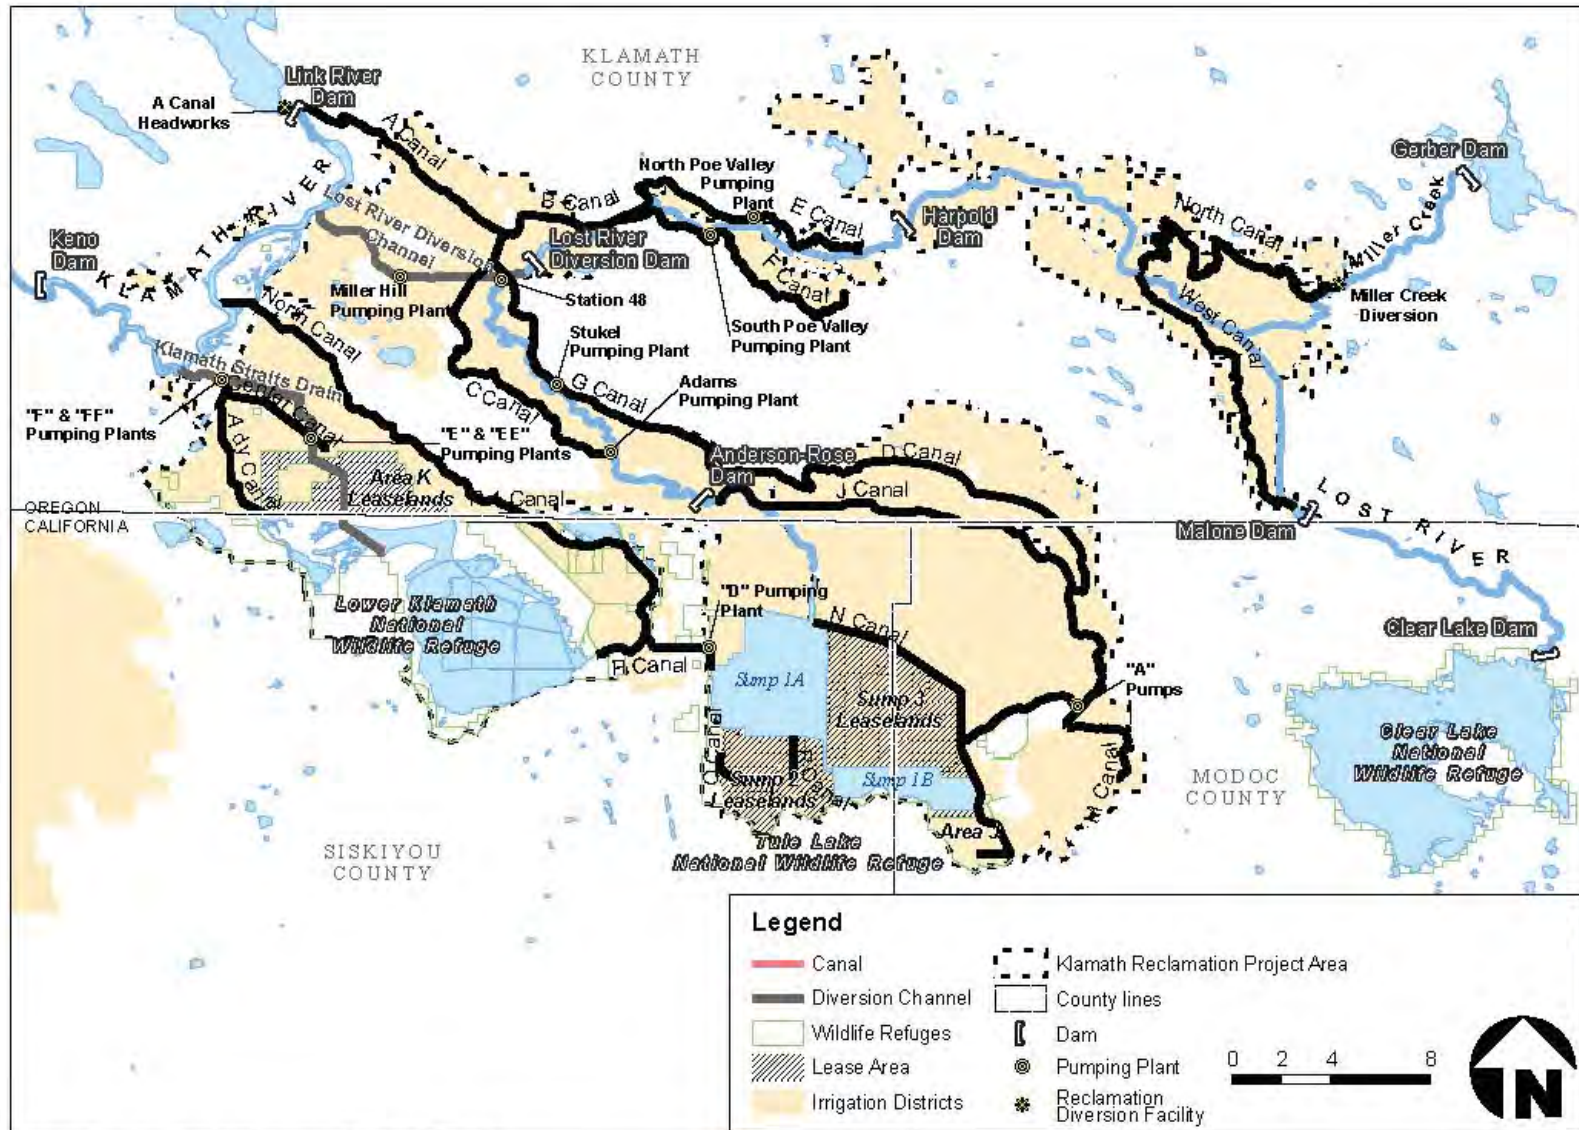

Figure 2-13. On-Project Area.

On-Project Water Management

Diversion Limitations

The proposed limitations on diversions to Reclamation’s Klamath Project are described in Section 15 and Appendix E-1 of the KBRA. The diversion limitations would result in the availability of irrigation water to be approximately 100,000 acre-feet less than the current demand in the driest years to protect mainstem flows (Klamath Settlement Parties 2010). Implementation of the diversion limitations would include assurances of increased reliability of diversions. The amount of water that can be diverted to on-Project users, including the Lower Klamath NWR and Tule Lake NWR, varies by season and by water year forecast (whether a year is forecast to be wet or dry) (Table 2-20). The forecast to be used to set diversion limits each year is the Natural Resources Conservation Service 50 percent exceedence forecast for net inflow to Upper Klamath Lake. The 50 percent exceedence forecast is a prediction that there is a 50 percent chance that the actual stream flow will exceed the forecast value (and a 50 percent chance that flows will be less than the forecast value). Although Reclamation’s Klamath Project diverts water from a variety of sources, the Upper Klamath Lake forecast would be used to set the diversion limits each Spring and would generally characterize whether a particular year is expected to be wet or dry.

Table 2-20. Reclamation’s Klamath Project Diversion Limitations per KBRA Appendix E-1

Season	Forecast (acre-feet) ¹	Diversion Limits (acre-feet)
Phase I²		
March–October		
	287,000 or less	378,000 (which includes a 48,000 Refuge Allocation (RA))
	287,000 to 569,000	378,000 to 420,640 (which includes 48,000 to 55,640 for the RA) ³
	More than 569,000	445,000 (which includes a 60,000 RA)
November–February	N/A	80,000 (which includes a 35,000 RA)
Phase II²		
March–October		
	287,000 or less	388,000 (which includes a 48,000 RA)
	287,000 to 569,000	388,000 to 430,640 (which includes 48,000 to 55,640 for the RA) ⁴
	More than 569,000	445,000 (which includes a 60,000 RA)
November–February	N/A	80,000 (which includes a 35,000 RA)

Notes

1. “Forecast” means the March 1st Natural Resources Conservation Service 50 percent exceedence forecast (meaning there is a 50 percent chance that flow will exceed the forecast amount) for net inflow to Upper Klamath Lake during the period of April 1 to September 30.
2. Phase I of the diversion limits represent the baseline agreement. Phase II allows additional diversions up to 10,000 acre-feet under certain circumstances and would apply after i) the physical removal of the dams and a free-flowing condition and volitional fish passage has been restored; or ii) 10,000 acre-feet of new storage has been developed in the upper basin; or iii) determination after February 1, 2020 that the increase is appropriate.
3. The Phase I allowable diversion in thousands of acre-feet is calculated by the formula $378 + \{42.64 \times [(Forecast - 287) / 282]\}$ and the refuge allocation is calculated by the formula $48 + \{7.64 \times [(Forecast - 287) / 282]\}$.
4. The Phase II allowable diversion in thousands of acre-feet is calculated by the formula $388 + \{42.64 \times [(Forecast - 287) / 282]\}$ and the refuge allocation is calculated by the formula $48 + \{7.64 \times [(Forecast - 287) / 282]\}$.

Reclamation's Klamath Project would follow these limitations as much as practicable during the interim period before full implementation of the On-Project Plan. The On-Project Plan would identify what measures might be needed to fully implement the diversion limitations, such as conservation easements or efficiency measures. However, until the On-Project Plan is fully implemented, it might not be possible for water managers to comply completely with the diversion limitations in all years. Full implementation of the On-Project Plan is defined as completion of any measures necessary to allow full implementation of the diversion limitations.

The diversion limitations would not be binding on the parties to the KBRA until Appendix E-1 is filed in an appropriate forum. Appendix E-1 is currently formatted as a filing in the Oregon Water Resources Department (OWRD) water rights adjudication process; however, it is anticipated that that adjudication process will be completed before the Appendix is filed. In that case, the appendix would be reformatted for filing with the most appropriate forum and context, which likely would include a filing with OWRD as it concerns matters of water rights. Prior to filing, the appendix would be signed by the Department of the Interior, Reclamation and USFWS, and irrigation districts within the Klamath Project. Figure 2-14 shows the key KBRA milestones towards full implementation of diversion limits.

Additional On-Project Water Management Provisions

The KBRA contains additional provisions regarding management of water and facilities on Reclamation's Klamath Project. These provisions include direction on a) developing a plan for how water would be allocated and delivered to the Lower Klamath NWR; b) management of lease lands at the Lower Klamath NWR and Tule Lake NWR; c) the use of groundwater and a prohibition on adverse impacts to certain springs; d) payment schedule for D Pumping Plant costs; and e) management of Keno and Link River Dams.

Refuge Allocation and Management

The refuge allocation would be the amount of water that Lower Klamath NWR and Tule Lake NWR would receive from Reclamation's Klamath Project facilities as described in the KBRA and is shown in Table 2-20 (while the refuges receive some water from other sources, the amounts are minimal compared to water from Reclamation's Klamath Project facilities). The Refuge Allocation includes water for a) Lower Klamath NWR wetlands; b) Lower Klamath NWR cooperative farming lands; c) refilling of the Tule Lake NWR sumps after intentional draining; d) refuge-approved walking wetlands on lease lands, cooperative farm lands, or lands within Reclamation's Klamath Project but outside of the Klamath Basin National Wildlife Refuge System; and e) certain conveyance losses.

The parties to the KBRA are to develop agreements on the parameters of delivery of water to the refuges including schedules, volumes by time of year and points of diversion, and a system to determine whether water has "passed through" the refuge without being consumed. Agreement on the general parameters of delivery of the Refuge Allocation was to be completed by 2011.

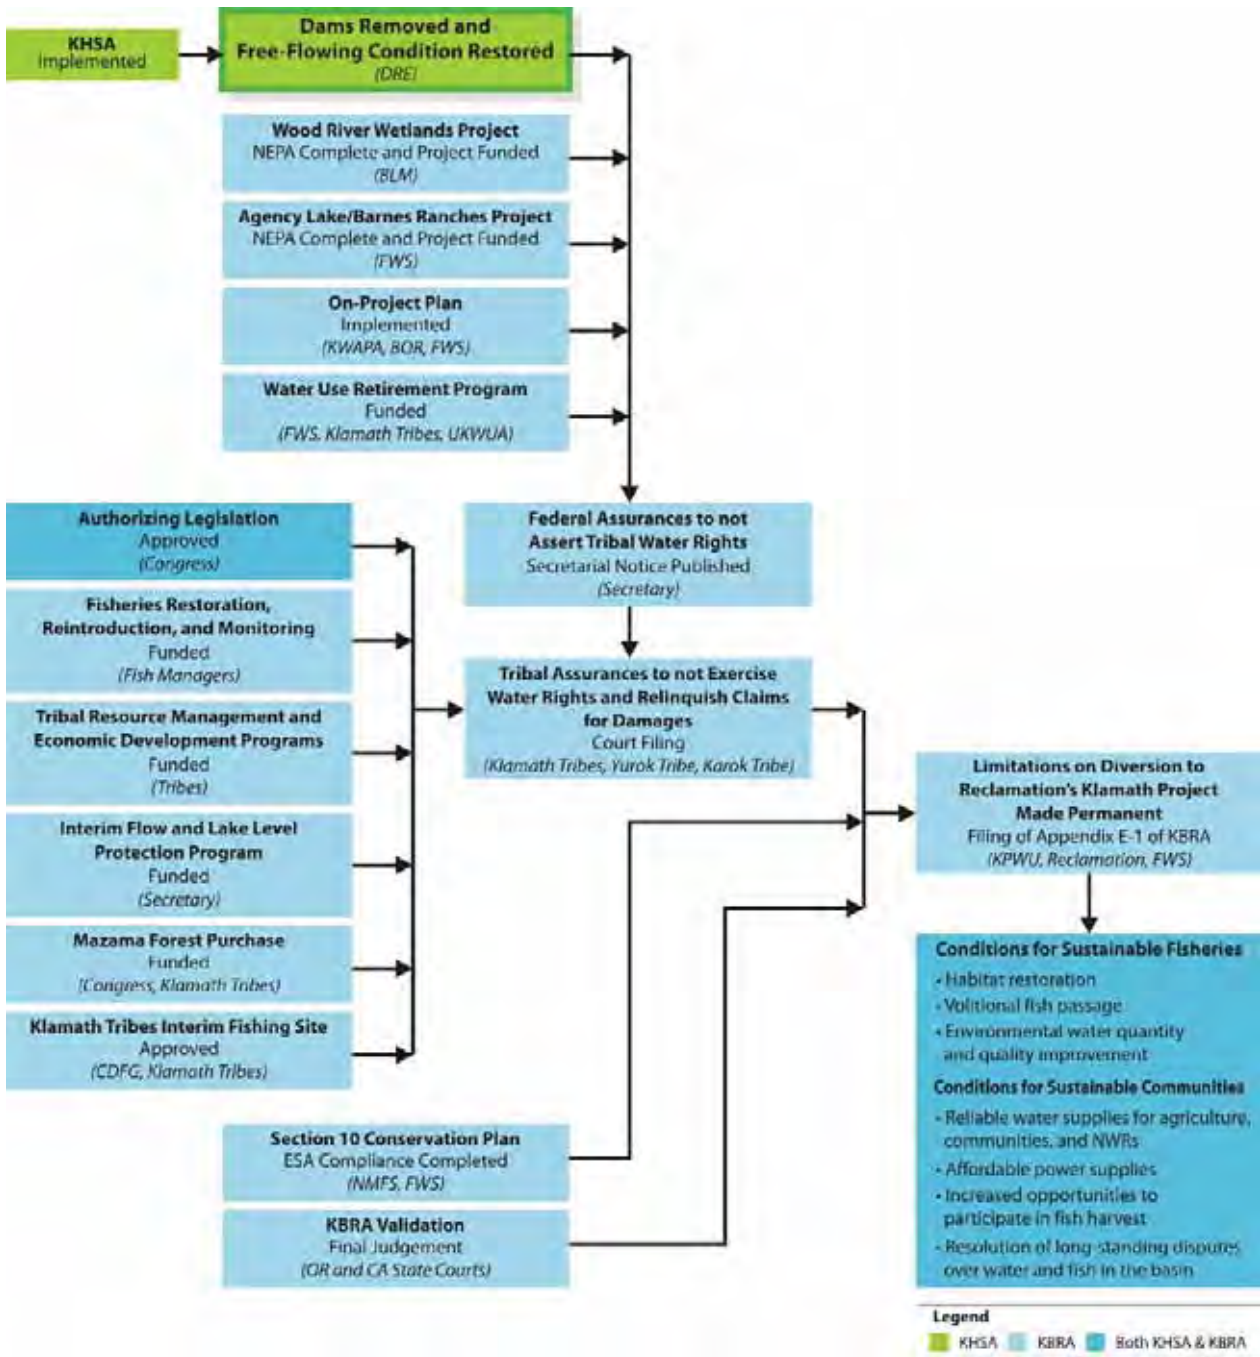

Figure 2-14. Key Milestones before Diversion Limits are Implemented.

An anticipated schedule for specific projects under this element is identified in Appendix C-2 of the KBRA including walking wetland construction 2013–2021.

Groundwater Management

The KBRA includes provisions for groundwater studies to evaluate potential effects of groundwater pumping and to provide baseline information needed to meet an objective of “no adverse impact” on specified springs in the basin. An adverse effect on springs is defined in the KBRA as a 6 percent reduction in flow and the year 2000 is used as a baseline. If future studies show that a 6 percent reduction or greater does not affect fisheries, then groundwater withdrawals may be increased. The results of the groundwater studies and ongoing monitoring of the effects of groundwater use would be included in the On-Project Plan (KBRA Section 15.2.4).

The anticipated schedule for the groundwater technical studies is between 2012 and 2014 (KBRA Appendix C-2). United States Geological Survey and OWRD would be the Lead Agencies to conduct groundwater technical investigations. The scope of these studies is described in Appendix E-2 of the KBRA. If investigations or monitoring identify an adverse impact, the parties to the KBRA will work together to modify the On-Project Plan and/or remedy the impact (KBRA Section 15.2.4.B.v). A fund for remedying adverse impacts due to groundwater use is identified in KBRA Appendix C-2.

On-Project Plan

The On-Project Plan is intended to set the framework for implementation of the diversion limits to Reclamation’s Klamath Project (KBRA Section 15.2). The On-Project Plan would align supply and demand for water users within Reclamation’s Klamath Project and is to include the specific objective that groundwater pumping would not adversely affect springs within the basin.

The On-Project Plan would include details on appropriate responses in the event of summer or winter shortages. The KBRA specifies how and under what circumstances a deficit would be shared among on-Project users and the Lower Klamath NWR and Tule Lake NWR in the event of a summer shortage of water available for diversion. A plan for management of winter shortages is to be developed. The On-Project Plan would reference the Winter Shortage Plan, the Drought Plan, the Emergency Response Plan, and other plans to be developed as appropriate.

Full implementation of the On-Project Plan is to occur no later than March 1, 2022. To implement the On-Project Plan, managers may need to take a variety of actions including acquisition or negotiation of conservation easements; forbearance agreements; land acquisitions; efficiency measures; conservation measures, development of groundwater sources; or creation of additional storage. The anticipated schedule to develop and implement the On-Project Plan is between 2012 and 2021 (KBRA Appendix C-2).

Winter Shortage Plan

In the event that there is insufficient water available for diversion to Reclamation’s Klamath Project during the winter months (November through February) a plan would be

developed to identify how shortages would be shared between the Reclamation's Klamath Project water users including the Lower Klamath NWR and Tule Lake NWR. This plan was intended to be completed by 2011 (KBRA Section 15.1.2.F).

Emergency Response Plan

An Emergency Response Plan would be developed to prepare water managers for potential failure of Reclamation's Klamath Project facilities or dikes on Upper Klamath Lake or Lake Ewauna that affects the storage and delivery of water needed to implement the commitments under the KBRA (KBRA Section 19.3). The emergency response plan is to include: a) a process to prepare for potential emergencies; b) funding sources to respond to emergencies; c) the priority of funding emergency responses; d) potential emergency response measures, including emergency NEPA review, as necessary; and e) a process to implement emergency responses. The Emergency Response Plan is intended to be completed in 2011 and implemented as needed.

Water Use Retirement Program

The voluntary WURP is intended to permanently increase the flow of water into Upper Klamath Lake by 30,000 acre-feet per year to support restoration of fish populations (KBRA Section 16.2.2). In exchange for this benefit to the Upper Klamath Lake fisheries, the Klamath Tribes would be willing to settle certain water rights claims with water users in the Upper Klamath Basin.

The WURP is intended to be part of the Off-Project Water Settlement (OPWAS, see below), but may also be implemented independently by the Upper Basin Team. It is expected that the WURP will take up to 10 years to be fully implemented and implementation would start with the completion of the OPWAS in 2012. The anticipated schedule for implementation of the WURP is between 2012 and 2016 (KBRA Appendix C-2).

The WURP may be implemented through a variety of measures including retirement of water rights, forbearance agreements, short-term water leasing, split season irrigation, upland management techniques, water efficiency measures, dry land cropping, and natural storage improvements such as wetlands or improved riparian areas.

The OWRD would determine when the required 30,000 acre-feet of water is permanently assigned to Upper Klamath Lake. The additional storage that would be provided by the Williamson River Delta, Wood River Wetlands, and Agency Lake/Barnes Ranches projects would not apply towards successful implementation of the WURP.

Off-Project Water Management

Off-Project Water Settlement (OPWAS)

The OPWAS is intended to provide a forum for resolving long-standing water disputes between the Upper Klamath Water Users Association, Klamath Tribes, and the Bureau of Indian Affairs (KBRA Section 16) in the Off-Project Area. The Off-Project Area

includes the Wood River, Sprague River, Sycan River, and Williamson River sub-basins (Figure 2-15). The intent is to negotiate a settlement that resolves the off-Project irrigators' contests to claims in Tribal Cases under the Klamath Basin water rights adjudication process. In the event that not all such contests are resolved through this process, then the intent is to provide reciprocal assurances for maintenance of instream flows and reliable irrigation water deliveries to the Off-Project Area. Under the KBRA, the OPWAS would include the WURP. The anticipated schedule for development and implementation of the OPWAS is between 2012 and 2021 (KBRA Appendix C-2).

Off-Project Reliance Program

The Off-Project Reliance Program is intended to avoid or mitigate the immediate effects of unexpected circumstances affecting water availability downstream from Upper Klamath Lake that could affect the amount of water available for irrigation in the Off-Project Area (KBRA Section 19.5). Due to the way that water rights are prioritized throughout the basin, circumstances that affect water availability for diversion to on-Project users could affect off-Project users upstream.

The program would be developed by the Upper Klamath Water Users Association with input and assistance from off-Project irrigators, Reclamation, and USFWS. The program is intended to be developed prior to the successful conclusion of the WURP but would not be implemented until a) 30,000 acre-feet of additional flow is added to Upper Klamath Lake through the WURP; b) the OWRD finds that additional instream flow has been added; and c) KBRA Appendix E-1 has become effective (i.e., the diversion limits to Reclamation's Klamath Project are fully implemented).

Actions that avoid the impacts of unexpected circumstances might include providing funding for water leasing to increase water availability for irrigation in the Upper Klamath Basin, or mitigating the economic impacts of lost agricultural production (KBRA Section 19.5). Because the Off-Project Reliance Program could not be implemented until the WURP was completed and Appendix E-1 was effective, it would not be likely to start until after 2021.

Power for Water Management Program

The Power for Water Management program is intended to deliver power to eligible users at a cost that is targeted at or below the average cost for similarly situated Reclamation irrigation and drainage projects in the surrounding area. The goals of the program include providing affordable electricity for (i) efficient use, distribution, and management of water within Reclamation's Klamath Project and the Klamath Basin NWR System, and facilitate the return of water to the Klamath River as part of the implementation and administration of the On-Project Plan; (ii) implementation of the WURP and OPWAS; (iii) meeting the objectives of the Fisheries Restoration Program; and (iv) providing power cost security to assist in maintaining sustainable agricultural communities in the Upper Klamath Basin (KBRA Section 17.1).

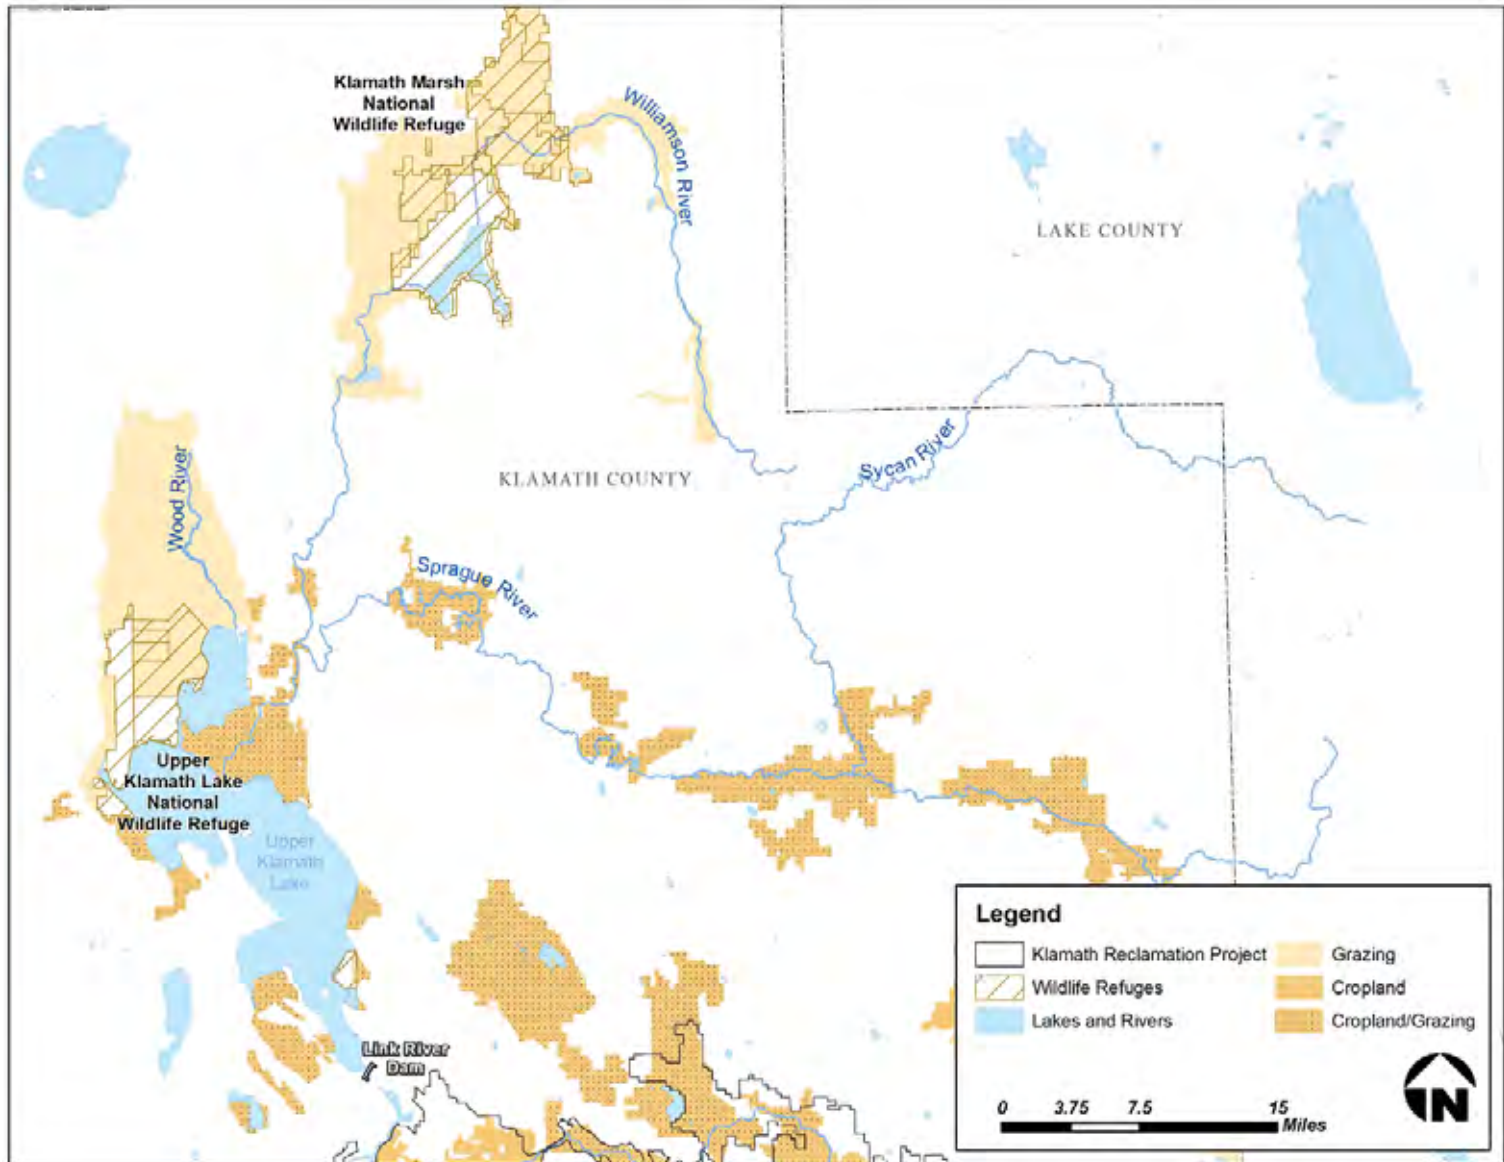

Figure 2-15. Off Project Irrigation Area.

Under the KBRA, a power management entity would be established to deliver affordable power to eligible users. The program includes three components: the Interim Power Program, a Federal Power Program, and a Renewable Power Program. The Interim Power Program is intended to maintain the power cost target for eligible users while the other program elements are implemented (KBRA Section 17.5). The anticipated schedule is between 2012 and 2021 (KBRA Appendix C-2), although the specific implementation steps are yet to be identified by the power management entity.

The Federal Power Program is intended to obtain and provide for the transmission and delivery of Federal preference power to eligible power users (KBRA Section 17.6). The parties to the KBRA would need to request and be granted an allocation of Federal power before this element could be fully implemented.

The Renewable Power Program would increase the efficiency of power users both on- and off-Project and generate renewable energy in order to reduce power costs for eligible power users (KBRA Section 17.7). Implementation of the Renewable Power Program includes development of a financial and engineering plan to identify specific renewable energy resources and energy efficiency measures to be developed or invested in. The financial and engineering plan would specifically evaluate the potential for development of a biomass energy project (KBRA Section 17.7.2). The renewable energy plan is intended to be completed by 2012 (KBRA Appendix C-2).

Drought Plan

The Drought Plan is intended to provide a process to evaluate and adapt water resource management in the event of a drought or an extreme drought so as to avoid or minimize adverse effects. The Plan identifies water and resource management actions such that no Klamath Basin interest shall bear an unreasonable portion of burdens imposed or the risk of loss or injury as a result of drought or extreme drought (KBRA Section 19.2). The Drought Plan defines what conditions constitute a drought year. The water years 1992 and 1994 are defined as representing extreme drought conditions.

Full implementation of the KBRA would include the availability of drought relief funds to help offset the impacts of a drought on water users. Measures suggested in the KBRA that might be taken in the event of a drought include conservation measures, the use of stored water developed for use on Reclamation's Klamath Project, water leasing, use of groundwater, exercise of water rights priorities, and reduction in the diversion to Reclamation's Klamath Project (KBRA Section 19.2). The Drought Plan has been drafted and submitted to the Department of the Interior pursuant to KBRA Section 19.2.3 and implementation would be ongoing as needed.

Climate Change

The KBRA provides for an assessment of how long-term climate change may affect fisheries and communities in the Klamath Basin (KBRA Section 19.4). The technical assessment of climate change is scheduled to occur in 2013. Depending on the results of the technical assessment, the parties may need to negotiate supplemental terms to the KBRA in order to achieve the goals of the agreement.

Environmental Water Management

Environmental water is the quantity and quality of instream water available to support fisheries and other aquatic resources. Section 20 of the KBRA lists the obligations of the parties to the KBRA to provide environmental water as described in various sections of the KBRA, including:

- Support dam removal under KHSA (KBRA Section 8).
- Limit diversions to Reclamation's Klamath Project (KBRA Section 15 and Appendix E-1).
- Retire water uses upstream of Upper Klamath Lake to produce additional instream flows and maintain lake levels through a voluntary WURP (KBRA Section 16.2.2).
- Develop additional water storage in the basin (KBRA Section 18).
- Develop and implement Fisheries Restoration Plans (KBRA Section 10).
- Develop and implement Fisheries Reintroduction Plans (KBRA Section 11).
- Provide for real-time management of stored environmental water (KBRA Section 20.3).
- Implement an Interim Flow and Lake Level Protection Program (KBRA Section 20.4).
- Support instream water rights applications (KBRA Section 20.5).
- Support the development and implementation of TMDLs on the Klamath River and actions that protect water quality generally (KBRA Section 20.5.4).
- Oppose proposals for additional out-of-basin transfers of water (KBRA Section 20.5.4).

Environmental water may be stored and managed by means such as the operation of the Agency Lake/Barnes Ranches project. In order to determine whether to store water at any particular time, the parties would need to understand the real-time water budget of the basin. Implementation of real-time water management would occur through installation of tools such as water flow monitoring gauges and snowpack gauges (see Table 2-21).

Under the KBRA, flows for environmental water and lake level management would be increased by at least 30,000 acre-feet through the voluntary WURP. To achieve environmental water goals during the interim period, an Interim Flow and Lake Level Protection Program is proposed in the KBRA (KBRA Section 20.4). This program would purchase or lease water rights from willing sellers to increase the amount of water in the Klamath River and Upper Klamath Lake until permanent instream water supply enhancements could be put into effect.

Table 2-21. KBRA Environmental Water Management Projects

KBRA Project	Anticipated Schedule
Real Time Water Management	2012–2021
Water Flow Monitoring and Gauges	2012–2021
Snowpack Gauges	2012–2021
Adaptive Management: Science and Analysis	2012–2021
Calibration and improvements to KLAMSIM or other modeling and predictions	2012–2021
Interim Flow and Lake Level Program	2012–2021

Source: KBRA Appendix C-2

Under the KBRA, the parties agree to withdraw any contests to the existing Instream Water Rights applications filed by ODFW or the Oregon State Parks and Recreation Department and to support any other instream water right claims. The KBRA also includes a provision that the parties would support the conversion of existing PacifiCorp water rights to instream uses when the hydroelectric dams are removed from service.

Water protection and improvement are key objectives of the KBRA. However, the KBRA does not include a separately defined water quality program. KBRA Section 20.5 on the protection of environmental water includes general statements about the importance of protecting water quality and the agreement that the parties to the KBRA would support the development and implementation of appropriate TMDLs (KBRA Section 20.5.4). However, this section does not include any specific actions or prerequisites for other actions.

Regulatory Assurances Program

The KBRA provides for reintroduction of salmon and other aquatic species in the Upper Klamath Basin, which continued to have potential regulatory or other legal consequences for land or water users upstream of the current site of Iron Gate Dam. Therefore, the KBRA includes a set of regulatory assurances to avoid or minimize new regulation or other legal or funding burdens that might occur to land or water users upstream of Iron Gate Dam from introduction or reintroduction of aquatic species. The KBRA does not supersede existing laws or regulations nor does it modify existing laws or create exemptions. Plans and projects to be developed under the auspices of the KBRA would still need to comply with laws and regulations in force when discretionary decisions are made on those projects and plans.

The KBRA includes a commitment from Reclamation, upon receipt of funding and in compliance with applicable law, to construct entrainment reduction facilities such as fish screens to prevent fish from entering diversion facilities on Reclamation’s Klamath Project (KBRA Section 21.1.3). Entrainment would be specifically evaluated and addressed at a) Lost River diversion channel or associated diversion points; b) North Canal, c) ADY Canal; and d) other diversions from Reclamation or Reclamation

contractor-owned facilities (Figure 2-13). The anticipated schedule for construction of these entrainment facilities would be between 2019 and 2020.

The parties to the KBRA have also agreed to coordinate with each other and communicate openly on a wide variety of issues in an effort to avoid surprises so that solutions can be sought without acrimony. The KBRA specifically mentions unforeseen circumstances and consequences of restoration and water delivery as situations that might require fresh coordination (KBRA Sections 21.1.4, 21.2, and 21.3).

Development of either a General Conservation Plan or a Habitat Conservation Plan is identified as a means to secure an incidental take permit under Section 10(a)(1)(B) of the Endangered Species Act. This would be one means to avoid or minimize regulatory burdens or costs arising from the reintroduction of fish species to the Upper Klamath Basin (KBRA Section 22). In that light, NOAA Fisheries Service and USFWS will lead the development of a General Conservation Plan or Plans for use by KBRA parties or others to apply for incidental take permits under the Endangered Species Act. While development of a conservation plan could begin as early as 2012, it would not be anticipated that a plan would be approved until the end of the interim period.

The KBRA identifies requirements related to incidental take authorizations under the California Endangered Species Act and provides for coordination between Federal and State agencies related to those authorizations. The California Department of Fish and Game may draft legislation regarding a limited authorization to incidentally take fully protected species that may be affected by implementation of the agreement (KBRA Section 24). The KBRA also contains a provision for consideration of any request that the Oregon Department of Environmental Quality perform a Use Attainability Analysis before proposing any new designated use due to the reintroduction of fish species (KBRA Section 25).

2.4.3.10.6 County and Tribal Programs **County Programs**

The County Programs under the KBRA recognize that there may be impacts and opportunities for each of the counties within the Klamath Basin. Klamath County has agreed to develop a plan for economic development if funding is available (KBRA Section 27). Funding would potentially come from KBRA authorizations and from State business development programs. The California Water Bond funding legislation, scheduled for a vote in 2012, proposes funding for economic development within Siskiyou County. The KHSA (Appendix G-1) describes this \$20 million in economic development funds that would be provided to Siskiyou County as a part of the dam removal action in the event of an Affirmative Determination and a positive vote on the Water Bond Fund. Humboldt and Del Norte Counties are not included in this economic development fund. Funds remaining in the Water Bond fund after covering facilities removal, CEQA mitigation, and actions to secure the City of Yreka's water supply, may be used for fish restoration projects within Siskiyou, Humboldt, and Del Norte Counties.

Similarly there may be property tax revenue losses and gains from the various effects of the KBRA. Property tax revenue changes could occur due to reduced agricultural land values from a) a reduction in water deliveries and b) the surrender of significant water rights. The Klamath County Program within the KBRA includes a provision to compensate Klamath County for these potential revenue changes upon the availability of funding. The anticipated schedule for identification of potential property tax impacts and compensation payments is 2016 (KBRA Appendix C-2). County programs for Siskiyou, Humboldt, and Del Norte Counties do not include a provision for compensation for changes in property tax revenues that may result from the removal of the hydroelectric facilities.

Tribal Programs

The KBRA includes provisions for each of the affected signatory tribes (the Klamath Tribes, Karuk Tribe, and Yurok Tribe) to receive assistance in developing their capacity to participate in both fisheries management and conservation management activities within the basin (KBRA Sections 31 and 32). In addition, each signatory tribe would prepare an economic development plan and work towards implementing that program (KBRA Sections 31 and 33). Preparation of economic development plans is anticipated to occur in 2013.

The Klamath Tribes have been working with the Trust for Public Lands and have acquired an option to purchase the Mazama Forest in the Upper Klamath Basin, once a part of the tribes' reservation lands. The parties to the KBRA agree to support the Tribes' efforts to secure funding and complete the purchase of this forestland (KBRA Section 33.2). Final acquisition of the Mazama Forest is anticipated to occur in 2012 or 2013. Complete funding to allow the Klamath Tribes to purchase the Mazama Forest is one of the key milestones towards the filing of KBRA Appendix E-1 and the full implementation of the diversion limits to Reclamation's Klamath Project.

Under Section 34 of the KBRA, the Klamath Tribes have petitioned the California Fish and Game Commission to establish an interim fishing site in the reach of the Klamath River between Iron Gate Dam and the Interstate 5 Bridge. The grant of this petition is one of the key milestones toward implementation of the KBRA.

2.4.4 Alternative 3: Partial Facilities Removal of Four Dams

The primary purpose of removing dams on the Klamath River is to restore volitional fish passage and free-flowing river conditions at each dam site, in order to advance restoration of anadromous fish populations. The Partial Facilities Removal of Four Dams Alternative would achieve these goals by partially removing the Four Facilities. The Partial Facilities Removal of Four Dams Alternative satisfies the KHSA and includes the same IMs as in the Proposed Action, implementation of the KBRA, transfer of Keno Dam to DOI, and decommissioning of PacifiCorp's East Side/West Side facilities. The ongoing resource management activities, TMDLs, biological opinions, and other regulatory conditions described under the No Action/No Project Alternative would also occur under this alternative. Inflows to Upper Klamath Lake and outflows from Keno

Dam are assumed to be the same under the Partial Facilities Removal of Four Dams Alternative as described above for the Proposed Action. Flows through the Hydroelectric Reach and downstream from the Iron Gate Gauge would also be the same as those in the Proposed Action (see Figure 2-8).

The Partial Facilities Removal of Four Dams Alternative would include removal of enough of each dam to allow free-flowing river conditions and volitional fish passage at all times. Under this alternative, portions of each dam would remain in place, along with ancillary buildings and structures such as powerhouses, foundations, tunnels, and pipes. Some of these remaining features would likely require perpetual maintenance and security measures to prevent unauthorized entry. Maintenance activities would include periodic repair and replacement of fencing and repainting/recoating facilities. All tunnel openings would be sealed with reinforced concrete to eliminate trespass concerns. All oils, hydraulic fluids, and other potential contaminants found in powerhouses and machinery would be removed prior to final decommissioning and securing of buildings. Table 2-22 provides a summary of facilities that would be removed or retained under the Partial Facilities Removal of Four Dams Alternative.

2.4.4.1 Deconstruction Actions

Deconstruction techniques for the Partial Facilities Removal of Four Dams Alternative are the same as for the Proposed Action, with no specialized means or methods necessary. Partial facilities removal would use the same equipment and be on a similar schedule to the Proposed Action. The following sections describe the scope of work and features for partial removal of each dam under this alternative.

2.4.4.1.1 J.C. Boyle

Partial facilities removal would require the complete removal of the embankment section, gated concrete spillway section, and concrete cutoff wall to the bedrock foundation. The DRE would also do the following:

- Remove the lower portion of the fish ladder to prevent potential fish stranding during peak flow events.
- Remove the abutment wall and upper portion of the fish ladder, because they could become unstable after the removal of the embankment and spillway sections.
- Recoat the 14-foot-diameter steel pipeline and supports to encapsulate potential heavy metals.
- Remove concrete walls for the water conveyance canal to allow drainage and animal migration, and prevent collapse due to rockfall.
- Remove the 78-foot-tall steel surge tank and the 150-ton gantry crane to prevent a potential future stability problem during a large seismic event.
- Remove the penstocks to avoid long-term maintenance issues related to the steel, which likely has coatings containing heavy metals.

Table 2-22. Summary of Features to be Removed or Retained with Alternative 3^{1,2}

Feature	J.C. Boyle	Copco 1	Copco 2	Iron Gate
Embankment/earth fill dam	Remove		Retain	Remove
Concrete dam structure	Remove	Remove	Remove	
Concrete wingwalls			Retain Right Wall	
Reservoir power intake structure	Retain	Retain	Retain	Remove
Spillway	Remove	Remove	Remove	Retain
Spillway control gates	Remove	Remove	Remove	
Concrete fish ladder	Remove			Remove
Concrete flume headgate structure	Retain			
Concrete canal intake screen	Retain			
Concrete flume	Remove Walls			
Concrete canal spillway	Remove			
Tunnel intake structure	Remove	Retain	Retain	Remove
Tunnel portals	Plug	Plug	Plug	Plug
Steel pipeline & supports	Retain			
Steel surge tank	Remove			
Wood-stave penstock			Remove	
Penstocks, supports, anchors	Remove	Retain	Retain	Remove
Powerhouse building		Retain	Retain	Retain
Powerhouse gantry crane	Remove			
Powerhouse concrete slab/structure	Retain	Retain	Retain	Retain
Powerhouse hazardous materials	Remove	Remove	Remove	Remove
Tailrace flume walls	Retain			
Tailrace channel	Fill	Fill	Fill	Fill
Switchyard	Remove	Remove	Retain	Remove
Warehouse & support buildings	Remove		Retain	
Fish Hatchery				Retain

Notes

1. Grayed-out cells indicate features that are not present at existing dam facilities and would therefore not need to be removed or retained.
2. Features indicated as retained under the Partial Facilities Removal of Four Dams Alternative are features that would be removed as part of the Proposed Action/Full Facilities Removal of Four Dams Alternative.

- Plug the downstream tunnel portal with concrete to avoid unauthorized entry.
- Remove the switchyard and warehouse building.
- Fence and seal the powerhouse.

Under the Partial Facilities Removal of Four Dams Alternative, the DRE would not remove the water intake structure, left abutment concrete gravity section, concrete headgate structure, intake screen, steel pipeline and supports, tailrace walls, and powerhouse concrete slab and structure, as shown in Figure 2-16. The DRE may partially fill and stabilize the headcut downstream from the forebay overflow discharge

Figure 2-16. View of J.C. Boyle Dam showing portion of dam and fish ladder to be removed for the Partial Facilities Removal Alternative.

canal (as in the Proposed Action). Partial removal would not produce as much concrete rubble as full removal would; therefore, the amount of fill would be dependent on the quantity of material available.

The DRE would leave the mechanical and electrical equipment in place with all power connections to the outside removed; however, it would remove any oil in the turbine governor and hydraulic control systems, transformers, oil storage tanks, or other equipment. The DRE would also remove other mechanical and electrical equipment containing potentially hazardous materials.

2.4.4.1.2 Copco 1 Dam and Powerhouse

To create a free-flowing condition and volitional fish passage through the Copco 1 site, the DRE would:

- Remove the concrete gravity arch dam and associated facilities (spillway gates, bridge deck, and piers) between the left abutment rock and the concrete intake structure on the right abutment to 5 feet below the existing streambed level at the dam.
- Seal the downstream end of the intake tunnel portal with concrete to avoid unauthorized entry.
- Remove unused transmission lines, poles, and the switchyard.
- Seal and fence the powerhouse.

Under the Partial Facilities Removal of Four Dams Alternative, the DRE would not remove the power generation water intake structure, penstocks, and powerhouse (Figure 2-17). Retention of these structures would require long-term maintenance, including the preservation of any items with coatings containing heavy metals. The DRE would handle mechanical and electrical equipment and equipment containing potentially hazardous materials in the same manner as for the J.C. Boyle Dam removal under this alternative.

Figure 2-17. Copco 1 showing portion of dam to be removed for the Partial Facilities Removal Alternative.

2.4.4.1.3 Copco 2 Dam and Powerhouse

To create a free-flowing condition and volitional fish passage through the Copco 2 site, the DRE would take the following actions:

- Remove the concrete gated spillway structure and concrete end sill between the existing sidewalls (see Figure 2-18) as well as associated facilities (spillway gates, bridge deck, and piers).
- Remove wood-stave penstock.
- Remove equipment on the right abutment embankment section to facilitate construction access to the gated spillway.
- Seal and fence powerhouse.

Under the Partial Facilities Removal of Four Dams Alternative, the embankment section on river right, intake structure on river left, conveyance system to the powerhouse, and powerhouse would remain in place. A small portion of the downstream basin apron slab would remain intact for structural stability of the right sidewall, provided that a potential fish barrier would not result.

Figure 2-18. Copco 2 dam showing portion of dam to be removed for the Partial Facilities Removal Alternative.

The DRE would handle mechanical and electrical equipment and equipment containing potentially hazardous materials in the same manner as for the J.C. Boyle and Copco 1 Dam removals under this alternative.

2.4.4.1.4 Iron Gate Dam and Powerhouse

Theoretically, the DRE could notch Iron Gate Dam instead of removing the full dam. The river channel would need a 100-foot opening to accommodate fish passage at high flows. Figure 2-19 shows Iron Gate Dam with a 100-foot-wide notch at the base of the dam with potential stable side slopes to the top of the dam. This figure illustrates that notching the dam would remove nearly the entire dam and would create the need to protect the newly exposed inner core of the dam for stability. The amount of effort required to notch the dam is comparable to removing the entire earthfill embankment. Likewise, the stabilization costs of the remaining structure would be comparable to the costs to remove the minor amount of remaining material. Therefore, under this alternative, the DRE would remove the entire embankment dam, concrete water intakes, water supply pipes, and fish facilities at the base of the dam, with methods and equipment requirements as described for the Proposed Action.

Figure 2-19. Section view of Iron Gate Dam showing 100-foot-wide bottom notch with different potential side slopes.

Facilities that would remain include the existing concrete spillway and powerhouse (Figure 2-20). The DRE would fill the spillway and chute with material removed from the dam embankment. The DRE would seal all tunnels at the upstream and downstream openings using reinforced concrete plugs to prevent unauthorized entry.

The Iron Gate Fish Hatchery downstream from the dam would remain in place. The KHSR requires PacifiCorp to secure an alternate water source to replace the existing water supply pipe from Iron Gate Dam.

Retention of the Iron Gate powerhouse would require the structure to be sealed and fenced. The DRE would handle mechanical and electrical equipment and equipment containing potentially hazardous materials in the same manner as for the other dam removals under this alternative.

Figure 2-20. Iron Gate dam showing portion of dam to be removed for the Partial Facilities Removal Alternative.

2.4.4.2 Schedule

The Partial Facilities Removal of Four Dams Alternative would follow a schedule similar to that of the Proposed Action. Figure 2-21 provides a schedule that is consistent with the schedule in Section 2.3.2 for Full Facilities Removal. The staging and methods would remain the same; however, the DRE would only remove portions of the dam and facilities. This alternative's schedule includes time to secure retained facilities by removing hazardous materials and installing fences and similar security features to prevent unwanted entry. Therefore, it is not likely that this alternative would result in a substantially shorter project schedule than the Proposed Action.

2.4.4.3 Workforce

Table 2-23 shows the estimated workforce necessary for deconstruction at each facility. The crews for the removals at Copco 1 and 2 Dams could move between the projects as necessary to perform critical path work, to reduce overall workforce numbers, depending on how the contract is released for the projects.

Figure 2-21. Anticipated Schedule for Partial Facilities Removal.

Table 2-23. Estimated Construction Workforce for Partial Removal at each Facility

Facility	Estimated Average Construction Workforce	Duration	Estimated Peak Workforce	Peak Period
J.C. Boyle	20 to 30 people	10 months	40–45	Jul 2020–Sep 2020
Copco 1	25 to 35 people	12 months	50–55	Nov 2019–Apr 2020
Copco 2	20 to 30 people	7 months	35–40	May 2020–Aug 2020
Iron Gate	30 to 40 people	18 months	75–80	Jun 2020–Sep 2020

2.4.4.4 Environmental Measures

The Partial Facilities Removal of Four Dams Alternative would incorporate standard measures to reduce environmental effects. These measures would be the same as those included in the Proposed Action (see Section 2.4.3).

2.4.4.5 Reservoir Restoration

The Partial Facilities Removal of Four Dams Alternative would include the same reservoir restoration actions described above for the Proposed Action. The restoration actions would include bank stabilization, revegetation, and decommissioning and or modification to existing recreation facilities surrounding the reservoir. Securing facilities left in place following partial facilities removal is not considered a component of this reservoir restoration action and would be completed as described above for this alternative.

2.4.4.6 Recreation Facilities

Changes to the recreation facilities surrounding the existing reservoirs would be the same as those in the Proposed Action (see Table 2-14).

2.4.4.7 Keno Transfer

The Partial Facilities Removal of Four Dams Alternative would include the transfer of Keno Dam as a connected action in the same fashion as for the Proposed Action. The description of the transfer presented in Section 2.4.3.7 characterizes how the transfer would be executed under the Partial Facilities Removal of Four Dams Alternative.

2.4.4.8 East and Westside Facilities – Programmatic Measure

The Partial Facilities Removal of Four Dams Alternative would include decommissioning the East Side and Westside Facilities in the same fashion as the Proposed Action. The description of the facility decommissioning presented in Section 2.4.3.8 characterizes how decommissioning would be completed under the Partial Facilities Removal of Four Dams Alternative.

2.4.4.9 City of Yreka Water Supply Pipeline Relocation – Programmatic Measure

The Partial Facilities Removal of Four Dams Alternative would include the relocation of the City of Yreka Water Supply Pipeline in the same fashion as the Proposed Action. The description of the relocation presented in 2.4.3.9 characterizes how the relocation would be completed under the Partial Facilities Removal of Four Dams Alternative.

2.4.4.10 KBRA – Programmatic Measures

The Partial Facilities Removal Alternative would include implementation of the KBRA in the same fashion as the Proposed Action. The description of the KBRA presented in Section 2.4.3.10 characterizes the plans, programs, and actions that would be pursued under the Partial Facilities Removal of Four Dams Alternative.

2.4.5 Alternative 4: Fish Passage at Four Dams

Alternative 4 would provide upstream and downstream fish passage at the Four Facilities. The Fish Passage at Four Dams Alternative would not satisfy the KHSA; consequently, the KBRA would not be implemented (although ongoing restoration activities in the No Action/No Project Alternative may continue). For the purposes of this analysis, alternatives that would not result in full implementation of the KHSA do not include the KBRA as a connected action to the alternative. Additionally, the transfer of Keno Dam to DOI would not move forward as a connected action.

The description of Alternative 4 uses information from the *United States Department of the Interior's Filing of Modified Terms, Conditions, and Prescriptions (Klamath Hydroelectric Project, No. 2082)* (DOI 2007) and from the *National Marine Fisheries Service Modified Prescriptions for Fishways and Alternatives Analysis for the Klamath Hydroelectric Project (FERC Project No. 2082)* (NOAA Fisheries Service 2007). These fishway prescriptions and mandatory conditions were developed during the FERC

relicensing process. Issues of Material Fact associated with the prescriptions and mandatory conditions were challenged; the resulting Administrative Law Judge decision found that PacifiCorp failed to meet its burden of proof on most factual issues in dispute. Attachment B of Appendix A includes the full list of prescriptions and mandatory conditions; several of the prescriptions include studies to determine if features are necessary (such as spillway and tailrace modification).

For the purposes of analysis in this EIS/EIR, however, Alternative 4 has been developed with some assumptions regarding details and feature designs for purposes of this analysis that are not included or not yet determined for the fishway prescriptions and do not reflect any final decision by NOAA Fisheries Service or USFWS regarding any differences from the express text of the fishway prescriptions or how any decision may be made under the terms of the fishway prescriptions. Alternative 4 thus includes some specific fishway facility design and construction details beyond what are specifically required in the prescriptions and are based on designs of similar fishway facilities used at other hydroelectric facilities. For example, the prescriptions include spillway modification at Copco 1 Reservoir; Alternative 4 includes a fish screen at the power intake and a fish collection device to divert fish from the spillway. Prior to advancing to feasibility-level of design, the Hydropower Licensee must obtain concurrence from NOAA Fisheries Service and USFWS related to proposed modifications for each independent facility, or any major feature of a facility (DOI 2007; NOAA Fisheries Service 2007).

Flows within the Hydroelectric Reach would change compared to the No Action/No Project Alternative because of the mandatory conditions related to releases from J.C. Boyle Dam and Powerplant. A key 4(e) condition requires at least 40 percent of J.C. Boyle inflow to be released into the Bypass Reach. Under this alternative, the J.C. Boyle Powerhouse would produce peaking power only one day a week to coincide with recreation releases. This alternative would generate less power than current production because of the change in peaking operations and the flow requirements for the J.C. Boyle Bypass Reach. Flows downstream from Iron Gate Dam, however, would be similar to those in the No Action/No Project Alternative (see Figure 2-7).

This alternative would be implemented through FERC licensure including 401 certifications to an entity that would operate the Four Facilities (the “Hydropower Licensee”). Inflows to Upper Klamath Lake, and outflows from Iron Gate Dam are assumed to be the same under the Fish Passage at Four Dams Alternative as described above for the No Action/No Project Alternative. The ongoing resource management activities, TMDLs, biological opinions, and other regulatory conditions described under the No Action/No Project Alternative would also occur under this alternative.

This section describes general information about the fish passage facilities that would be constructed, and the following sections discuss aspects unique to each facility. Typical upstream fish passage facilities at each dam would consist of pool and weir type fish ladders to provide the safe, timely, and effective upstream passage of Chinook and coho salmon, steelhead trout, Pacific lamprey, and redband trout. This type of fish ladder is

generally constructed from reinforced concrete and occasionally uses metal or wood hardware for adjustable components. In order to meet the prescribed fish passage criteria (DOI 2007; NOAA Fisheries Service 2007), the fish ladders would use 6-inch steps between each weir that would result in an overall structure slope of 4 and 6 percent. At a minimum, each ladder bay would measure 8 feet long by 6 feet wide by 5 feet deep to meet the minimum pool requirements (NOAA Fisheries Service 2008), which would drive the structure slope of 4 to 6 percent. The FERC Final EIS identified a 10 percent slope, but that slope would not meet current requirements for fish ladders. Figure 2-22 shows an example of a cast-in-place pool and weir fish ladder that is similar to that proposed for upstream fish passage at the Four Facilities under this alternative. Final design of these structures would likely exceed this minimum pool dimension by 50 to 100 percent in order to meet all regulatory criteria and minimize turbulence in the ladder bays. Table 2-24 provides a minimum footprint for each upstream fish ladder.

Figure 2-22. Example of cast-in-place pool and weir fish ladder.

Table 2-24. Minimum Structure Footprint and Dimensions for Fish Ladders at Each Dam

Dam	Vertical Drop (feet)	Min. Number of Pools	Min. Structure Length (feet)	Min. Structure Footprint (square feet)
J.C. Boyle	61	122	1,089	8,712
Copco 1	124	249	2,241	17,928
Copco 2	22	44	396	3,168
Iron Gate	157	314	2,826	22,608

Vertical Drop Source: CH2M Hill 2003

The J.C. Boyle and Copco 2 fish ladders are well within typical pool and weir fish ladders being designed today to meet fish passage criteria for the vertical drop. The Copco 1 and Iron Gate fish ladders are substantially longer and have a bigger elevation differential; however, there are two successful examples in Oregon where bigger elevation differentials have been overcome with pool and weir fish ladders for upstream fish passage. The two examples are the Faraday/North Fork ladder on the Clackamas River (196 feet tall, 1.9 miles long) and the Pelton ladder on the Deschutes River (230 feet tall, 2.8 miles long) (Ratliff et. al. 1999). The Pelton ladder was shut down in 1968 primarily due to downstream juvenile passage and not upstream passage.

Fishway prescriptions require two downstream entrances and associated entrance pools for each fish ladder (DOI 2007; NOAA Fisheries Service 2007). All fish ladders would require an auxiliary water supply (AWS) to ensure adequate attraction flows at the downstream and to draw fish into the fish ladder and moderate water temperatures. The AWS would consist of a pipeline or intake that draws water from the reservoir and releases it in the fish ladder and near the fishway entrance pools. To accommodate increased flows, the downstream bays of the fish ladder would be larger than upstream bays in the fish ladder.

Downstream fish passage facilities would vary at each dam. Generally, the facilities would include fish screens and collection facilities to screen the fish away from the intake structures for the power generation facilities and the spillways (if they are unsuitable for downstream passage). Table 2-25 summarizes the fish passage facilities that would be required at each dam under this alternative.

Table 2-25. Fish Passage Improvements under the Fish Passage at Four Dams Alternative

Dam	Upstream Fish Passage	Spillway Modifications ¹	Tailrace Barrier ¹	Fish Screens & Bypass
J.C. Boyle	New fish ladder over dam with auxiliary water supply (AWS) for attraction	Spillway modification to provide smooth transition	Extend river bank and install cutoff screen	New fish screen with bypass
Copco 1	New fish ladder over dam with AWS	Collection device	Extend river bank and install cutoff screen	New fish screen with bypass
Copco 2	New fish ladder over dam with AWS	Spillway modification to provide smooth transition	Extend river bank and install cutoff screen	New fish screen with bypass
Iron Gate	New fish ladder over dam with AWS, observation and sorting station in fish ladder	Spillway modification to provide smooth transition		New fish screen with bypass

Notes:

1. For the purposes of analysis in this EIS/EIR, Alternative 4 includes some specific fishway facility design and construction details that are beyond those required in the prescriptions. The modified prescriptions provide that the applicant is allowed to perform site-specific studies to determine if spillway modifications and tailrace barriers are necessary at the developments where these are prescribed. However, the modified prescriptions provide that spillway modifications and tailrace barriers shall be constructed and operated unless and until USFWS and NOAA Fisheries Service determine based on any such site-specific studies that any prescribed spillway modifications or tailrace barriers are unnecessary.

2.4.5.1 Construction Details

Construction of fish ladders represents the bulk of the work under this alternative. The Hydropower Licensee would construct the ladders from reinforced concrete using construction methods typical for civil infrastructure work.

Table 2-26 shows estimated quantities of concrete for each facility.

Table 2-26. Estimated Minimum Amount of Reinforced Concrete Necessary for Fish Ladder at Each Dam

Dam	Reinforced Concrete (yd ³)
J.C. Boyle	2,800
Copco 1	5,800
Copco 2	1,000
Iron Gate	7,000

The Hydropower Licensee would need to control water and isolate the work area from flowing water and aquatic organisms throughout the duration of construction. Control mechanisms would be installed prior to starting work for each dam removal. The Hydropower Licensee could control water in most areas using gravity diversions; however, pumps could be required to dewater isolated ponding. Dewatering would require electric, gasoline, or diesel powered pumps, along with flexible hosing to convey water. Pumps would discharge water away from the river into upland areas to prevent discharge of fine sediments to waterways.

The Hydropower Licensee would work in wet conditions in areas that cannot be dried. For in-water work, the Hydropower Licensee would use physical barriers of a type and in a manner similar to that used under the dam removal alternatives.

The following sections provide a detailed description of necessary fish passage facilities for each dam under the Fish Passage at Four Dams Alternative.

2.4.5.1.1 J.C. Boyle Fish Passage Facilities⁶

The J.C. Boyle site has the best access for construction equipment and staging for construction. Equipment and materials could be brought into the site on existing gravel access roads and temporary access roads where necessary.

Upstream Passage

J.C. Boyle Dam has an existing pool and weir concrete fish ladder on the north side of the spillway, but it does not meet current design criteria and must be replaced because of its

⁶ Feature design has been provided in this EIS/EIR to support effects analysis. If the Klamath Hydroelectric Project is relicensed, the licensee would be required to obtain concurrence from USFWS and NOAA Fisheries Service regarding fishway design and construction plans for each facility prior to advancing to feasibility-level of design (NOAA Fisheries Service 2007; DOI 2007).

configuration and poor structural condition. The Fish Passage at Four Dams Alternative would include removal of the existing fish ladder structure and construction of a new pool, weir, and reinforced concrete fish ladder on the north side of the dam spillway, at or near the same location as the existing fish ladder (see Figure 2-23).

Figure 2-23. Conceptual Layout of J.C. Boyle Fish Passage Facilities.

The overall difference in water levels from the downstream river to J.C. Boyle Reservoir ranges from 55 to 61 feet, depending on reservoir pool elevation. The new fish passage facilities would have multiple openings into the reservoir to accommodate the reservoir pool fluctuation while maintaining continual upstream passage. The new ladder would have two entrances to accommodate low flow and high flow conditions.

An AWS would be necessary for temperature and attraction flow mitigation. The AWS would draw water from the reservoir through a screened inlet and variable height intake structure to provide water temperature control. The AWS would pipe water into the fish ladder at two locations.

Construction of these facilities would begin with demolition and removal of the existing fish ladder using mechanical means (such as hydraulic shears or hoe-ram). The Hydropower Licensee would then install the new reinforced concrete fish ladder by constructing concrete forms, laying the reinforcement, and pouring concrete. The Hydropower Licensee would construct a cofferdam around the area where the fish ladder enters the reservoir to allow construction in dry conditions.

Downstream Fish Passage – Water Intake

The existing water intake has a design flow of 3,000 cfs, which requires a minimum fish screen of 7,500 square feet based on an approach velocity of 0.4 feet per second (ft/s). The Fish Passage at Four Dams Alternative would include a conventional fish screen at the J.C. Boyle water intake. The fish screen would terminate in a 36 inch diameter fish bypass pipe (approximately 40 cfs) that would run from the water intake to a bypass facility for recording downstream migrating fish and then continuing on to a controlled outfall in the river downstream from the dam. The fish screen would be stainless steel and the fish return pipe would be standard steel with concrete and steel support structures along the length of the pipe.

The fish screen would be fabricated offsite and installed by a crew of skilled workers using light equipment. This phase of construction would require extensive dewatering and work isolation effort in order to provide a dry or partially isolated work area. Dewatering could require reservoir water level manipulation or construction of coffer barriers with pumps to dewater the work area around the water intakes.

Downstream Fish Passage – Spillway

Radial gates regulate discharge over the J.C. Boyle Dam's concrete spillway section that terminates in an abrupt drop onto bedrock. Modifications to the spillway would likely include removing the drop at the downstream end of the spillway by building a cast-in-place concrete transition and minor channel modifications. This design would likely reduce fish mortality on the rock outcrop below the spillway and provide a smooth transition for downstream passage. Construction would involve a small amount of demolition and concrete placement; methods would be similar to the work on the new fish ladder.

Tailrace Barrier

The power generation turbines at J.C. Boyle Powerhouse are several miles downstream from the dam with a large outlet bay, or tailrace area, that flows into the Klamath River (see Figure 2-2). This tailrace has the potential for false attraction waters and needs a barrier. The Fish Passage at Four Dams Alternative would include extension of the bank of the Klamath River and installation of a stainless steel, wedge-wire cutoff screen.

2.4.5.1.2 Copco 1 Fish Passage Facilities⁷

The Copco 1 Dam site has difficult site access because of steep canyon terrain. The Fish Passage at Four Dams Alternative would include construction of temporary roads for site access and other special provisions to move materials, such as a tower crane or aerial tramway.

Upstream Passage

Fish Passage at Four Dams Alternative would include a new pool and weir fish ladder on the right side of Copco 1 Dam for upstream fish passage. The fish ladder would have an AWS plumbed into it at two locations to moderate water temperatures, flow in the fishway, and attraction flows at the downstream end of the fishway. The downstream entrance of the fish ladder would have two entrances for low water and high water conditions, as shown in Figure 2-24. The upstream end of the fish ladder that enters the reservoir area would also have multiple openings to accommodate water level fluctuations. Construction would require installation of the cast-in place concrete ladder and isolation of the area where the ladder connects to the reservoir.

Figure 2-24. Copco 1 Fish Ladder Configuration, Fish Screen, and Collection Device.

⁷ Feature design has been provided in this EIS/EIR to support effects analysis. If the Klamath Hydroelectric Project is relicensed, the licensee would be required to obtain concurrence from USFWS and NOAA Fisheries Service regarding fishway design and construction plans for each facility prior to advancing to feasibility-level of design (NOAA Fisheries Service 2007; DOI 2007).

Downstream Fish Passage

The existing facilities at Copco 1 Dam are not conducive to downstream fish passage because the juvenile salmonids travelling downstream would flow through the intake to the power generation facility or over the dam spillway during high flows. The Fish Passage at Four Dams Alternative would include a fish screen as the primary measure to ensure safe downstream passage (DOI 2007; NOAA Fisheries Service 2007).

Depending on the frequency of spill, a collection facility may also be necessary to prevent fish from moving toward the spillway area. For the purposes of this analysis, the Fish Passage at Four Dams Alternative includes construction of a collection facility that is integrated with the fish screen for Copco 1 Reservoir. The collection facility would protect the entire spillway area. The collection device would be fabricated off-site and shipped to the site using standard flatbed trucks. The Hydropower Licensee would assemble the pieces on-site. Once the structure was assembled, it would be put in place near the water intake area and secured.

The fish screen would be a steel structure using a typical fish screen configuration. The existing power generation water intake has a design flow of 3,200 cfs, which requires a minimum fish screen of 8,000 square feet based on an approach velocity of 0.4 ft/s. The fish screen would be at the intake structure on the right side of the dam. The fish screen would be anchored to the existing rock and concrete dam structure to ensure stability. The screen would direct fish to an approximately 36 inch diameter bypass pipe with a capacity of more than 60 cfs.

Tailrace Barrier

The Copco 1 Powerhouse tailrace configuration is similar to the Iron Gate facility. For the purposes of analysis, this analysis of Alternative 4 includes a tailrace barrier.⁸

2.4.5.1.3 Copco 2 Fish Passage Facilities⁹

The Copco 2 site has difficult access because of the narrow canyon and relatively steep road access into the site. The existing access road would require upgrades such as gravel surfacing and grading.

Upstream Fish Passage

The Fish Passage at Four Dams Alternative includes a concrete pool and weir fish ladder with 6-inch drops to provide volitional fish passage at Copco 2 Dam. The overall difference in water levels from the downstream river to Copco 2 Reservoir is about 20 to

⁸ The modified prescriptions provide that the applicant is allowed to perform site-specific studies to determine if spillway modifications and tailrace barriers are necessary at the developments where these are prescribed. However, the modified prescriptions provide that spillway modifications and tailrace barriers shall be constructed and operated unless and until USFWS and NOAA Fisheries Service determine based on any such site-specific studies that any prescribed spillway modifications or tailrace barriers are unnecessary.

⁹ Feature design has been provided in this EIS/EIR to support effects analysis. If the Klamath Hydroelectric Project is relicensed, the licensee would be required to obtain concurrence from USFWS and NOAA Fisheries Service regarding fishway design and construction plans for each facility prior to advancing to feasibility-level of design (NOAA Fisheries Service 2007; DOI 2007).

25 feet, depending on reservoir pool elevations. The new fish passage facilities would accommodate the reservoir pool fluctuation while maintaining continual upstream passage. Construction would require installation of the cast-in place concrete ladder and isolation of the area where the ladder connects to the reservoir.

The pool and weir fish ladder would be on the right side of the concrete spillway structure in the earth embankment. An AWS would be necessary for temperature and attraction flow mitigation. The AWS would draw water from the reservoir through a screened inlet. Figure 2-25 shows a conceptual layout for a fish ladder at Copco 2 Dam.

Figure 2-25. Copco 2 Fish Ladder and Fish Screen, along the left side of the river, for power water diversion.

In addition to the fish ladder, a transverse bedrock sill approximately 0.5 miles upstream of the Copco 2 Powerhouse in the Bypass Reach could create a fish passage barrier. A new FERC license would likely increase flows in the Bypass Reach and this barrier would not likely exist. As part of the license renewal process, a study would determine whether corrective measures would be needed at this barrier to provide fish passage.¹⁰ According to the mandatory prescriptions, sufficient flow would need to be released into the Bypass Reach to attract upstream-migrating fish into the fishway entrance pools and ensure that flows are sufficient to attract fish at the point of confluence between the Bypass Reach and the downstream powerhouse discharges. The prescriptions do not specify a flow rate in the Bypass Reach, but modeling the recommendations indicates that minimum flows would be approximately 438 cfs.

Downstream Fish Passage – Water Intake

The existing power generation water intake at Copco 2 Dam is on the left side of the concrete spillway structure. The water diversion capacity is 3,200 cfs, which would require a minimum 8,000 square feet of screen. A conventional fish screen for the water intake would minimize the length of the screen. The fish screen would terminate in an approximately 36-inch fish bypass pipe that would flow over the dam and into the downstream river area. As with the fish screen for the J.C. Boyle Development, the screen would be fabricated off-site and installation would require dewatering and isolation to provide a dry or partially isolated work area.

Downstream Fish Passage – Spillway

The Copco 2 spillway is controlled with radial gates that regulate discharge over the concrete spillway section. The existing elevation difference between the spillway crest and water level on the downstream side of the dam is approximately 13 feet. Modifications to the concrete apron and spillway would minimize or eliminate rapid changes in direction and abrupt velocity changes at the spillway apron for downstream moving fish. A transitional ramp would be installed at the midpoint of the spillway to transition flows smoothly into the water conditions downstream from the concrete apron. The transitional ramp would be formed using cast-in-place concrete similar to the existing spillway construction.

Tailrace Barrier

The power generation turbines for Copco 2 are 1.4 miles downstream from the dam with a large tailrace area that flows back into the Klamath River. The water flowing out through this tailrace has the potential to attract fish to a false pathway. Alternative 4 includes a tailrace barrier extending the bank line of the Klamath River and installing a cutoff screen to prevent fish from straying into the tailrace area (see Figure 2-26).

¹⁰ The prescriptions require modifications to the bedrock sill unless the licensee demonstrates through an evaluation approved by USFWS and NOAA Fisheries Service that indicates that it will not be a “barrier to fish passage under normal operating flows specified for the Copco 2 bypassed reach in the new license” (USFWS 2007; NOAA Fisheries Service 2007).

Figure 2-26. Modifications at the tailrace of the Copco 2 Powerplant would extend the bank and install a tailrace barrier screen (red dots).

(Source: Klamath Riverkeeper)

2.4.5.1.4 Iron Gate Dam Fish Passage Facilities¹¹

The Iron Gate Development has difficult site access because of steep canyon terrain. It would require construction of temporary roads for site access and a tower crane or aerial tramway to move construction materials.

Upstream Fish Passage

The Fish Passage at Four Dams Alternative would include installation of a fish ladder on the left side of Iron Gate Dam near the existing penstock pipe, as shown in Figure 2-27. The fish ladder would have two entrances with entrance pools at the downstream end of the fish ladder. An AWS would feed water into the fish ladder at two locations to help with attraction flows and water temperatures. Multiple openings would be necessary where the fish ladder connects to the reservoir to allow for water level fluctuation. Construction would require installation of the cast-in place concrete ladder and isolation of the area where the ladder connects to the reservoir.

¹¹ Feature design has been provided in this EIS/EIR to support effects analysis. If the Klamath Hydroelectric Project is relicensed, the licensee would be required to obtain concurrence from USFWS and NOAA Fisheries Service regarding fishway design and construction plans for each facility prior to advancing to feasibility-level of design (NOAA Fisheries Service 2007; DOI 2007).

Figure 2-27. Conceptual fish passage facilities layout for Iron Gate Dam showing fish ladder, water intake screen, and spillway transition modifications.

Downstream Fish Passage – Water Intake

The existing power generation water intake structure at Iron Gate Dam is on the left side of the embankment dam. The water intake design flow is 1,735 cfs and would require a minimum fish screen of 4,340 square feet based on an approach velocity of 0.4 ft/s. A conventional fish screen would be the best option for screening the water intake to address the substantial size of the screen. The fish screen would terminate in a 36-inch-diameter fish bypass pipe (approximately 40 cfs) that would run from the water intake to a fish bypass facility for identification of downstream migrating juveniles and then continue downstream to the river below the dam. The fish screen would be stainless steel and the fish return pipe would be standard steel with concrete and steel support structures along the length of the pipe. As with the fish screen for the J.C. Boyle facility, the fish screen would be fabricated off-site and installation would require dewatering and isolation to provide a dry or partially isolated work area.

Downstream Fish Passage – Spillway

The Iron Gate spillway is an unregulated, free overflow from the reservoir area. Likely modifications to the spillway would include building a smoother transition at the downstream end using cast-in-place concrete to form an ogee-type drop structure that would connect the downstream river levels to the free flowing spill conditions. This modification would reduce fish mortality on the rock outcrop below the spillway. In addition, the Hydropower Licensee would use concrete to fill the area just upstream of the free outfall at the downstream end of the spillway to make a consistent hydraulic transition and reduce potential harm during downstream passage of primarily juvenile fish.¹²

2.4.5.2 Schedule

The schedule would likely follow the schedule prescribed in the FERC relicensing process. The prescriptions include a schedule for implementation and recommend that downstream facilities be installed prior to upstream passage facilities (DOI 2007; NOAA Fisheries 2007). Table 2-27 shows the schedule for implementation (including design, permitting, and construction) of the fish passage facilities at each dam, based on these constraints.

Table 2-27. Timetable for Implementation of Fish Passage Improvements at each Dam from Date of FERC License Renewal

Dam	Upstream Fish Passage	Spillway Modifications	Tailrace Barrier	Screens & Bypass
J.C. Boyle	4 years	4 years	4 years	4 years
Copco 1	6 years	6 years	8 years	6 years
Copco 2	6 years	6 years	8 years	6 years
Iron Gate	5 years	5 years	N/A	5 years

Key:
N/A: Not Applicable

2.4.5.3 Workforce

Table 2-28 shows the estimated workforce necessary for construction at each facility. Each facility would also have 5 to 10 on-site construction administrative personnel (e.g., inspectors, field engineers) for the duration of the project.

¹² The modified prescriptions provide that the applicant is allowed to perform site-specific studies to determine if spillway modifications and tailrace barriers are necessary at the developments where these are prescribed. However, the modified prescriptions provide that spillway modifications and tailrace barriers shall be constructed and operated unless and until USFWS and NOAA Fisheries Service determine based on any such site-specific studies that any prescribed spillway modifications or tailrace barriers are unnecessary.

Table 2-28. Estimated Average Construction Workforce for Fish Passage at Four Dams

Facility	Estimated Construction Workforce	Duration
J.C. Boyle	10 to 20 people	4-6 months
Copco 1	15 to 25 people	9 months
Copco 2	10 to 20 people	4-6 months
Iron Gate	15 to 30 people	12 months

2.4.5.4 Environmental Measures

The Fish Passage at Four Dams Alternative would incorporate standard measures to reduce environmental effects. These measures would be the same as those included in the Proposed Action (see Section 2.4.3).

2.4.5.5 Trap and Haul around Keno Impoundment – Programmatic Measure

NOAA Fisheries Service and DOI prescriptions include a measure to trap and haul fall-run Chinook salmon upstream and downstream around Keno Impoundment. The prescriptions call for seasonal trap and haul operations from June 15 to November 15 when water quality conditions are not suitable for fish (dissolved oxygen concentration less than 6 mg/l or temperature above 20 degrees Celsius) (DOI 2007; NOAA Fisheries Service 2007). Upstream operations would include construction of a collection and handling facility downstream from Keno Dam; these fish would be released upstream of Link River Dam. Downstream operations would include construction of a collection and handling facility at or adjacent to Link River Dam that would collect downstream migrating fish. These fish would be released downstream from Keno Dam. The exact details of the collection facilities, haul routes, or necessary road improvements are not yet defined; therefore, this measure is analyzed in this EIS/EIR at a programmatic level.

2.4.6 Alternative 5: Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative consists of the full removal of Iron Gate and Copco 1 facilities and installation of upstream and downstream fish passage facilities at both the J.C. Boyle and Copco 2 Dams. On Copco 2 and J.C. Boyle Dams, ladders would be less complex to construct and provide volitional fish passage because of dam height and reservoir length. Iron Gate and Copco 1 Dams also provide less power; therefore, removal would have less effect on power generation. Removing Iron Gate and Copco 1 Reservoirs, the two largest impoundments in the Hydroelectric Reach, would also address water quality problems driven by reservoir size, such as increased water temperature, low dissolved oxygen, and toxic algal blooms in the summer and fall.

In order to meet current criteria for volitional fish passage, J.C. Boyle and Copco 2 Dams would require new upstream and downstream fish passage facilities. The fish passage facilities at J.C. Boyle and Copco 2 Dams would be the same as in the Fish Passage at Four Dams Alternative; Section 2.4.5 describes these facilities in detail. Similar to the

Fish Passage at Four Dams Alternative, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would incorporate most of the prescriptions from the FERC relicensing process related to fish passage at J.C. Boyle and Copco 2 Dams (see Attachment B of Appendix A for a list of prescriptions). Alternative 5 would not incorporate the prescriptions related to peaking power at J.C. Boyle and recreation releases. In Alternative 5, Copco 2 Dam would be the only dam remaining downstream from J.C. Boyle Dam. Copco 2 Reservoir is very small, and does not have adequate capacity to reregulate flows associated with peaking operations so that they are suitable for fish downstream. Therefore, Alternative 5 would not include peaking operations or recreation releases on any days at J.C. Boyle Dam.

Alternative 5 flows would be driven by releases from J.C. Boyle Dam because of the lack of downstream reregulation. The prescriptions would require 40 percent of J.C. Boyle releases to enter the Bypass Reach; therefore, these flows would be greater than the No Action/No Project Alternative. Flows at the Iron Gate Gauge would be generally similar to the No Action/No Project Alternative to maintain suitable flows for fish, although they may experience small variations because Iron Gate and Copco 1 Dams would not be in place to control flow patterns.

Removal of Iron Gate and Copco 1 Dams would be the same as in the Proposed Action; Section 2.4.3 describes the removal plans in more detail. Inflows to Upper Klamath Lake, and outflows from Copco 2 Dam and fish ladder and the Copco 2 Powerhouse are assumed to be nearly the same under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative as described above for the No Action/No Project Alternative.

A Hydropower Licensee would implement this alternative through licensure by FERC and would be responsible for its long term operation and maintenance. Implementation of the KBRA is not included in the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative. The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would not satisfy the KHSA; consequently, the KBRA would not be implemented (although ongoing restoration activities in the No Action/No Project Alternative may continue). For the purposes of this analysis, alternatives that would not result in full implementation of the KHSA do not include the KBRA as a connected action to the alternative. Additionally, the transfer Keno Dam to DOI would not move forward as a connected action. The ongoing resource management activities, TMDLs, biological opinions, and other regulatory conditions described under the No Action/No Project Alternative would also occur under this alternative.

2.4.6.1 Schedule

This alternative would follow a schedule similar to that of the Proposed Action, because two of the dams are being removed and fish passage would be necessary as soon as possible after dam removal. Similar to Alternative 4, downstream fishways at each site would be completed before upstream fishways. Figure 2-28 shows the schedule for construction of the fish passage facilities at two dams and for removal of the remaining two dams, based on these constraints.

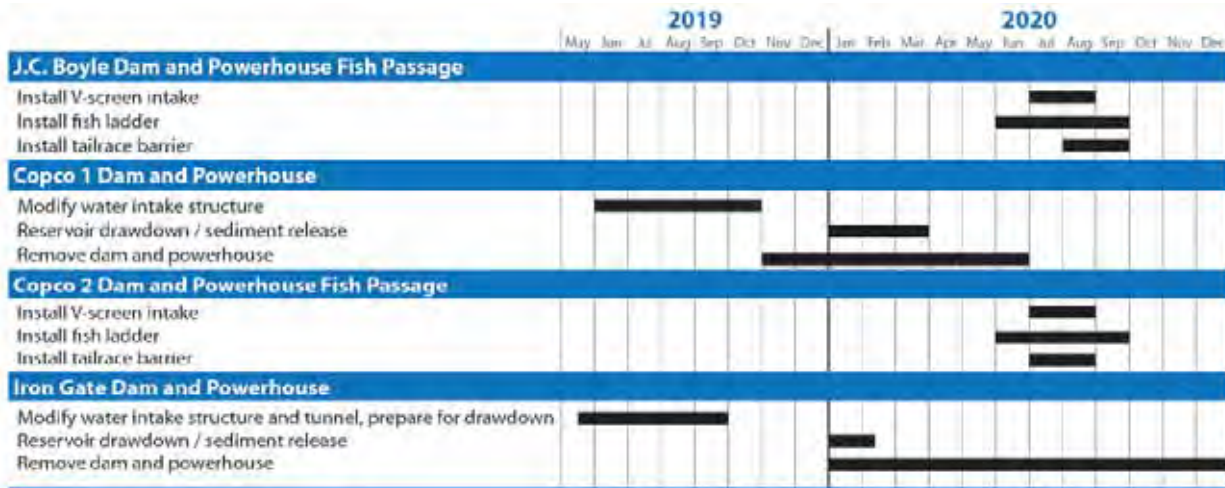

Figure 2-28. Anticipated schedule for Fish Passage at J.C. Boyle and Copco 2 Dams with Removal of Copco 1 and Iron Gate Dams.

2.4.6.2 Workforce

Table 2-29 shows the estimated workforce necessary for each facility under this alternative. In addition to the average construction workforce, there would be 5 to 10 on-site construction management staff (e.g., inspectors, field engineers) at each site for the duration of the project. The deconstruction efforts at Copco 1 and Iron Gate Dams would constitute the bulk of the efforts in this alternative.

Table 2-29. Estimated Construction Workforce for Full Removal of Iron Gate and Copco 1 Dams with Fish Passage at Copco 2 and J.C. Boyle Dams

Facility	Estimated Average Construction Workforce	Duration	Estimated Peak Workforce	Peak Period
J.C. Boyle	10 to 15 people	4 to 6 months	15–20	Jul 2020–Sep 2020
Copco 1	30 to 35 people	12 months	50–55	Nov 2019–Apr 2020
Copco 2	10 to 15 people	4 to 6 months	15–20	Jul 2020–Sep 2020
Iron Gate	35 to 40 people	18 months	75–80	Jun 2020–Sep 2020

2.4.6.3 Environmental Measures

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would incorporate standard measures to reduce environmental effects. These measures would be the same as those included in the Proposed Action (see Section 2.4.3).

2.4.6.4 Recreation Facilities

Recreation facilities near J.C. Boyle Reservoir would stay intact, and the Copco 2 area does not have any developed recreation facilities. Recreation facilities at Iron Gate and Copco 1 (see Table 2-30) would be removed.

Table 2-30. Recreation Facilities under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative

Site Name	Existing Facilities	Facilities Following Dam Removal
<i>Sites at J.C. Boyle Reservoir (Oregon)</i>		
Pioneer Park	Two day-use areas with picnic tables, fire rings, and portable toilets	This site would remain, there would be no improvements or changes
Topsy Campground	Campground, day-use area, boat launch	This site would remain, there would be no improvements or changes
<i>Sites at Copco 1 Reservoir (California)</i>		
Mallard Cove	Day-use picnic area and boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Copco Cove	Picnic area and boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
<i>Sites at Iron Gate Reservoir (California)</i>		
Fall Creek Trail	Day-use area and trail	This site would remain, there would be no improvements or changes
Jenny Creek	Day-use area and campground	This site would remain, there would be no improvements or changes
Wanaka Springs	Day-use area, campground, boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Camp Creek	Day-use area, campground, boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Juniper Point	Primitive campground and boat dock	All facilities would be removed. Parking area would be regraded, seeded, and planted
Mirror Cove	Campground and boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Overlook Point	Day-use area	All facilities would be removed. Parking area would be regraded, seeded, and planted
Long Gulch	Picnic area and boat launch	All facilities would be removed. Parking area would be regraded, seeded, and planted
Dutch Creek	Day-use area	All facilities would be removed. Parking area would be regraded, seeded, and planted
Iron Gate Fish Hatchery Public Use Area	Day-use area and boat launch	This site would remain, there would be no improvements or changes

Source: Reclamation 2011

2.4.6.5 Trap and Haul around Keno Impoundment – Programmatic Measure

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would include trap and haul measures to move fish around Keno Impoundment when

water quality is not suitable for fish. The measures would be the same as those described in the Fish Passage at Four Dams Alternative (see Section 2.4.5). The exact details of the collection facilities, haul routes, or necessary road improvements are not yet defined; therefore, this measure is analyzed in this EIS/EIR at a programmatic level.

2.4.6.6 City of Yreka Water Supply Pipeline Relocation – Programmatic Measure

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would include the relocation of the City of Yreka Water Supply Pipeline in the same fashion as the Proposed Action. The description of the relocation presented in 2.4.3.9 characterizes how the relocation would be completed under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative.

2.5 Preferred Alternative

Both Alternative 2 and Alternative 3 include removal of the Four Facilities and implementation of KBRA and both alternatives more fully meet the Purpose and Need (Sections ES.3 and 1.5.2.1). Some key benefits provided by implementation of Alternative 2 and Alternative 3 include (for a full discussion of the Alternatives, see Chapter 3):

- Provides optimal anadromous fish passage to and from at least 420 miles of historical habitat above Iron Gate Dam by creating a free flowing river in the Hydroelectric Reach in 2020
- Anadromous fish would access low gradient historical habitat of critical importance to spawning and rearing under Copco 1 and Iron Gate Reservoirs
- Provides for natural recruitment of spawning gravel and river processes within and below the Hydroelectric Reach through dam removal
- Largely eliminates in 2020 elevated late summer/fall water temperatures in and below the Hydroelectric Reach by removing the largest reservoirs
- Largely eliminates 2020 dissolved oxygen and pH problems produced in reservoirs in the Hydroelectric Reach and transported downstream
- Largely eliminates in 2020 algal toxins produced in the Hydroelectric Reach and transported downstream
- Reduces concentration of myxospores associated with carcasses accumulating below hatchery facilities, thus reducing disease

Removal of the Four Facilities and implementation of KBRA are important components of a durable, long-term solution for local communities and tribes regarding the development, administration, allocation, and advancement of water and native fishery resources of the Klamath Basins. Alternative 2 and Alternative 3 provide a greater opportunity for expanding restoration of salmonids, which, over time would improve

harvest opportunities of salmonids, and when compared to the other alternatives, resolve more societal hardships and conflicts that result from over-allocation of scarce natural resources.

Although Alternative 2 and Alternative 3 are similar, Alternative 2 would remove nearly all structures associated with the Four Facilities, while Alternative 3 would allow some structures to remain. By leaving no structures along the shore of the Klamath River, Alternative 2 leads to positive permanent changes in the human environment such as improvements to scenic quality, less long-term maintenance by land-management agencies, and is more protective of public safety. For these reasons Alternative 2 is the preferred alternative.

Chapter 3

Affected Environment/Environmental Consequences

3.1 Introduction

This chapter describes, for each resource area, the affected environment or environmental setting for the region of the Klamath Basin potentially affected by the dam removal and connected actions, should they be implemented. This chapter presents the analyses of the impacts that would result from the No Action/No Project Alternative or implementation of the Proposed Action and alternatives described in Chapter 2. This chapter also presents mitigation measures to reduce or eliminate the impacts. The sections of this chapter, by resource area, are as follows:

- | | | | |
|------|--|------|---|
| 3.2 | Water Quality | 3.14 | Land Use, Agricultural and Forest Resources |
| 3.3 | Aquatic Resources | 3.15 | Socioeconomics |
| 3.4 | Algae | 3.16 | Environmental Justice |
| 3.5 | Terrestrial Resources | 3.17 | Population and Housing |
| 3.6 | Flood Hydrology | 3.18 | Public Health and Safety, Utilities and Public Services, Solid Waste, Power |
| 3.7 | Groundwater | 3.19 | Scenic Quality |
| 3.8 | Water Supply/Water Rights | 3.20 | Recreation |
| 3.9 | Air Quality | 3.21 | Toxic/Hazardous Materials |
| 3.10 | Greenhouse Gases/Global Climate Change | 3.22 | Traffic and Transportation |
| 3.11 | Geology, Soils, and Geologic Hazards | 3.23 | Noise and Vibration |
| 3.12 | Tribal Trust | | |
| 3.13 | Cultural and Historical Resources | | |

Paleontological resources, which may appear in an Environmental Impact Statement (EIS) or an Environmental Impact Report (EIR) for other projects, were not considered in detail in this Klamath Facilities Removal EIS/EIR, with the exception of their potential presence in a diatomite bed near Copco Reservoir, because the Lead Agencies determined that the volcanic nature of the local geology at the dam sites precluded the presence of these resources in the project area. The potential for project related effects on paleontological resources at this diatomite deposit are described in Section 3.11, Geology, Soils, and Geologic Hazards.

3.1.1 Format of the Environmental Analysis

3.1.1.1 Area of Analysis

This document defines and describes an area of analysis for each resource area. In some cases, the area of analysis consists only of facility deconstruction/construction areas, or nearby areas that would be affected directly by the effects of deconstruction/construction, such as for the analysis of noise impacts. More often, the area of analysis includes the entire Klamath Basin. The area of analyses for water supply/water rights and for land use, agricultural and forest resources, for example, includes the entire Klamath Basin because implementation of the Klamath Hydroelectric Settlement Agreement (KHSA) and Klamath Basin Restoration Agreement (KBRA) could affect these resources not only at the project sites, but also in areas upstream of and downstream from them. In a few cases, the area of analysis is even more geographically broad, such as for socioeconomics.

3.1.1.2 Regulatory Framework

Each resource area is evaluated within the existing framework of Federal, State, and local laws, regulations, policies, and plans. For each resource area, the sub-sections of this chapter briefly list the laws and regulations that are relevant and applicable to the affected environment, area of analysis, and analysis of impacts. Chapter 6 of this EIS/EIR provides further discussion on how laws, regulations, policies, and plans would be addressed through implementation of the Proposed Action or alternatives.

3.1.1.3 Wild and Scenic River Act Component Analysis

The analysis of potential effects on Wild and Scenic River (WSR) components is presented in Section 3.20, Recreation.

3.1.1.4 Coastal Zone Management Act Consistency Determination

The Coastal Zone Management Act requires any applicant seeking a Federal License or permit that could affect land or water uses or resources of the California coastal zone to perform a Federal Consistency Determination for the proposed project. The determination provides a certification that the Proposed Action will be conducted in a manner that to the maximum extent possible is consistent with the policies of the California Coastal Management Program as outlined in the California Coastal Act (CCA) of 1976. The analysis of the consistency between the policies of the California Coastal Act and the Proposed Action is discussed in the following section:

- Discussion of CCA Section 30231 - Section 3.3.4.3 page 3.3-180
- Discussion of CCA Section 30236 - Section 3.3.4.3 page 3.3-181

The focused analysis in Section 3.3.4.3 considers at specific CCA policies; however, this information supplements the more comprehensive analysis of the near-shore impacts in Section 3.2, Water Quality and Section 3.3, Aquatic Resources.

3.1.1.5 Basis of Comparison for the Affected Environment/Environmental Setting

The analysis of impacts requires a basis for comparison of conditions during project construction and post-project. The National Environmental Policy Act (NEPA) basis of comparison is the No Action Alternative. Under the California Environmental Quality Act (CEQA), the basis of comparison is conditions at the time of the Notice of Preparation. As discussed in Chapter 2, the No Action Alternative is similar to conditions at the time of the Notice of Preparation; therefore, the basis of comparison for NEPA and CEQA are generally the same for this document. The impact analysis for each resource considered both the NEPA and CEQA basis of comparison together and, in cases where these baselines differ, further discussion is provided.

3.1.1.6 Environmental Consequences

The methods used to evaluate impacts are described for each resource area. In general, the Lead Agencies identified the impacts that would result from implementation of each of the alternatives within the context of the environmental baseline and regulatory framework. The Lead Agencies used a variety of data sources, models, design documents, interviews, and various other types of research and analysis to predict the impacts. The Lead Agencies then determined the magnitude or significance of the impacts based on significance criteria, where required.

3.1.1.6.1 Significance Criteria

For each resource area, this chapter presents specific significance criteria that the Lead Agencies used to assess the significance level of the impacts under CEQA. Pursuant to NEPA, significance is used to determine whether an EIS or some other level of documentation is required, and once the decision to prepare an EIS is made, the magnitude of the impact is evaluated and no further judgment of significance is required. Therefore, any determinations of significance are for CEQA purposes only.

3.1.1.6.2 Impact Discussion

The impacts of each alternative are discussed in Chapter 3 by resource area and alternative. Each resource area section is structured so that an *italicized* impact statement introduces potential changes that could occur from implementation of each alternative. A discussion of how the resource area would be affected by the impact then follows this initial statement. The impact discussion is concluded with a **bold** significance determination that indicates if there is no impact to a resource area or if the impact to a resource area is beneficial, less than significant, or significant.

3.1.1.6.3 Mitigation Measures

For those impacts that would be significant, the Lead Agencies identified feasible mitigation measures, if they exist, to reduce the level of the impact. The discussion of mitigation measures presented in this chapter includes an assessment of which, if any, significant impacts would remain after mitigation. Chapter 5, Other Required Disclosures, describes any irreversible and irretrievable commitments of resources that the Lead Agencies identified as part of this analysis.

Although existing adverse conditions associated with the No Action/No Project Alternative identified in this chapter would continue, it is not necessary or appropriate to formulate a mitigation measure and ascribe mitigation responsibility for these impacts. In accordance with the intent and requirements of CEQA (Guidelines Section 15126.6), delineating the nature and significance of impacts associated with the No Action/No Project Alternative serves to provide a basis for comparing the impacts of approving the proposed project with the impacts of not approving the proposed project. In particular, the evaluation of alternatives, including the “no project” alternative, serves to determine whether the significant impacts of the alternatives can be avoided or substantially lessened. The analysis presented for the No Action/No Project Alternative in this chapter has determined that the existing adverse conditions would continue for reasons not attributable to the Proposed Action or alternatives; this provides information to be considered by decisionmakers in evaluating the impacts that are attributable to the Proposed Action.

3.1.1.6.4 Scope of the KBRA Evaluation

This EIS/EIR provides a project-level analysis of the KHSA and alternatives¹, but it evaluates the KBRA on a programmatic level. While the general goals of the KBRA actions and programs are known, the specific actions that would occur are not yet defined, and additional environmental analyses according to NEPA, CEQA, and other permits and authorizations would be required as necessary once the KBRA activities are defined at a project-level. The Lead Agencies considered the goals, programs, and plans as described in KBRA Appendix C-3 (summarized in this EIS/EIR in Chapter 2) in the impact analyses to determine their anticipated direct, indirect, and cumulative effects on each resource. Additionally, each section contains an analysis of the potential combined effects of KBRA actions and facility removal actions in the KHSA. These combined effects are described as a part of the programmatic significance determination on the specific KBRA actions. The KBRA programs described at a sufficient level of detail to support the programmatic analysis completed in this EIS/EIR are outlined in Table 3.1-1:

Table 3.1-1 KBRA Plans and Programs Analyzed

KBRA Program	Sections Analyzed
Phase 1 Fisheries Restoration Plan	3.2 Water Quality, 3.3 Aquatic Resources, 3.4 Algae, 3.5 Terrestrial Resources, 3.6 Flood Hydrology, 3.9 Air Quality, 3.10 Global Climate Change/Greenhouse Gases, 3.11 Geology and Soils, 3.13 Cultural and Historic Resources, 3.15 Socioeconomics, 3.16 Environmental Justice, 3.17 Population and Housing, 3.18 Public Health and Safety, Utilities and Public Services, Solid Waste, Power, 3.19 Scenic Quality, 3.20 Recreation, 3.21 Toxic and Hazardous Materials, 3.22 Traffic and Transportation, 3.23 Noise and Vibration

¹ With the exceptions of the East and Westside Facility Decommissioning, an action connected to the Proposed Action and Alternative 3, and the trap and haul program included in Alternatives 4 and 5, both of which are analyzed at the programmatic level.

Table 3.1-1 KBRA Plans and Programs Analyzed

KBRA Program	Sections Analyzed
Phase 2 Fisheries Restoration Plan	3.2 Water Quality, 3.3 Aquatic Resources, 3.4 Algae, 3.5 Terrestrial Resources, 3.6 Flood Hydrology, 3.9 Air Quality, 3.10 Global Climate Change/Greenhouse Gases, 3.11 Geology and Soils, 3.13 Cultural and Historic Resources, 3.15 Socioeconomics, 3.16 Environmental Justice, 3.17 Population and Housing, 3.18 Public Health and Safety, Utilities and Public Services, Solid Waste, Power, 3.19 Scenic Quality, 3.20 Recreation, 3.21 Toxic and Hazardous Materials, 3.22 Traffic and Transportation, 3.23 Noise and Vibration
Fisheries Monitoring Plan	3.3 Aquatic Resources, 3.15 Socioeconomics; 3.16 Environmental Justice

3.1.1.6.5 Best Available Information

The Lead Agencies have used their best efforts to identify and disclose as much relevant information as possible in the EIS/EIR based on the review of the best available information at the time of the issuance of the Notice of Intent, as well as, new information developed to support the Secretarial Determination process. Under CEQA, the Lead Agency is not required to conduct every test or perform all research, studies, or experimentation at the commenter’s request (Pub. Resources Code, Section 21091(d)(2)(B), CEQA Guidelines sec. 15151 and 15204). The Lead Agencies implemented various processes to ensure that only high quality and objective science will contribute to the Secretarial Determination, including, but not limited to:

- All new Federal scientific studies used followed Federal guidance requirements on peer review and scientific integrity, including the procedures adopted by the Departments of the Interior and Commerce (DOI and DOC) in response to the 2004 Office of Management and Budget Bulletin on Peer Review, the Presidential Memorandum on Scientific Integrity dated March 9, 2009 (which was incorporated into Appendix J of the KHSA), the Office of Science and Technology Policy 2010 guidance memorandum on scientific integrity, the 2011 DOI Memorandum on Science Integrity (for DOI agencies), and as well as internal procedures used by the Bureau of Land Management (BLM), United States Geological Survey (USGS), Bureau of Reclamation (Reclamation), U.S Fish and Wildlife Service (USFWS), and the National Oceanic and Atmospheric Administration (NOAA) Fisheries Service.
- Any new Federal scientific studies or reports were developed by a Program Manager, who was supported by a Technical Management Team, which included nine sub-teams covering various disciplines (Engineering, Geomorphology, and Constructability; Environmental Compliance; Biological; Water Quality; Tribal/Cultural; Real Estate; Recreation; and Communications). The quality and objectivity of these products and reports all benefited from the expertise of sub-team members representing multiple Federal agencies.
- During the period of project design and execution of new Federal studies, the public and stakeholders were briefed at frequent intervals via public meetings. Public input from these meetings closed data gaps, refined study approaches, and provided additional studies or data to incorporate into the analyses. This involvement of the public improved the quality and the breadth of the science, and ensured that the final reports addressed questions and concerns raised by the public, Indian tribes, and local agencies (e.g., counties).
- When warranted, new studies were undertaken to fill data gaps and to better inform the Secretarial Determination. Some example new studies included: (1) reservoir sediment drilling and diver inspections of the dam foundations prior to preparing a feasibility engineering plan for dam removal; (2) hydrologic modeling to predict drawdown and transport of reservoir bottom sediments downstream; (3) chemical analysis of sediments and fish tissues to assess the effects of these suspended sediments on humans and biota if they were transported downstream or exposed as new land surfaces; (4) a model of the expected response of Chinook salmon to the Proposed Action; (5) economic analysis of the effects to various sectors on implementing the agreements, locally, regionally and nationally and on Indian Tribes, among many other studies.
- All scientific reports produced by the Technical Management Team (TMT) were reviewed by independent subject matter experts (outside of the Klamath Secretarial Determination process) in accordance with the policies of the agency producing the report. Peer reviews were undertaken to ensure that the reported results were reliable, objective, accurate and scientifically sound.

- In some cases, an existing report important for the Secretarial Determination process had not previously been peer reviewed. Prior to use in contributing to the Secretarial Determination, these previously unreviewed reports were assigned to an independent contractor to obtain one or more critique(s) by subject matter experts to verify their reliability, objectivity, accuracy and to verify their scientific veracity.
- An independent contractor convened four expert panels to evaluate and make findings regarding the likely trajectory of fish populations under both the Proposed Action and the No Action alternatives. The majority of panel members were not from Federal agencies, but were from universities or consulting firms. The four panels evaluated: resident native fish (trout and suckers), lamprey, coho salmon and steelhead, and Chinook salmon. These panels provided an independent evaluation of the information that was available at the time of their deliberations in preparation of their reports. These independent analyses were largely consistent with the findings in the Technical Management Team reports, which provided increased confidence in the science process and the findings relative to fish and fisheries.

One of the goals of scientific analysis is to develop new information and to increase the certainty of conclusions (i.e., reduce scientific uncertainty). Using best available information, however, cannot remove all scientific uncertainty from a decision. No amount of investigating, hypothesis testing, modeling, or peer reviewing will ensure perfect knowledge about how the Klamath River ecosystem would respond to future large changes/actions (e.g., alternatives 2 through 5) or even 50 years of “no action” (e.g., alternative 1). Scientific uncertainty is inherent in any analysis of present and future conditions, particularly in a system as complex as the Klamath Basin.

It is important to understand what is meant by the term scientific “uncertainty” because it has a very different meaning than the meaning more commonly used by the public outside the realm of science; this difference in word usage often leads to serious misunderstandings when science results are communicated. Science and engineering use the word “uncertainty” to define how well something is known, not whether it is known. Because nothing measured, estimated, modeled, or predicted can be known with perfect accuracy and certainty, scientists seek to describe the statistical variability of a number, a range of possibilities, and/or the relative level of confidence in a conclusion. By defining uncertainty, scientists seek to clarify the strength and accuracy of a conclusion. This definition of scientific uncertainty should not be confused with the more common definition of uncertainty (outside the realm of science and engineering), which typically conveys that something is completely unknown, that a result is unreliable, or that the state of knowledge is confused.

In some cases, scientific uncertainty is quantifiable and is often described as the estimated amount an observed, calculated, or modeled value may differ from the true value. For example, a study may show that we have 98 percent confidence that the true value will fall within a defined range of values. This defined range of values is referred to as the 98 percent confidence interval. For estimating the potential cost of removal of

the Four Facilities, engineers were able to determine a most probable cost, as well as the 98 percent confidence interval around the most probable cost, in order to define the range of possible removal costs.

In other cases how well something is known cannot be quantified and uncertainty is often described in relative terms, such as predicting how an ecosystem (e.g., Klamath River) may respond to a potential action (e.g., dam removal). Based on the best available information and analyses, scientists convey the likelihood of these predictions with descriptions such as “highly likely,” “probable,” or other caveats intended to disclose the level of certainty in a conclusion. For example, predicting the potential benefits of dam removal on juvenile salmon disease in the Klamath Basin cannot be known with perfect accuracy, but most fishery biologists believe removal of the Four Facilities would decrease the infection rates. A lack of certainty of the exact response of the ecosystem does not preclude a conclusion that juvenile salmon disease would likely decrease. This conclusion is based on studies of other river systems, investigations of salmon disease in the Klamath River, and knowledge of the specific factors contributing to salmon disease and how these factors would change if dams were removed.

In order to provide a sound foundation for a Secretarial Determination on removal of the Four Facilities, multiple strategies were used to weigh the validity of hypotheses, reach scientific conclusions, and decrease scientific uncertainty around those conclusions. These strategies included: (1) developing new studies, that test multiple hypotheses, in order to fill critical information gaps; (2) developing numerical models (when gathering empirical data is not possible) to predict the probable ecosystem response; (3) repeating investigations on critical topics to ensure past results are reproducible; (4) obtaining independent expert opinions on important topics; and (5) drawing conclusions based on the weight of evidence and multiple lines of evidence.

Using multiple lines of evidence refers to a process when conclusions are not drawn from a single study but from two or more studies that have different approaches. For example, the conclusion that dam removal and KBRA implementation could increase Chinook production in the Klamath Basin was based on a recent synthesis of previous study findings (Hamilton et al. 2011), two new independent modeling studies (Hendrix 2011; Lindley and Davis 2011), a Chinook expert panel report (Goodman et al. 2011), among others. Although the authors of each of these four peer-reviewed reports used different approaches and assumptions, as well as presented different levels of confidence in quantifying their conclusions and scientific uncertainty, they all concluded that Chinook salmon would increase in number relative to the “no action alternative” of leaving dams in place and not implementing KBRA. Considering several diverse lines of evidence decreased scientific uncertainty and strengthened this overarching conclusion.

In some situations, where studies present conflicting results, the “weight of evidence” for a conclusion considers the quantity of evidence supporting that conclusion as well as when and how studies were done; generally weight is given to more recent studies and

studies done with more scientific rigor (e.g., peer review). When there is a significant amount of conflicting information, a conclusion is often expressed with a higher degree of uncertainty.

During the period of time when the EIS/EIR was being developed, new scientific information has become available that has improved our understanding of the complicated interactions between river ecosystems, aquatic resources, and the people that rely on those resources in the Klamath Basin. That new information has been incorporated into the EIS/EIR as it has become available. Through the diligent efforts of the scientific community, the state of scientific knowledge in the Klamath Basin continues to improve and will result in valuable reports and information in the future. Therefore we fully anticipate that new scientific information will become available in the interim period between issuance of the Final EIS/EIR and the Secretarial Determination, particularly in the areas of active research on juvenile salmon disease, life cycle models of Klamath Basin salmon, causes of water quality problems in the Klamath River and Upper Klamath Lake, and the poor survival of juvenile endangered suckers in Upper Klamath Lake. An example of a draft report that will likely become finalized (and citable) in late 2012 is a Klamath coho life cycle model that analyzes the potential effects of dam removal on threatened coho salmon; a draft of this report (Cramer 2011) can be found at <http://www.fishsciences.net/projects/klamathcoho/model.php>. As with all EIS/EIR, however, only current best available information can form the basis of a NEPA/CEQA analysis; as new scientific information becomes available the Lead Agencies shall evaluate whether subsequent NEPA/CEQA analysis is needed before any decision is made regarding dam removal.

3.2 Water Quality

This section describes the effects of the Proposed Action and alternatives on water temperature, suspended sediments, nutrients (total phosphorus [TP], total nitrogen [TN], ortho-phosphorus, nitrate, and ammonium), dissolved oxygen, pH, algal toxins and chlorophyll-*a*, and inorganic and organic contaminants within the area of analysis. Effects of the Proposed Action and alternatives on the algal community (phytoplankton, aquatic macrophytes, riverine phytoplankton and periphyton) in the area of analysis are discussed in Section 3.4, Algae. Algal toxins are a water quality concern that affects designated beneficial uses of water, so this section also includes a brief analysis of project effects on algal toxins as related to beneficial uses. Similarly, water quality parameters relevant to the analysis of fish disease and parasitism (e.g., water temperature, nutrient availability) are included here as part of the Proposed Action effects analysis; the full analysis of fish disease and parasitism is in Section 3.3, Aquatic Resources.

3.2.1 Area of Analysis

The area of analysis for water quality includes the three main tributaries to Upper Klamath Lake (Wood, Williamson, and Sprague Rivers), Upper Klamath Lake, Link River, and the mainstem Klamath River in the Upper Klamath Basin and the mainstem Klamath River, the Klamath Estuary, and the marine nearshore environment in the Lower Klamath Basin (see Figure 3.2-1). For the purposes of the Klamath Facilities Removal Environmental Impact Statement/Environmental Impact Report (EIS/EIR) the area of analysis is organized into the following analysis segments:

Upper Klamath Basin

- Wood, Williamson, and Sprague Rivers
- Upper Klamath Lake
- Link River Dam to Klamath River upstream of J.C. Boyle Reservoir
- Hydroelectric Reach (J.C. Boyle Reservoir to Iron Gate Reservoir)

Lower Klamath Basin

- Iron Gate Dam to Salmon River
- Salmon River to Klamath Estuary
- Klamath Estuary
- Marine nearshore

Table 3.2-1 lists the river mile (RM) locations of the above reaches and of features relevant to the water quality area of analysis.

Table 3.2-1. Location of Klamath Basin Features Relevant to the Water Quality Area of Analysis

Feature	River Mile ¹
Upper Klamath Basin	
Wood River	282.3+
Williamson, and Sprague rivers	272.3+
Upper Klamath Lake/Agency Lake	254.3 to 282.3
Link River Dam	253.7
Keno Impoundment/Lake Ewauna	233.0 to 253 (Lake Ewauna ≈247 to 253)
Keno Impoundment at Miller Island	246
Klamath Straits Drain (at Pumping Plant F)	240.5
J.C. Boyle Reservoir	224.7 to 228.3
Oregon-California State line	208.5
Copco 1 Reservoir	198.6 to 203.1
Copco 2 Reservoir	198.3 to 198.6
Iron Gate Reservoir	190.1 to 196.9
Lower Klamath Basin	
Klamath River confluence with Shasta River	176.7
Klamath River confluence with Scott River	143.0
Seiad Valley	129.4
Klamath River confluence with Salmon River	66.0
Hoopa Valley Tribe	≈45 to 46
Weitchpec	43.5
Klamath River confluence with Trinity River	42.5
Klamath River at Turwar	5.8
Klamath Estuary	0 to ≈2

Notes:

¹River Mile (RM) refers to distance upstream of the mouth of the Klamath River.

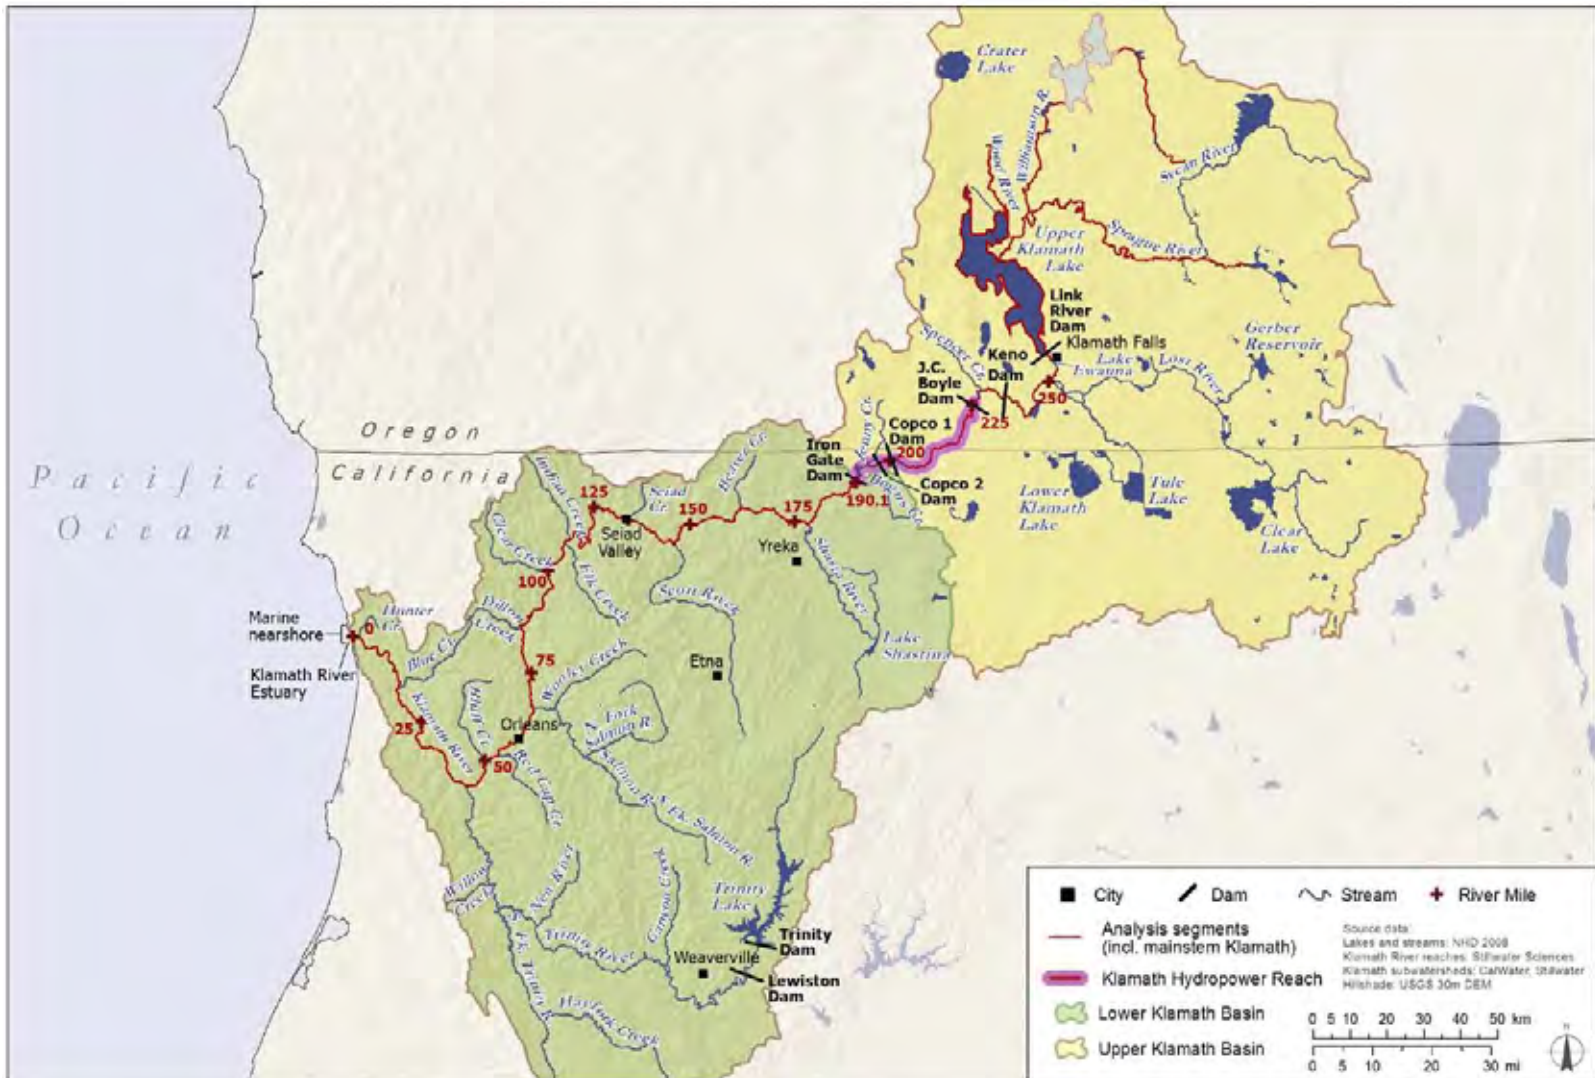

Figure 3.2-1. Water Quality Area of Analysis

3.2.2 Regulatory Framework

Multiple Federal, State, and tribal programs and planning documents are applicable to the regulation and protection of water quality in the area of analysis, including but not limited to the following:

- Clean Water Act (Title 33 U.S.C. §1313 [1972])
- Safe Drinking Water Act (Title 42 U.S.C. Chapter 6A §300f-j [1973 as amended])
- Oregon Administrative Rules for Water Pollution Control (OAR 340-041)
- North Coast Region Basin Plan (as required by Sections 13240–13247 of Porter-Cologne Water Quality Act)
- Hoopa Valley Tribe Water Quality Control Plan
- Coastal Zone Management Act
- California Ocean Plan (C.W.C. §13170.2)

3.2.2.1 Designated Beneficial Uses of Water

Beneficial uses of water are designated by the Oregon Department of Environmental Quality (ODEQ), the State and Regional Water Quality Control Boards, and the Hoopa Valley Tribe. Other tribal water quality programs, including the development and adoption of beneficial uses, are underway by the Karuk Tribe, the Resighini Rancheria, and the Yurok Tribe. These tribes have not yet completed processes for United States Environmental Protection Agency (USEPA) approved delegation under the Clean Water Act (CWA) (North Coast Regional Water Quality Control Board [NCRWQCB] 2010a). Approved beneficial uses within the area of analysis are presented below (Table 3.2-2).

3.2.2.2 Water Quality Standards

3.2.2.2.1 Freshwater

Water quality standards for fresh surface waters have been established by ODEQ, NCRWQCB, and the Hoopa Valley Tribe to protect the designated beneficial uses listed in Table 3.2-2.

Oregon Revised Statutes ORS 468B.025(1) states "...no person shall: (a) Cause pollution of any waters of the State or place or cause to be placed any wastes in a location where

such wastes are likely to escape or be carried into the waters of the State by any means; and (b) Discharge any wastes into the waters of the State if the discharge reduces the quality of such waters below the water quality standards established by rule for such waters by the Environmental Quality Commission.” ORS 468B.050 and 468B.053 provide for ODEQ to issue permitted exemptions from ORS 468B.025(1).

The California Porter-Cologne Act defines water quality using chemical, physical, biological, bacteriological, radiological, and other properties and characteristics of water that affect its use. It further defines water quality objectives as the limits or levels of water quality constituents or characteristics that are established for the reasonable protection of beneficial uses of water or the prevention of nuisance within a specific area.

Water quality objectives adopted by the Hoopa Valley Tribe establish water quality objectives for those portions of the Trinity and Klamath rivers under the jurisdiction of the tribe. The Yurok and Karuk Tribes have also adopted water quality objectives, as has the Resighini Rancheria; however, the associated water quality plans have not yet been approved by USEPA (NCRWQCB 2010a, see also discussion regarding tribal beneficial uses in Section 3.2.2.1). Surface-water quality objectives relevant to the Proposed Action and alternatives are listed in Table 3.2-3 through 3.2-7.

Table 3.2-3. Oregon Surface-Water Quality Objectives Relevant to the Proposed Action and Alternatives

Parameter	Criteria/Description ¹
Biocriteria OAR 340-041-0011	Waters of the State must be of sufficient quality to support aquatic species without detrimental changes in the resident biological communities.
Dissolved Oxygen OAR 340-041-0016	Sufficient concentrations of dissolved oxygen are necessary to support aquatic life.
	Coldwater aquatic life 8.0 mg/L minimum
	Cool water aquatic life 6.5 mg/L minimum
	Warm water aquatic life 5.5 mg/L minimum
	Spawning 11.0 mg/L minimum
	Spawning 8.0 mg/L minimum intergravel
Nuisance Algae Growth OAR 340-041-0019	Algal growth which impairs the recognized beneficial uses of the water body is not allowed. For natural lakes that do not thermally stratify, reservoirs, rivers and estuaries, average chlorophyll-a concentrations at or above 0.015 mg/l identify water bodies where phytoplankton may impair the recognized beneficial uses.
pH OAR 340-041-0021 & OAR 340-041-0185	pH values may not fall outside the range of 6.5–9.0. When greater than 25 percent of ambient measurements taken between June and September are greater than pH 8.7, and as resources are available according to priorities set by the Department, the Department will determine whether the values higher than 8.7 are anthropogenic or natural in origin.

Table 3.2-3. Oregon Surface-Water Quality Objectives Relevant to the Proposed Action and Alternatives

Parameter	Criteria/Description ¹
	Waters impounded by dams existing on January 1, 1996, which have pHs that exceed the criteria are not in violation of the standard, if the Department determines that the exceedance would not occur without the impoundment and that all practicable measures have been taken to bring the pH in the impounded waters into compliance with the criteria.
Temperature OAR 340-041-0028 & OAR 340-041-0185	<p>Water temperature must protect designated temperature-sensitive, beneficial uses, including specific salmonid life cycle stages in waters of the State.</p> <p>Redband or Lahonton cutthroat trout habitat 20°C (68°F)</p> <p>Coolwater species (no salmonids) – Basin-specific Criterion From June 1 to September 30, no NPDES point source that discharges to the portion of the Klamath River designated for cool water species may cause the temperature of the water body to increase more than 0.3°C (0.5°F) above the natural background after mixing with 25% of the stream flow. Natural background for the Klamath River means the temperature of the Klamath River at the outflow from Upper Klamath Lake plus any natural warming or cooling that occurs downstream. This criterion supersedes OAR 340-041-0028(9)(a) during the specified time period for NPDES permitted point sources.</p> <p>Natural Conditions Criteria. Where the department determines that the natural thermal potential of all or a portion of a water body exceeds the biologically-based criteria, the natural thermal potential temperatures supersede the biologically-based criteria, and are deemed to be the applicable temperature criteria for that water body.</p>
Turbidity OAR 340-041-0036	<p>Numeric criterion generally prohibits turbidity increases which exceed 10-percent above background.</p> <p>Dredging, Construction or other Legitimate Activities: Permit or certification authorized under terms of CWA Section 401 or 404 (Permits and Licenses, Federal Water Pollution Control Act) or OAR 14I-085-0100 et seq. (Removal and Fill Permits, Division of State Lands), with limitations and conditions governing the activity set forth in the permit or certificate.</p>
Toxic material OAR 340-041-0033	Toxic substances may not be introduced above natural background levels in waters of the State in amounts, concentrations, or combinations that may be harmful, may chemically change to harmful forms in the environment, or may accumulate in sediments or bioaccumulate in aquatic life or wildlife to levels that adversely affect public health, safety, or welfare or aquatic life, wildlife, or other designated beneficial uses) Levels of toxic substances may not exceed the criteria listed in Table 20 [from the OAR] and the new Table 40 ²

Source: ODEQ (OAR 340-041).

¹ Relevant beneficial uses are shown in bold and all caps. If no beneficial use is specified, the objective or criteria applies to all beneficial uses.

² On June 16, 2011, ODEQ revised human health criteria for toxic pollutants using a fish consumption rate of 175 grams per day, which is based on tribal consumption rates for tribes that live in Oregon. The new criteria were approved by USEPA on October 17, 2011. This section also applies to the revised iron, manganese, and arsenic criteria the commission adopted in December 2010 and April 2011, respectively.

Table 3.2-4. California Surface-Water Quality Objectives

Parameter	Description ¹
Suspended Material	Waters shall not contain suspended material in concentrations that cause nuisance or adversely affect beneficial uses.
Settleable Material	Waters shall not contain substances in concentrations that result in deposition of material that causes nuisance or adversely affect beneficial uses.
Sediment	The suspended sediment load and suspended sediment discharge rate of surface waters shall not be altered in such a manner as to cause nuisance or adversely affect beneficial uses.
Turbidity	Turbidity shall not be increased more than 20% above naturally occurring background levels. Allowable zones of dilution within which higher percentages can be tolerated may be defined for specific discharges upon the issuance of discharge permits or waiver thereof.
Temperature	COLD, WARM (for nontidal waters) The natural receiving water temperature of intrastate waters shall not be altered unless it can be demonstrated to the satisfaction of the NCRWQCB that such alteration in temperature does not adversely affect beneficial uses. The temperature of any COLD or WARM freshwater habitat shall not be increased by more than 2.8°C (5°F) above natural receiving water temperature.
Dissolved Oxygen	WARM, MAR, Inland Saline Water Habitat (SAL), COLD, SPWN Klamath River Mainstem Specific Water Quality Objectives based on natural receiving water temperatures (see Table 3.2-5 for minimum DO concentrations in mg/L) <ul style="list-style-type: none"> • From Oregon-California State line (RM 208.5) to the Scott River (RM 143), 90% saturation October 1-March 31 and 85% saturation April 1-September 30. • From Scott River (RM 143) to Hoopa Valley Tribe boundary (≈RM 45), 90% saturation year round. • From Hoopa Valley Tribe boundary to Turwar (RM 5.8), 85% saturation June 1-August 31 and 90% saturation September 1-May 31. • For upper and middle Klamath River Estuary (RM 0-2), 80% saturation August 1-August 31, 85% saturation September 1-October 31 and June 1-July 31, and 90% saturation November 1-May 31. • EST For Lower Klamath River Estuary (RM 0), DO content shall not be depressed to levels adversely affecting beneficial uses as a result of controllable water quality factors.
Biostimulatory Substances	Waters shall not contain biostimulatory substances in concentrations that promote aquatic growths to the extent that such growths cause nuisance or adversely affect beneficial uses.
Nitrate – N	MUN 45 mg/L as NO ₃ ²
Nitrate + Nitrite	MUN 10 mg/L as N ³

Table 3.2-4. California Surface-Water Quality Objectives

Parameter	Description ¹
pH	The pH shall not be depressed below 6.5 units nor raised above 8.5 units
	COLD, WARM Changes in normal ambient pH levels shall not exceed 0.2 units within the range specified above.
	For the Klamath River upstream of Iron Gate Dam, including Iron Gate & Copco reservoirs, and the Klamath River downstream from Iron Gate Dam pH shall not be depressed below 7 units nor raised above 8.5 units.
Toxicity	All waters shall be maintained free of toxic substances in concentrations that are toxic to, or that produce detrimental physiological responses in human, plant, animal, or aquatic life.
Pesticides	No individual pesticide or combination of pesticides shall be present in concentrations that adversely affect beneficial uses. There shall be no bioaccumulation of pesticide concentrations found in bottom sediments or aquatic life. Waters designated for use as domestic or municipal supply shall not contain concentrations of pesticides in excess of the limiting concentrations set forth in California Code of Regulations, Title 22, Division 4, Chapter 15, Article 4, Section 64444.5 (Table 5), and listed in Table 3-2 of the Basin Plan.
Chemical Constituents	Waters designated for use as domestic or municipal supply (MUN) shall not contain concentrations of chemical constituents in excess of the limits specified in California Code of Regulations, Title 22, Chapter 15, Division 4, Article 4, Section 64435 (Tables 2 and 3), and Section 64444.5 (Table 5), and listed in Table 3-2 of the Basin Plan. Waters designated for use as agricultural supply (AGR) shall not contain concentrations of chemical constituents in amounts which adversely affect such beneficial use.

Source: NCRWQCB 2011 unless otherwise noted.

¹ Relevant beneficial uses are shown in bold and all caps. If no beneficial use is specified, the objective or criteria applies to all beneficial uses.

² Maximum contaminant level for domestic or municipal supply.

³ Maximum contaminant level (shall not be exceeded in water supplied to the public) as specified in Table 64431-A (Inorganic Chemicals) of Section 64431, Title 22 of the California Code of Regulations (CCR), as of April 23, 2007.

Table 3.2-5. Minimum DO Concentrations Based on Percent Saturation Criteria¹ (NCRWQCB 2010a)

DO Concentrations (mg/L)	Jan	Feb	March	April	May	June	July	August	Sept	Oct	Nov	Dec

Lower Estuary – Narrative Objective												

¹ The “Alternative 3” analysis conducted by the NCRWQCB (2010a) to arrive at the DO concentrations listed in this table is not the same as the Alternative 3 referred to in the Klamath Facilities Removal EIS/EIR. Estimates of site-specific natural temperatures inherent to the DO percent saturation estimates are derived from the T1BSR run of the Klamath TMDL model (NCRWQB 2010a).

Table 3.2-6. Hoopa Valley Tribe Surface-Water Quality Objectives

Parameter	Criteria/Description ¹
Ammonia (NH ₃ , as mg/L N)	COLD Because ammonia toxicity to fish is influenced by pH, waters designated for the purpose of protection of threatened and endangered fish species in cold freshwater habitat shall meet conditions for ammonia based on maximum one-hour (acute) and 30-day average (chronic) concentrations linked to pH by a formula (HVTEPA 2008).
Periphyton	150 mg chlorophyll- <i>a</i> /m ²
Dissolved oxygen ²	COLD 8.0 mg/L minimum
	SPWN 11.0 mg/L minimum
	SPWN 8.0 mg/L minimum in inter-gravel water
Total Nitrogen (TN) ^{3,4}	0.2 mg/L
Total Phosphorous (TP)	0.035 mg/L
pH	The pH in the Klamath River shall be between 7.0 and 8.5 at all times
Microcystis aeruginosa cell density	MUN, REC-1 <5,000 cells/mL for drinking water <40,000 cells/mL for recreational water
Microcystin toxin Concentration	MUN, REC-1 <1 µg/L total microcystins for drinking water <8 µg/L total microcystins for recreational water
Total potentially toxigenic cyanobacteria species ⁵	MUN, REC-1 <100,000 cells/mL for recreational water
Cyanobacterial scums	MUN, REC-1 There shall be no presence of cyanobacterial scums
Nitrate	MUN 10 mg/L

Source: HVTEPA (2008)

¹ Relevant beneficial uses are shown in bold and all caps. If no beneficial use is specified, the objective or criteria applies to all beneficial uses.

² HVTEPA (2008) includes a natural conditions clause stating “If dissolved oxygen standards are not achievable due to natural conditions, then the COLD and SPAWN standard shall instead be dissolved oxygen concentrations equivalent to 90% saturation under natural receiving water temperatures.” USEPA has approved the Hoopa Valley Tribe definition of natural conditions; the provision that site-specific criteria can be set equal to natural background and the procedure for defining natural background have not been finalized as of June 2011.

³ HVTEPA (2008) includes a natural conditions clause stating “If total nitrogen and total phosphorus standards are not achievable due to natural conditions, then the standards shall instead be the natural conditions for total nitrogen and total phosphorus.” USEPA has approved the Hoopa definition of natural conditions; the provision that site-specific criteria can be set equal to natural background and the procedure for defining natural background have not been finalized as of June 2011.

⁴ 30-day mean of at least two sample per 30-day period.

⁵ Includes: *Anabaena*, *Microcystis*, *Planktothrix*, *Nostoc*, *Coelosphaerium*, *Anabaenopsis*, *Aphanizomenon*, *Gloeotrichia*, and *Oscillatoria*.

3.2.2.2.2 Marine

Narrative and numeric water quality objectives to support designated beneficial uses under the Ocean Plan are listed below in Table 3.2-7.

Table 3.2-7. California Marine Water Quality Objectives Relevant to the Proposed Action and Alternatives

Water Quality Objective ¹	Description
Physical Characteristics	<ul style="list-style-type: none"> ● Floating particulates and grease and oil shall not be visible. ● The discharge of waste shall not cause aesthetically undesirable discoloration of the ocean surface. ● Natural light shall not be significantly reduced at any point outside the initial dilution zone as the result of the discharge of waste. ● The rate of deposition of inert solids and the characteristics of inert solids in ocean sediments shall not be changed such that benthic communities are degraded.
Chemical Characteristics	<ul style="list-style-type: none"> ● The dissolved oxygen concentration shall not at any time be depressed more than 10% from that which occurs naturally, as the result of the discharge of oxygen demanding waste materials. ● The pH shall not be changed at any time more than 0.2 units from that which occurs naturally. ● The dissolved sulfide concentration of waters in and near sediments shall not be significantly increased above that present under natural conditions. ● The concentration of substances set forth in Chapter II, Table B (SWRCB 2001), in marine sediments shall not be increased to levels which would degrade indigenous biota. The concentration of organic materials in marine sediments shall not be increased to levels that would degrade marine life. ● Nutrient materials shall not cause objectionable aquatic growths or degrade indigenous biota. ● Numerical Water Quality Objectives for discharges are listed in California State Water Resources Control Board (SWRCB 2001), including objectives for the protection of marine aquatic life (i.e., metals, inorganics, organics, chronic and acute toxicity, pesticides and PCBs, radioactivity) and objectives for the protection of human health (noncarcinogenic and carcinogenic compounds).

Source: SWRCB (2001) unless otherwise noted.

¹ WQOs for bacterial characteristics and elevated temperature (thermal) wastes are not included, as these water quality parameters are not anticipated to be affected by the Project.

3.2.2.3 Water Quality Impairments

Section 303(d) of the CWA requires States to identify water bodies that do not meet (as of February 2012) water quality objectives and are not supporting their designated beneficial uses. These water bodies are considered to be impaired with respect to water quality. ODEQ and NCRWQCB have both included the Klamath Basin and specifically, the Klamath and Lost Rivers on their CWA Section 303(d) lists of water bodies with water quality impairments (see Table 3.2-8).

Table 3.2-8. Water Quality Impaired Water Bodies within the Area of Analysis¹

Water Body Name	Water Temperature	Sedimentation	pH	Organic Enrichment/ Low Dissolved Oxygen	Nutrients	Ammonia	Chlorophyll-a	Microcystin
Oregon²								
Sprague River and tributaries	X ^s		X ^s	X ^s				
Williamson River and tributaries	X							
Upper Klamath Lake and Agency Lake			X	X			X	
Upper Klamath River (Keno Dam to Link River Dam, including Keno Impoundment/Lake Ewauna)			X ^s	X ^{sp,s,f,w (3)}		X ^{sp,s,f,w}	X ^s	
Upper Klamath River Oregon-California State line to Keno Dam (including J.C. Boyle Reservoir) ⁽⁴⁾	X ^{sp,s,f,w (5)}			X ^{sp,s,f,w (3)}				
California								
Lower Lost River (Tule Lake, Lower Klamath Lake National Wildlife Refuge, and Mt Dome)			X		X			
Middle Klamath River Oregon-California State line to Iron Gate Dam (including Copco Lake Reservoir [1 and 2] and Iron Gate Reservoir)	X			X	X			X
Middle Klamath River Iron Gate Dam to Scott River Reach ⁶	X			X	X			X
Shasta River	X			X				
Scott River	X	X						
Salmon River	X							
Middle and Lower Klamath River Scott River to Trinity River Reach ⁷	X			X	X			X
Lower Klamath River-Trinity River to Mouth	X	X		X	X			

Notes:

- ¹ While there are additional water quality impaired waterbodies in the area of analysis, the waterbodies listed in this table are the ones that are directly relevant to the water quality analysis for this Klamath Facilities Removal EIS/EIR.
- ² Oregon lists specific reaches of the Klamath River by river mile and includes specific seasons, in some cases (Kirk et al. 2010).
- ³ Listed for dissolved oxygen only (non-spawning) (Kirk et al. 2010).
- ⁴ Oregon defines particular river miles for their listings.
- ⁵ Non-spawning (Kirk et al. 2010).
- ⁶ Selected minor tributaries to the Middle and Lower Klamath River that are impaired for sediment and sedimentation include Beaver Creek, Cow Creek, Deer Creek, Hungry Creek, and West Fork Beaver Creek (USEPA 2010a).
- ⁷ Minor tributaries to the Middle and Lower Klamath River that are impaired for sediment and sedimentation include China Creek, Fort Goff Creek, Grider Creek, Portuguese Creek, Thompson Creek, and Walker Creek (USEPA 2010a).

Key:

- Sp = Listed for spring season
 S = Listed for summer season
 F = Listed for fall season
 W = Listed for winter season

3.2.2.4 Total Maximum Daily Loads

For water quality impaired water bodies (i.e., 303[d]-listed water bodies), Total Maximum Daily Loads (TMDLs) must be developed by the State with jurisdiction over the water body to protect and restore beneficial uses of water. TMDLs (1) estimate the water body’s capacity to assimilate pollutants without exceeding water quality standards; and, (2) set limits on the amount of pollutants that can be added to a water body while still protecting identified beneficial uses. ODEQ and the NCRWQCB cooperated on the development of TMDLs for the impaired water bodies of the Klamath Basin (see Table 3.2-8). Table 3.2-9 lists the status of TMDLs in the Klamath Basin. Table 3.2-9 is followed by a brief narrative summary of TMDLs for each water body to provide relevant context for TMDL-related discussions in Section 3.2.4.3, Effects Determinations. Additional information regarding the Oregon TMDLs can be found on ODEQ’s Web site <http://www.deq.state.or.us/WQ/TMDLs/klamath.htm> and for the California TMDLs on the North Coast Regional Water Quality Control Board Web site: http://www.waterboards.ca.gov/northcoast/water_issues/programs/tmdls/

Table 3.2-9. Status of TMDLs in the Klamath Basin as of February 2012

Water Body	Pollutant/Stressor	Agency	Original Listing Date	TMDL Completion Date ¹
Oregon				
Upper Klamath Lake Drainage	Temperature, dissolved oxygen, and pH	ODEQ	1998	2002
Upper Klamath and Lost Rivers (in Oregon)	Temperature, dissolved oxygen, pH, ammonia toxicity, and chlorophyll-a	ODEQ	1998	2012
California				
Lower Lost River (Tule Lake, Lower Klamath Lake National Wildlife Refuge, and Mt Dome) ²	pH and nutrients	USEPA	1992 (Nutrients), 2002 (pH)	2008
Klamath River	Temperature, organic enrichment/low dissolved oxygen ³ , nutrient, and microcystin ⁴	NCRWQCB	1992 (Temperature and nutrients), 1998 (Dissolved oxygen), 2006 and 2010 (Microcystin)	2010
Shasta River	Temperature and dissolved oxygen	NCRWQCB	1992 (Dissolved oxygen), 1994 (Temperature)	2007

Table 3.2-9. Status of TMDLs in the Klamath Basin as of February 2012

Water Body	Pollutant/Stressor	Agency	Original Listing Date	TMDL Completion Date¹
Scott River	Temperature and sediment	NCRWQCB	1992 (Sediment), 1996 (Temperature)	2006
Salmon River	Temperature	NCRWQCB	1992	2005
Trinity	Sediment	USEPA	1992	2001
South Fork Trinity	Sediment	USEPA	1992	1998

Notes:

¹ The TMDL completion date is the year the USEPA approved or is expected to approve the TMDL.

² The Upper Lost River upstream of the Oregon border (i.e., in California), Clear Lake Reservoir, and tributaries were previously listed for water temperature and nutrients. In 2004, North Coast Regional Board staff completed an analysis of beneficial uses and water quality conditions in the Upper Lost River watershed (in California) and concluded that the water temperature and nutrient listings were not warranted.

³ Listing applies only to the mainstem Klamath River.

⁴ Listings occurred in 2006 for the mainstem Klamath River from the Oregon-California State line to Iron Gate Dam (including Copco and Iron Gate Reservoirs), and in 2010 for the mainstem Klamath River from Iron Gate Dam to the Trinity River.

North Coast Regional Water Quality Control Board

3.2.2.4.1 Upper Klamath Lake Drainage TMDLs

The Upper Klamath Lake TMDLs cover temperature, dissolved oxygen, and pH. The geographic extent of the Upper Klamath Lake TMDLs includes the northern portion of the Upper Klamath Basin, which comprises three sub-basins (i.e., Upper Klamath Lake, Williamson River, and Sprague River). TMDL targets were developed for (1) TP loading as the primary method of improving pH and dissolved oxygen conditions in Upper Klamath and Agency Lakes; (2) heat loads for anthropogenic and background nonpoint sources throughout the basin; (3) dissolved oxygen in the Sprague River (USEPA 1987); and, (4) pH in the Sprague River. Specific implementation actions, including designated Best Management Practices (BMPs), are under development by the designated management agencies (DMAs) (ODEQ 2002).

3.2.2.4.2 Upper Klamath River and Lost River (in Oregon) TMDLs

The Upper Klamath River and Lost River TMDLs cover temperature, dissolved oxygen, pH, ammonia toxicity, and chlorophyll-*a*. ODEQ approved the Upper Klamath and Lost River subbasins TMDLs in December 2010 and USEPA is expected to approve these TMDLs in 2011 (S. Kirk, pers. comm., 9 March 2011). The TMDLs cover the southern

portion of the Upper Klamath Basin including (1) the Klamath River from Upper Klamath Lake to the Oregon-California State line and (2) impounded and riverine sections of the Lost River from the State line downstream from the Malone Dam to the State line upstream of Tule Lake, and the Klamath Straits Drain from the State line to the confluence with the Klamath River. The TMDLs require reductions in phosphorus, nitrogen, and biochemical oxygen demand (BOD) loading from both point sources and nonpoint sources in the Upper Klamath River, as well as augmentation of dissolved oxygen in the impoundments. There are no permitted point sources of elevated water temperatures for these TMDLs. The heat load allocation for nonpoint sources is equivalent to 0.2°C (0.4 F) above applicable criteria. The Upper Klamath River and Lost River TMDLs were designed to ensure that Oregon's water quality criteria for the Klamath River would be attained at the point where the Lost River discharges into the Klamath River. Specific implementation actions, including designated BMPs, will be developed by the DMAs (Kirk et al. 2010).

3.2.2.4.3 Lower Lost River (in California) TMDLs

The Lower Lost River TMDLs cover pH and nutrients. The geographic extent of the Lower Lost River TMDLs in California includes the Lost River from the Oregon-California State line near Anderson-Rose Dam to the Klamath Straits Drain at the Oregon-California State line, including the Tule Lake and Lower Klamath National Wildlife Refuge areas. Water from the Lower Lost River can be diverted into the Klamath River via the Lost River Diversion Dam and the Klamath Straits Drain (after passing through Tule Lake, the P Canal system, and, in some cases, the Lower Klamath National Wildlife Refuge). The Lower Lost River TMDLs were designed to ensure that California's numeric dissolved oxygen water quality standard would be attained in the Lower Lost River. Implementation measures focus on water quality effects from Reclamation's Klamath Project, the U.S. Fish and Wildlife Service (USFWS) Klamath Refuges, and the Tulelake Wastewater Treatment Plant (USEPA 2008). Note that these TMDLs do not apply to the Upper Lost River; the Upper Lost River upstream of the Oregon border (i.e., in California), Clear Lake Reservoir, and tributaries were previously listed for water temperature and nutrients. In 2004, North Coast Regional Board staff completed an analysis of beneficial uses and water quality conditions in the Upper Lost River watershed and concluded that the water temperature and nutrient listings were not warranted.

3.2.2.4.4 Klamath River TMDLs

The Klamath River TMDLs cover temperature, organic enrichment/low dissolved oxygen, nutrient, and microcystin. The geographic extent of the California Klamath River TMDL analyses includes the river from State line to the Pacific Ocean. The TMDLs do not specifically address existing sedimentation/siltation impairments in the Klamath River from the Trinity River to the Pacific Ocean; currently, sediment TMDLs for the Trinity and South Fork Trinity Rivers address these impairments. Additionally, the Action Plans do not cover tribal lands. The TMDLs assign three load allocations to the Klamath Hydroelectric Project (KHP) in California (NCRWQCB 2010a):

- Create a compliance lens in Copco and Iron Gate Reservoirs, such that water temperature and dissolved oxygen conditions are suitable for cold water fish during the critical summer period.
- Annual TP and TN loading reduction (TP=22,367 lbs and TN=120,577 lbs) to offset the reduced nutrient assimilative capacity¹ in the reservoirs (as compared to a free-flowing river condition) that is associated with nuisance blooms of green algae and cyanobacteria in the reservoirs. TMDL targets are established for chlorophyll-*a*, *Microcystis aeruginosa* cell density, and microcystin.
- Daily average (and daily maximum) increase in water temperatures relative to inflow temperatures for reservoir tailrace waters (0.1°C [0.18°F] for Iron Gate and 0.5°C [0.9°F] for Copco 1 and 2).

The first two load allocations include a provision for the use of reservoir management measures to achieve the TMDL targets. Numerous implementation actions are described in NCRWQCB (2010b).

Even though pH infrequently meets California North Coast Basin Plan Water Quality Objectives for the Klamath River, it was not listed under the 303(d) list for the River in 2006 (Table 3.2-8), prior to the development of the 2010 TMDLs; instead it was explicitly incorporated into the TMDLs as a nutrient-related water quality impairment including the KHP. The linkage between these impairments is discussed in the TMDL Staff Report (NCRWQCB 2010a). As such, meeting the nutrient objectives will mitigate pH impairments.

3.2.2.4.5 Shasta River TMDLs

The Shasta River TMDLs for temperature and dissolved oxygen cover the Shasta River, a tributary to the mainstem Klamath River, located in the central portion of the Lower Klamath Basin. The TMDL extends from the headwaters to the confluence with the Klamath River, and includes tributaries to the Shasta River and Lake Shastina. Implementation actions build upon ongoing watershed restoration and enhancement work (e.g., increasing riparian vegetation to decrease water temperature and improve bank stability; controlling tailwater discharges to prevent the release of elevated temperature and nutrient enriched waters; promoting efficient water use to increase dedicated cold water flow; addressing proximal land use activities that contribute to low dissolved oxygen and high water temperatures in the watershed, such as timber harvest and road building) (NCRWQCB 2006, 2007).

3.2.2.4.6 Scott River TMDLs

The Scott River TMDL for temperature and sediment covers the Scott River, a tributary to the mainstem Klamath River, located in the central portion of the Lower Klamath Basin. The TMDL extends from the headwaters of the Scott River to its confluence with

¹ The phrase “assimilative capacity” here refers to the maximum amount of nutrients that can enter the reservoirs and still allow for water quality conditions in the reservoirs to meet water quality objectives (e.g., dissolved oxygen and microcystin).

the mainstem Klamath River. Implementation of the Scott River TMDL is expected to achieve water quality standards for water temperature and sediment within 40 years of plan approval. Implementation actions include the following (NCRWQCB 2011):

- Controlling road-caused sediment;
- Reviewing dredge mining effects;
- Promoting the preservation of riparian vegetation and regulating its suppression and/or removal;
- Implementing water conservation practices;
- Studying groundwater uses and effects;
- Ensuring flood control and bank stabilization activities
- Minimizing vegetation removal/suppression and sediment delivery;
- Regulating discharges related to timber harvest; and,
- Minimizing the effect of grazing.

3.2.2.4.7 Salmon River TMDL

The Salmon River TMDL for temperature covers the Salmon River, a tributary to the mainstem Klamath River located in the southern portion of the Lower Klamath Basin. The Salmon River TMDL target for water temperature applies throughout the Salmon River watershed and is necessary to achieve the Basin Plan water quality objective for temperature. The Basin Plan criterion requires no alteration of temperature without demonstrations that an increase will not adversely affect beneficial uses nor may the temperature of any cold water be increased by more than 5°F above natural receiving temperature (NCRWQCB 2005). The North Coast Regional Board signed a Memorandum of Understanding with the United States Forest Service (USFS), which manages 98 percent of the lands within the Salmon River watershed, regarding USFS activities within the basin and implementation of the Salmon River TMDL.

3.2.2.4.8 Trinity River TMDL

The Trinity River TMDL for sediment covers the portions of the mainstem Trinity River watershed governed by California water quality standards (i.e., not lands under tribal jurisdiction) in the southern portion of the Lower Klamath Basin, to the confluence of the Trinity and Klamath rivers; the TMDL does not apply to the South Fork Trinity River. The Trinity River TMDL target for sediment is a set loading capacity of 125 percent of the background sediment delivery rate (USEPA 2001). Examples of ongoing implementation actions include, but are not limited to, completing watershed and road analyses in USFS and Bureau of Land Management (BLM) lands, watershed restoration, limiting suction dredge operations, comprehensive aquatic monitoring, improving Timber Harvest Plan (THP)s, and continued road/erosion control and fuels management.

3.2.2.4.9 South Fork Trinity River TMDL

The South Fork Trinity River TMDL for sediment covers the South Fork Trinity River from its headwaters in the North Yolla Bolly Mountains in the southern portion of the Lower Klamath Basin, to the confluence with the Trinity River, and includes Hayfork Creek and other smaller tributaries. The TMDL for sediment is approximately 737 tons per square mile per year. Ongoing implementation actions include encouraging

landowner-based sediment reduction plans, specifying requirements for sediment reduction plans, and providing alternative land management guidelines (USEPA 1998). Additional actions include developing a monitoring process for the basin.

3.2.3 Existing Conditions/Affected Environment

3.2.3.1 Overview of Water Quality Processes in the Klamath Basin

Water quality in the Klamath River is affected by the geology and meteorology of the Klamath Basin, as well as current and historical land- and water-use practices. Cold air temperatures and precipitation generally occur from November to March (see Section 3.6, Flood Hydrology), corresponding to periods of higher flows and colder water temperatures. Warmer air temperatures and drier conditions occur from April to October (see Section 3.6, Flood Hydrology), corresponding to periods of lower flows and warmer water temperatures. The relatively low relief, volcanic terrain of the Upper Klamath Basin (see Section 3.11, Geology, Soils, and Geologic Hazards) supports large, shallow natural lakes (Upper Klamath Lake, Agency Lake, Tule Lake, Lower Klamath Lake) and wetlands, with soils that are naturally high in phosphorus. Human activities in the upper basin, including wetland draining, agriculture, ranching, logging, and water diversions have altered seasonal stream flows and water temperatures, increased concentrations of nutrients (nitrogen and phosphorus) and suspended sediment in watercourses, and degraded other water quality parameters such as pH and dissolved oxygen concentrations. The Lower Klamath Basin is composed of generally steeper, mountainous terrain (see Section 3.11, Geology, Soils, and Geologic Hazards), where historical hillslope and in-channel gold mining and extensive logging have occurred, along with agricultural and ranching activities that divert water in many of the lower tributary basins. These activities have altered streamflows, increased concentrations of suspended sediment and nutrients in watercourses, and increased summer water temperatures.

The presence and operation of the Four Facilities in the Klamath Hydroelectric Reach of the Upper Klamath Basin affect many aspects of water quality in the Klamath River. The most common effects of hydroelectric projects on water quality result from changes in the physical structure of the aquatic ecosystem. Dams slow the transport of water downstream, intercept and retain sediment, organic matter, nutrients, and other constituents that would otherwise be transported downstream, as well as alter seasonal water temperatures when compared to free-flowing stream reaches.

- **River and reservoir water temperatures.** The primary effects of hydroelectric project operations on the natural temperature regime of streams and rivers are related to alterations in water surface area, depth, and velocity due to water diversions into or out of the stream corridor, including reservoir impoundments and conveyance through pipelines or penstocks. These changes influence the amount of heat entering and leaving water bodies (such as from solar radiation and nighttime re-radiation), which determines the water temperature. Because reservoirs are often deep, they can retain their water temperature for weeks or months, thereby shifting the natural water temperature patterns below reservoirs.

For example, water released from reservoirs in the springtime is typically cooler than would naturally occur because the reservoir retains some of the cold water it received in the winter. Similarly, water released from reservoirs in the fall is typically warmer than would naturally occur because the reservoir still contains water that was heated during the summer months. Additionally, due to surface heating of the reservoir in the late spring and summer, a warmer, less dense water layer forms on the reservoir surface (the epilimnion), which overlies colder, denser water (the hypolimnion). This process is called thermal stratification and often persists for months.

- **Reservoir mixing and dissolved oxygen.** The water column in most deep reservoirs has a characteristic thermal and chemical structure that is independent of the size of the reservoir. With thermal stratification (in summer and fall), the isolated deeper water is not exposed to the atmosphere and often completely loses its supply of dissolved oxygen over a period of weeks or months as organic matter in bottom sediments decays. Releases of this deeper, oxygen-depleted water from the bottom of the reservoir can cause serious problems for downstream fish and other aquatic biota. In the fall, thermal stratification typically breaks down as the surface layer cools and wind mixing of the water column occurs. This process is called reservoir turnover.
- **Algae in reservoirs.** Because large reservoirs have long retention times for water and thermally stratify in the summer months, they often provide ideal conditions for the growth of suspended algae (phytoplankton) in the epilimnion. Depending upon available nutrients, extensive phytoplankton blooms can develop in these reservoirs. Algal photosynthesis during the day releases dissolved oxygen and consumes carbon dioxide. At night, algal respiration consumes dissolved oxygen and releases carbon dioxide. This can result in wide swings in dissolved oxygen and pH, which is stressful to aquatic biota. Under nutrient-rich conditions, harmful blooms of blue-green algae can occur, producing cyanotoxins (e.g., cyclic peptide toxins that act on the liver such as microcystin, alkaloid toxins such as anatoxin-a and saxitoxin that act on the nervous system). Cyanotoxins have been found to be harmful to a wide range of biota including exposed fish, shellfish, livestock, and humans. Releases of impounded waters can transport algae and/or toxins to downstream waters and algal blooms can die abruptly (“crash”), releasing cyanotoxins into the water column. The subsequent decomposition of organic matter associated with algal remains can create periods of low dissolved oxygen in reservoir bottom waters.
- **Nutrient cycling in reservoirs and internal loading.** Nutrients entering reservoirs can undergo many changes and be involved in many biochemical processes. On an annual basis, the majority of nutrients entering a reservoir from a watershed are eventually discharged downstream, with only a small fraction being retained in the reservoir bottom sediments. Dissolved nutrients (e.g., orthophosphorus, nitrate, and ammonium) entering a reservoir can be used directly by algae when growing conditions are good. Some of these algae eventually die and settle to the bottom of reservoirs, also contributing nutrients (and organic matter) to the bottom sediments. Under low oxygen conditions, nutrients contained within bottom sediments can be re-released to the water column, creating a source

- of internal nutrient loading to the reservoir. This is particularly important for phosphorus and results in highly enriched bottom waters during periods of reservoir stratification. At turnover, these nutrient rich waters are mixed throughout the reservoir, can be released downstream, and can result in a secondary (fall) algae bloom.
- **Sediment deposition in reservoirs.** The characteristically slow-moving waters in reservoirs result in trapping of deposition of fine sediments and organic particulate matter. Contaminants found in the bottom sediments of reservoirs are typically transported from the watershed in association with particulate matter. Trace metals are mostly attached to (inorganic) clays and silts. Organic contaminants, such as pesticides and dioxin, are attached (adsorbed) to organic matter.

The following sections summarize general water quality trends by parameter in the Klamath River, from the upper basin to the lower basin. Additional detail, including data from multiple agency and tribal monitoring programs throughout the Klamath Basin, is presented in Appendix C.

3.2.3.2 Water Temperature

Water temperatures in the Klamath Basin vary seasonally and by location. In the Upper Klamath Basin, water temperatures are typically very warm in summer months as ambient air temperatures heat surface waters. Water temperatures (measured as 7-day-average maximum values) in Upper Klamath Lake and much of the reach from Link River Dam to the Oregon-California State line exceed 20°C (68°F) in June through August. Both Upper Klamath Lake and the Keno Impoundment/Lake Ewauna undergo periods of intermittent, weak summertime stratification, but water temperatures in these water bodies are generally similar throughout the water column and among the warmest in the Klamath Basin (peak values >25°C [>77°F]). Upper basin locations influenced by groundwater springs, such as the Wood River and the mainstem Klamath River downstream from J.C. Boyle Dam, have relatively constant water temperatures year-round and can be 5–15°C (9–27°F) cooler than other local water bodies during summer months, depending on the location.

Water temperatures in the Klamath Hydroelectric Reach are influenced by the presence of the Four Facilities. The relatively shallow depth and short hydraulic residence times in J.C. Boyle Reservoir do not support thermal stratification (Federal Energy Regulatory Commission [FERC] 2007; Raymond 2008, 2009, 2010) and this reservoir does not directly provide a source of cold water to downstream reaches during summer (National Research Council [NRC] 2004). However, current power-peaking operations at the J.C. Boyle Powerhouse contribute to the availability of cold water in the river just downstream from the dam (≈RM 221), where cold groundwater springs enter the river. During daily peaking operations at J.C. Boyle Powerhouse, warm reservoir discharges are

diverted from the Bypass Reach allowing cold groundwater to dominate flows in the river (PacifiCorp 2006a). Water temperatures in the Bypass Reach can decrease by 5–15°C (9–27°F) when bypass operations are underway (Kirk et al. 2010).

Iron Gate and Copco 1 Reservoirs are the two deepest reservoirs in the Klamath Hydroelectric Reach. These reservoirs thermally stratify beginning in April/May and the surface and bottom waters do not mix again until October/November (Raymond 2008, 2009, 2010). The large thermal mass of the stored water in the reservoirs delays the natural warming and cooling of riverine water temperatures on a seasonal basis such that spring water temperatures in the Klamath Hydroelectric Reach are generally cooler than would be expected under natural conditions, and summer and fall water temperatures are generally warmer (NCRWQCB 2010a). In the Hydroelectric Reach, maximum weekly maximum temperatures (MWMTs), which generally occur in late July, regularly exceed the range of chronic effects temperature thresholds (13–20°C [55.4–68°F]) for full salmonid support in California (NCRWQCB 2010a).

The temporal water temperature pattern of the Hydroelectric Reach is repeated in the Klamath River immediately downstream from Iron Gate Dam, where water released from the reservoirs is 1–2.5°C (1.8–4.5°F) cooler in the spring and 2–10°C (3.6–18°F) warmer in the summer and fall as compared to modeled conditions without the dams (PacifiCorp 2004a, Dunsmoor and Huntington 2006, NCRWQCB 2010a). This trend is discussed in more detail in Section 3.2.4.3.2.1, Lower Klamath Basin. Immediately downstream from Iron Gate Dam (RM 190.1), water temperatures are also less variable than those documented farther downstream in the Klamath River (Karuk Tribe of California 2009, 2010).

Farther downstream, the presence of the Four Facilities exerts less influence and water temperatures are more influenced by solar energy, the natural heating and cooling regime of ambient air temperatures, and tributary inputs of surface water. Meteorological control of water temperatures result in increasing temperature with distance downstream from Iron Gate Dam. For example, daily average temperatures between June and September are approximately 1–4°C (1.8–7.2°F) higher near Seiad Valley (RM 129.4) than those just downstream from the dam (Karuk Tribe of California 2009, 2010; see Appendix C for more detail). By the Salmon River (RM 66), the effects of the Four Facilities on water temperature are significantly diminished. Downstream from the Salmon River, the influence of the dams on water temperature in the Klamath River is not discernable from the modeled data (PacifiCorp 2005, NCRWQCB 2010a, Dunsmoor and Huntington 2006).

Downstream from the Salmon River (RM 66), summer water temperatures begin to decrease slightly with distance as coastal meteorology (i.e., fog and lower air temperatures) decrease longitudinal warming (Scheiff and Zedonis 2011) and cool water tributary inputs increase the overall flow volume in the river. In general, however, the slight decrease in water temperatures in this reach is not sufficient to support cold water fish habitat during summer months. Daily maximum summer water temperatures have been measured at values greater than 26°C (78.8°F) just upstream of the confluence with

the Trinity River (Weitchpec [RM 43.5]), decreasing to 24.5°C (76.1°F) near Turwar Creek (RM 5.8) (Yurok Tribe Environmental Program [YTEP] 2005, Sinnott 2010). As is the case further upstream, MWMTs in the Klamath River downstream from Iron Gate Dam to the Klamath River estuary regularly exceed the range of chronic effects temperature thresholds (13–20°C [55.4–68°F]) for full salmonid support in California (NCRWQCB 2010a).

Water temperatures in the Klamath River estuary are linked to temperatures and flows entering the estuary, salinity of the estuary and resulting density stratification, as well as the timing and duration of the formation of a sand berm across the estuary mouth. When the estuary mouth is open, denser salt water from the ocean sinks below the lighter fresh river water, resulting in a salt wedge that moves up and down the estuary with the daily tides (Horne and Goldman 1994, Wallace 1998, Hiner 2006). The salt water wedge results in thermal stratification of the estuary with cooler, high salinity ocean waters remaining near the estuary bottom, and warmer, low salinity river water near the surface. Under low-flow summertime conditions, when the mouth can close, surface water temperatures in the estuary have been observed at 18–24°C (64.4–75.2°F) and greater (Wallace 1998, Hiner 2006, Watercourse Engineering, Inc. 2011). Input of cool ocean water and fog along the coast minimizes extreme water temperatures much of the time (Scheiff and Zedonis 2011).

3.2.3.3 *Suspended Sediments*

For the purposes of the Klamath Facilities Removal EIS/EIR, suspended sediment refers to suspended material in the water column. Bed materials, such as gravels and larger substrates, are discussed in Section 3.3.3.2, Aquatic Resources – Existing Conditions/Affected Environment – Physical Habitat Descriptions. Two types of suspended material are important to water quality in the Klamath Basin and are discussed below: algal-derived (organic) suspended material and mineral (inorganic) suspended material. Sources of each type of suspended material differ, as do spatial and temporal trends for each, within the Upper and Lower Klamath Basins.

Suspended sediments in the tributaries to the Upper Klamath Lake are generally derived from mineral (inorganic) materials, with peak values associated with winter and spring high flows. Of the three main tributaries to the Upper Klamath Lake, the Sprague River has been identified as a primary source of sediment to Upper Klamath Lake. Because phosphorus is naturally high in Klamath Basin sediments, the Sprague River is also an important source of this nutrient to the lake (Gearheart et al. 1995, ODEQ 2002, Connelly and Lyons 2007). Sources of the sediment inputs within the Sprague River drainage include agriculture, livestock grazing and forestry activities, and road-related erosion (ODEQ 2002, Connelly and Lyons 2007, Rabe and Calonje 2009).

Between Link River at Klamath Falls (RM 253.1) and the upstream end of J.C. Boyle Reservoir (RM 224.7), algal-derived (organic) suspended material is the predominant form of suspended material affecting water quality. Summer and fall algal-derived (organic) suspended materials decrease with distance downstream, as algae are exported

from Upper Klamath Lake and into the Keno Impoundment/Lake Ewauna, where they largely settle out of the water column (Sullivan et al. 2009). Data from June through November during 2000–2005 indicate that the largest relative decrease in mean total suspended solids (TSS) in the upper Klamath River occurs between Link River Dam and Keno Dam (see Appendix C for more detail). Suspended materials generally continue to decrease through the Hydroelectric Reach (PacifiCorp 2004b), where further interception, decomposition, and retention of algal-derived (organic) suspended materials originating from Upper Klamath Lake occurs, as well as dilution from the springs downstream from J.C. Boyle Dam. However, increases in suspended material can occur in Copco 1 and Iron Gate reservoirs due to *in situ* summertime algal blooms, which can adversely affect beneficial uses.

In the winter months, suspended material in the Hydroelectric Reach is dominated by mineral sediment loads from several tributaries that join the river in this reach (primarily Shovel Creek, Spencer Creek, Jenny Creek, Fall Creek). The suspended materials (silts, clays with diameters < 0.063 mm), which are primarily transported during high flow events, generally settle out in the KHP reservoirs such that water column concentrations generally decrease with distance downstream in the Hydroelectric Reach (see also Appendix C, Section C.2.1). Likewise, the reservoirs trap bedload or fluvial sediment (coarse sand, gravels, and larger materials with diameters > 0.063 mm) from the tributaries. On the scale of the entire Klamath Basin, the trapping of fine sediments and suspended materials does not appear to be a critical function with respect to the overall cumulative sediment delivery including downstream tributaries (see also Section 3.11.3.3 for a discussion of basin sediment supply and transport), since a relatively small (3.4 percent) fraction of total sediment supplied to the Klamath River on an annual basis originates from the upper and middle Klamath River (i.e., from Keno Dam to the Shasta River). Beneficial uses in the upper Klamath River are currently not impaired due to mineral (inorganic) suspended material (see Table 3.2-8).

Just downstream from Iron Gate Dam (RM 190.1), summer and fall suspended sediment concentrations become relatively low. Between Iron Gate Dam and Seiad Valley (RM 129.4), suspended materials can increase due to the transport of in-reservoir algal blooms to downstream reaches of Klamath River, as well as river bed scour and resuspension of previously settled materials (YTEP 2005, Sinnott 2007, Armstrong and Ward 2008, Watercourse Engineering, Inc. 2011). Further downstream, near the confluence with the Scott River (RM 143.0) concentrations of suspended materials tend to decrease with distance as suspended materials gradually settle out of the water column farther downstream or are diluted by tributary inputs (see Appendix C for more detail).

Mineral (inorganic) suspended sediments begin to have prominence again in the Klamath River downstream from Iron Gate Dam, as major tributaries to the mainstem contribute large amounts of mineral (inorganic) suspended sediments to the river during winter and spring (Armstrong and Ward 2008). Steeper terrain and land use activities such as timber harvest and road construction result in high sediment loads during high-flow periods. Two of the three tributaries that contribute the largest amount of sediment to the Klamath River are in this reach; the Scott River (RM 143) (607,300 tons per year or 10 percent of

the cumulative average annual delivery from the basin), and the Salmon River (RM 66.0) (320,600 tons per year or 5.5 percent of the cumulative average annual delivery from the basin) (Stillwater Sciences 2010). The Trinity River contributes 3,317,300 tons per year of sediment to the Klamath River or 57 percent of the cumulative average annual delivery from the basin (Stillwater Sciences 2010) (see Appendix C for more detail).

3.2.3.4 Nutrients

Primary nutrients including nitrogen and phosphorus are affected by the geology of the surrounding watershed of the Klamath River, upland productivity and land uses, as well as a number of physical processes affecting aquatic productivity within reservoir and riverine reaches. Nitrogen arriving in Upper Klamath Lake has been attributed to upland soil erosion, runoff and irrigation return flows from agriculture, as well as *in situ* nitrogen fixation by cyanobacteria (ODEQ 2002). Although the relatively high levels of phosphorus present in the Upper Klamath Basin's volcanic rocks and soils have been identified as a major contributing factor to phosphorus loading to the lake (ODEQ 2002), land use activities in the Upper Klamath Basin have also been linked to increased nutrient loading (Kann and Walker 1999, Snyder and Morace 1997, Bradbury et al. 2004, Colman et al. 2004, Eilers et al. 2004; see Appendix C, Section C.3.1.2 for more detail), subsequent changes in its trophic status, and associated degradation of water quality. Extensive monitoring and research has been conducted for development of the Upper Klamath Lake TMDLs (ODEQ 2002) that shows the lake is a major source of nitrogen and phosphorus loading to the Klamath River (see Appendix C for additional details). Nutrient and organic matter inputs from the Lost River Basin via Klamath Straits Drain and the Lost River Diversion Channel are also an important source of nutrients to the Upper Klamath River (Sullivan et al. 2009, et al. 2011; Kirk et al. 2010) (see Appendix C, Section C.3.1.3 for additional detail). Allowing for seasonal reservoir dynamics in the Hydroelectric Reach, nutrient levels in the Klamath River generally decrease with distance downstream from Upper Klamath Lake due to particulate trapping in reservoirs, dilution, and uptake along the river channel. In a recent study of nutrient dynamics in the Klamath River, May through December nutrients for 2005–2008 followed a decreasing longitudinal pattern, with the highest concentrations (approximately 0.1–0.5 mg/L TP and 1–4 mg/L TN) measured in the Klamath River downstream from Keno Dam (RM 228–233) (Asarian et al. 2010). On an annual basis, nutrients typically decrease through the Hydroelectric Reach due to the dilution by the springs downstream from J.C. Boyle Reservoir. Nutrient concentrations in the springs, which represent natural sources, are approximately 0.22 mg/L TN (almost exclusively dissolved) and approximately 0.06 – 0.08 mg/L TP, which is also mostly dissolved (Asarian et al. 2010). Settling of particulate matter and associated nutrients in Copco 1 and Iron Gate Reservoirs also contributes to the overall decreasing trend for nutrients in the Hydroelectric Reach on an annual basis. On a seasonal basis, TP, and to a lesser degree, TN can increase in this reach due to the release (export) of dissolved forms of phosphorus (ortho-phosphorus) and nitrogen (ammonium) from reservoir sediments during periods of summer and fall hypolimnetic anoxia (see Appendix C for additional

details). The seasonal nutrient releases can occur during periods of in-reservoir algal growth, and in the case of TP can be transported downstream to the Lower Klamath River where they may stimulate periphyton growth.

Downstream from the Four Facilities, TP values typically range 0.1–0.25 mg/L in the Klamath River between Iron Gate Dam and Seiad Valley, with the highest values occurring just downstream from the dam. TN concentrations in the river downstream from Iron Gate Dam generally range from <0.1 to over 2.0 mg/L and are generally lower than those in upstream reaches due to reservoir retention and dilution by springs in the Hydroelectric Reach (Asarian et al. 2009) (see Appendix C for additional details). Further decreases in TN occur in the mainstem river due to a combination of tributary dilution and in-river nutrient spiraling processes by periphyton (Mulholland 1996). These processes strongly affect nitrogen concentrations in flowing rivers through removal processes such as denitrification and/or assimilation and storage related to biomass uptake (Asarian et al. 2010), or by late-seasonal recycling of nutrients downstream as active periphyton growth wanes. Ratios of nitrogen to phosphorus (TN:TP) measured in the Klamath River downstream from Iron Gate Dam suggest the potential for nitrogen-limitation of primary productivity with some periods of co-limitation by both nitrogen and phosphorus. However, concentrations of both nutrients are high enough that other factors (i.e., light, water velocity, or available substrate) may be more limiting to primary productivity than nutrients are, particularly in the vicinity of Iron Gate Dam (FERC 2007, Hoopa Valley Tribe Environmental Protection Agency [HVTEPA] 2008, Asarian et al. 2010) (see Appendix C for additional details). This is particularly important with regard to factors controlling periphyton growth in this portion of the Klamath River (see Section 3.4, Algae).

Downstream from the confluence with the Salmon River, nutrient concentrations continue to decrease in the Klamath River as compared with those measured farther upstream due to tributary dilution and nutrient retention. Contemporary data (2005–2008) indicate that TP concentrations in this reach are generally 0.05–0.1 mg/L with peak values occurring in September and October. For TN, contemporary data indicate that on a seasonal basis, this nutrient increases from May through November, with peak concentrations (<0.5 mg/L) typically observed during September and October. Both TP and TN are at or above the Hoopa Valley Tribe numeric criterion of 0.2 mg/L TN and 0.035 mg/L TP (see Table 3.2-6).

Nutrient levels in the Klamath Estuary experience inter-annual and seasonal variability. Measured levels of TP in the estuary are typically below 0.1 mg/L during summer and fall (June–September) and TN levels are consistently below 0.6 mg/L (June–September) (Sinnott 2011). While the California Basin Plan water quality objective for biostimulatory substances is narrative rather than numeric, as with upstream reaches, the measured levels in the Klamath Estuary may promote algal growth at levels that cause nuisance effects or adversely affect beneficial uses (see Table 3.2-4).

3.2.3.5 Dissolved Oxygen

Dissolved oxygen concentrations in the Klamath Basin depend on several factors, including water temperature (colder water absorbs more oxygen), water depth and volume, stream velocity (as related to mixing and re-aeration), atmospheric pressure, salinity, and the activity of organisms that depend upon dissolved oxygen for respiration. This last factor (respiratory consumption) is strongly influenced by the availability of nitrogen and phosphorus for supporting algal and aquatic plant growth.

In tributaries to Upper Klamath Lake, limited data indicate that dissolved oxygen varies from <7–13 mg/L (Kann 1993, ODEQ 2002). Concentrations in the lake itself exhibit high seasonal and spatial variability, ranging from less than 4 mg/L to greater than 10 mg/L. High nutrient loading is the primary cause of eutrophication and subsequent low dissolved oxygen levels in Upper Klamath Lake. Water quality data collected by the Klamath Tribes contains periods of weeks during the summer months when dissolved oxygen levels in the lake are continuously below the ODEQ criterion of 5.5 mg/L for support of warm water aquatic life (Kann et al. 2010). Low (0–4 mg/L) dissolved oxygen concentrations occur most frequently in August, the period of declining algal blooms in the lake and warm water temperatures (ODEQ 2002, Walker 2001) (see Appendix C for additional details).

In the downstream Keno Impoundment/Lake Ewauna, dissolved oxygen reaches very low levels (< 1–2 mg/L) during July–October as algae transported from Upper Klamath Lake settle out of the water and decay. Four facilities discharge treated wastewater to the Keno Impoundment/Lake Ewauna; however, these facilities contribute a very small amount (<1.5% of the organic material loading) to the overall oxygen demand in the Keno Reach. Decomposition of algae transported from Upper Klamath Lake appears to be the primary driver of low oxygen in the Keno Impoundment/Lake Ewauna. Organic matter and nutrient inputs from the Lost River Basin via Klamath Straits Drain and the Lost River Diversion Channel also contribute to low dissolved oxygen levels in this reach (Sullivan et al. 2009, et al. 2011; Kirk et al. 2010) (see Appendix C, Section C.4.1.3 for additional detail).

During summer, the reservoirs of the Four Facilities exhibit varying degrees of dissolved oxygen super-saturation (i.e., >100% saturation) in surface waters (due to high rates of internal photosynthesis by algae) and hypolimnetic oxygen depletion in bottom waters (due to microbial decomposition of dead algae). Although J.C. Boyle Reservoir, a relatively long, shallow reservoir, does not stratify, large variations in dissolved oxygen are observed at its discharge due to high oxygen demand from water in the upstream reach from Link River Dam through the Keno Impoundment/Lake Ewauna, and in Upper Klamath Lake (see Appendix C for more detail). Copco 1 and Iron Gate Reservoirs thermally stratify beginning in April/May and do not mix again until October/November (FERC 2007). Dissolved oxygen in Iron Gate and Copco 1 surface waters during summer months is generally at or, in some cases above, saturation while levels in hypolimnetic waters reach minimum values near 0 mg/L by July (see Appendix C for more detail).

Based upon measurements collected immediately downstream from Iron Gate Dam, dissolved oxygen concentrations regularly fall below 8 mg/L (the Basin Plan minimum dissolved oxygen criterion is now based on percent saturation, see Table 3.2-5) (Karuk Tribe of California 2001, 2002, 2007, 2009). Continuous Sonde data collected at other Klamath River locations downstream from Iron Gate Dam during summer 2004–2006, show that roughly 45 to 65 percent of measurements immediately downstream from the dam did not achieve 8 mg/L. Daily fluctuations of up to 1–2mg/L measured in the Klamath River downstream from Iron Gate Dam (RM 190.1) have been attributed to daytime algal photosynthesis and nighttime bacterial respiration (Karuk Tribe of California 2002, 2003; YTEP 2005; NCRWQCB 2010a). Farther downstream in the mainstem Klamath River, near Seiad Valley (RM 129.4), dissolved oxygen concentrations increase relative to the reach immediately downstream from Iron Gate Dam, but continue to exhibit variability, with mean daily values ranging from approximately 6.5 mg/L to (supersaturated concentrations of) approximately 10.5 mg/L, from June through November, 2001–2002 and 2006–2009 (Karuk Tribe of California 2001, 2002, 2007, 2009).

Measured concentrations of dissolved oxygen in the mainstem Klamath River downstream from Seiad Valley (RM 129.4) continue to increase with increasing distance from Iron Gate Dam. Dissolved oxygen concentrations near Orleans (RM 59) continue to be variable, with typical daily values ranging from approximately 6.5 mg/L to (supersaturated concentrations of) 11.5 mg/L from June through November, 2001–2002 and 2006–2009 (Karuk Tribe of California 2001, 2002, 2007, 2009; Ward and Armstrong 2010; NCRWQCB 2010a). Further downstream, near the confluence with the Trinity River (RM 42.5) and at the Turwar gage (RM 5.8), minimum dissolved oxygen concentrations below 8 mg/L (the Basin Plan minimum dissolved oxygen criterion prior to 2010) have been observed for extended periods of time during late summer/early fall (YTEP 2005, Sinnott 2010). In 2010, minimum dissolved oxygen concentrations remained above 2010 amended Basin Plan minimum dissolved oxygen concentration criteria based on percent saturation (see Appendix C for additional details).

Dissolved oxygen concentrations in the Klamath Estuary vary both temporally and spatially; concentrations in the deeper, main channel of the estuary are generally greater than 6 to 7 mg/L throughout the year (Hiner 2006, YTEP 2005). Low dissolved oxygen concentrations (<1 to 5 mg/L) have been observed during summer months in the relatively shallow, heavily vegetated south slough (Hiner 2006, Wallace 1998). The low levels of dissolved oxygen observed in the slough are likely due to high rates of growth and subsequent decomposition of algae and macrophytes, which are not abundant elsewhere in the estuary.

3.2.3.6 pH

Because the Klamath River is a weakly buffered system (i.e., has typically low alkalinity <100 mg/L; PacifiCorp [2004a], Karuk Tribe of California [2010]) it is susceptible to photosynthesis-driven daily and seasonal swings in pH. In the Upper Klamath Basin, summertime pH levels are elevated above neutral (i.e., up to 8.2 in the Wood River

subbasin and 8.5–9.5 in the Sprague River). These elevated pH levels have been linked primarily to high rates of photosynthesis by periphyton (i.e., benthic or attached algae) (ODEQ 2002). During November–April, pH levels in Upper Klamath Lake are near neutral (Aquatic Scientific Resources [ASR] 2005) but increase to very high levels (>10) in summer (ODEQ maximum pH is 9.0, see Table 3.2-3). Extended periods of pH greater than 9 have been associated with large summer algal blooms in Upper Klamath Lake (Kann 2010). On a daily basis, algal photosynthesis can elevate pH levels by up to 2 pH units over a 24-hour period. Generally, pH in the reach from Link River Dam through the Keno Impoundment/Lake Ewauna increases from spring to early summer and decreases in the fall; however, there are site-dependent variations in the observed trend. Peak values can exceed the ODEQ maximum of 9.0 (see Appendix C for additional details).

In the Hydroelectric Reach, pH is seasonally variable, with levels near neutral during the winter, increasing in the spring and summer. Peak values (8–9.2) have been recorded during the months of May and September with lower values documented June through August (7.5–8) (Raymond 2010), where the ODEQ pH maximum is 9 units (for the Klamath River upstream of the Oregon-California State line; Table 3.2-3) and the California pH maximum is 8.5 units (for the river downstream from State line; Table 3.2-4). Longitudinally, the lowest pH values were recorded downstream from J.C. Boyle Reservoir and the highest values in Copco and Iron Gate Reservoirs (Raymond 2008, 2009, 2010). High pH levels typically coincide with high algal photosynthesis rates at or near the water surface during periods of thermal stratification and high nutrient concentrations in the KHP reservoirs (Raymond 2008).

In the Lower Klamath Basin, seasonally high pH values continue to occur, with the highest pH values generally occur during late-summer and early-fall months (August–September). Daily cycles in pH also occur in this reach, with pH usually peaking during later afternoon or early evening, following the period of maximum photosynthesis (NCRWQCB 2010a). The California North Coast Basin Plan pH maximum of 8.5 units (Table 3.2-4) is regularly exceeded in the Klamath River downstream from Iron Gate Dam for the May–October 2005 dataset (see Appendix C for more detail). The most extreme pH exceedances typically occur just upstream of Shasta River; values generally decrease with distance downstream (FERC 2007; Karuk Tribe of California 2007, 2009, 2010). During the summer months, pH values also are elevated in the Lower Klamath River from Weitchpec downstream to approximately Turwar Creek (see Appendix C for more detail). pH was incorporated into the Klamath River TMDLs as a nutrient-related water quality impairment including in the Project reservoirs (see Section 3.2.2.4.4) and as such, meeting the nutrient objectives of the TMDLs will mitigate pH impairments. In the Klamath Estuary, pH ranges between approximately 7.5 and 9, with peak values also occurring during the summer months (YTEP 2005). Daily variations in pH are typically on the order of 0.5 pH units, and fluctuations tend to be somewhat larger in the late summer and early fall. When large daily fluctuations are observed, they are likely caused by algal blooms that are transported into the estuary.

3.2.3.7 Chlorophyll-*a* and Algal Toxins

As primary producers, algae are critical components of riverine and lacustrine ecosystems. Their presence and abundance affect food web dynamics as well as physical water quality parameters (e.g., dissolved oxygen, pH, turbidity, and nutrients), the latter through rates of photosynthesis, respiration, and decay of dead algal cells (Horne and Goldman 1994). Cyanobacteria are also photosynthetic and can often be a nuisance aquatic species, occurring as large seasonal blooms that alter surrounding water quality. Some cyanobacteria species produce cyanotoxins (e.g., cyclic peptide toxins such as microcystin that act on the liver, alkaloid toxins such as anatoxin-a and saxitoxin that act on the nervous system). Cyanotoxins can cause irritation, sickness, or in extreme cases, death to exposed organisms, including humans (World Health Organization [WHO] 1999). Species capable of producing microcystin include *M. aeruginosa*, while species in the genus *Anabaena* can produce anatoxin-a and saxitoxin. More complete listings of specific toxins produced by genera of cyanobacteria worldwide are provided in Lopez et al. (2008) and ODEQ (2011).

Chlorophyll-*a*, a pigment produced by photosynthetic organisms including algae and cyanobacteria, is often used as a surrogate measure of algal biomass. Algae suspended in the water column (phytoplankton) can be represented as a concentration of chlorophyll-*a* (mg/L), while algae attached to bottom sediments or channel substrate (periphyton) can be represented as an areal biomass (mg chl-*a*/m²). Periphyton data are discussed in Section 3.4, Algae.

In the tributaries to Upper Klamath Lake, algae are generally present as periphyton (i.e., benthic or attached algae) species. Periphyton in these streams can cause water quality impairments for dissolved oxygen and pH (see Appendix C for more detail). In Upper Klamath Lake, algae are dominated by phytoplankton or suspended algae. Large summertime blooms of cyanobacteria are typically dominated by *Aphanizomenon flos-aquae*, with relatively smaller amounts of *M. aeruginosa* present. Despite this, *M. aeruginosa* is believed to be responsible for the production of microcystin in the lake, with concentrations in 2007–2008 equal to or greater than the WHO limit for drinking water (1 µg/L) and peaked at 17 µg/L, which is above the Oregon Department of Public Health guidelines for issuing public health advisories. Additional microcystin data collection in Upper Klamath Lake is ongoing, including studies of possible effects of algal toxins on native suckers (Vanderkooi et al. 2010, see Section 3.3, Aquatic Resources for more detail).

High (i.e., near 300 µg/L) summer chlorophyll-*a* concentrations in the Keno Impoundment/Lake Ewauna are due to large populations of algae, predominantly *A. flos-aquae*, entering the Klamath River from Upper Klamath Lake in summer (Kann 2006; Sullivan et al. 2008, et al. 2009, et al. 2010; FERC 2007). Such high concentrations do not persist farther downstream in J.C. Boyle Reservoir; however, in the two largest reservoirs (i.e., Copco 1 and Iron Gate) in the Hydroelectric Reach, chlorophyll-*a* concentrations increase again. Seasonal algal blooms and elevated chlorophyll-*a* concentrations have been observed in the Hydroelectric Reach historically, including a USEPA survey in Iron Gate Reservoir in 1975 documenting algal blooms in

March, July, and October, and including diatoms and blue green algae (USEPA 1978). More contemporary data indicates that chlorophyll-*a* levels in Copco 1 and Iron Gate Reservoirs can be 2 to 10 times greater than those documented in the mainstem river, although they are not as high as those found in the Keno Impoundment/Lake Ewauna (NCRWQCB 2010a) (see Appendix C for more detail). High levels of microcystin also occur during summer months in Copco 1 and Iron Gate Reservoirs; peak measured concentrations exceeded the California State Water Resources Control Board (SWRCB)/Office of Environmental Health and Hazard Assessment (OEHHA) public health threshold of 8 µg/L (SWRCB et al. 2010) by over 1000 times in Copco 1 Reservoir during 2006–2009 and extremely high concentrations (1,000–73,000 µg/L) were measured during summer algal blooms in both Copco 1 and Iron Gate Reservoirs during 2009 (Watercourse Engineering 2011, see Appendix C for more detail).

Throughout the Klamath River, high chlorophyll-*a* concentrations have been shown to correlate with the toxigenic cyanobacteria blooms where *M. aeruginosa* was present in high concentrations and sharp increases in microcystin levels above WHO numeric targets (Kann and Corum 2009) and SWRCB, California Department of Public Health, and OEHHA guidelines (SWRCB et al. 2010). Since 2007, high levels of microcystin have prompted the posting of public health advisories around the reservoirs and, during certain years, along the length of the Klamath River during summer months. In 2010, the KHP reservoirs and the entire river downstream from Iron Gate Dam (including the estuary) were posted to protect public health due to elevated cyanobacteria cell counts and cyanotoxin (i.e., microcystin) concentrations.

Microcystin can also bioaccumulate in aquatic biota (Kann 2008, Kann et al. 2011); 85 percent of fish and mussel tissue samples collected during July through September 2007 in the Klamath River, including Iron Gate and Copco 1 Reservoirs, exhibited microcystin bioaccumulation (Kann 2008) (see Appendix C for more detail). Estuarine and marine nearshore effects (e.g., sea otter deaths) from cyanobacteria exposure have been reported in other California waters; however, none have been documented to date for the Klamath Estuary or marine nearshore (Miller et al. 2010). Section 3.3.3.2, Physical Habitat Descriptions - Water Quality - Algal Toxins presents a discussion of algal toxins as related to fish health.

3.2.3.8 Inorganic and Organic Contaminants

In general, information regarding contaminants in the Upper Klamath Basin upstream of the Hydroelectric Reach is unavailable. Human activities such as illegal dumping may be a source of inorganic and organic contaminants to the lower Sprague and Williamson river sub-basins (Rabe and Calonje 2009). Arsenic is an exception to this; natural geologic sources of arsenic may be causing relatively high levels of this chemical element in the Upper Klamath Basin (Smith et al. 2009; GeoEngineers 2011; D. Smith, USGS, Denver, CO, written communication, June 25, 2012), as is the case in other south central and southeastern Oregon basins (Sturdevant 2010). Generally elevated background nickel concentrations have also been found in soils in the Klamath Basin

(Smith et al. 2009; GeoEngineers 2011; D. Smith, USGS, Denver, CO, written communication, June 25, 2012; see Appendix C for more detail).

3.2.3.8.1 Water Column Contaminants

Existing water quality data are available from the California Surface Water Ambient Monitoring Program (SWAMP). SWAMP data from 2001 through 2005 indicate that at eight monitoring sites from the California-Oregon State line (RM 208.5) to Klamath River at Klamath Glen (RM 5.8) the majority of inorganic constituents (i.e., arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, and zinc), were in compliance with water quality objectives. Aluminum concentrations in some samples may have been slightly elevated above USEPA freshwater aquatic life and secondary standards for drinking water, where a greater sampling frequency would be required to determine actual exceedances. Grab samples were analyzed for 100 pesticides, pesticide constituents, isomers, or metabolites; 50 polychlorinated biphenyls (PCBs) congeners; and 6 phenolic compounds. Results indicated no PCBs and only occasional detections of pesticides (NCRWQCB 2008) (see Appendix C for more detail).

3.2.3.8.2 Sediment Contaminants

To investigate the potential for toxicity of the sediments trapped in the reservoirs of the Four Facilities, Shannon & Wilson, Inc. (2006) collected sediment samples from J.C. Boyle, Copco 1, and Iron Gate Reservoirs during 2004–2005 and analyzed them for contaminants including acid volatile sulfides, metals, pesticides, chlorinated acid herbicides, PCBs, volatile organic compounds (VOCs), semi-volatile organic compounds (SVOCs), cyanide, and dioxins. No herbicides or PCBs were found above screening levels and only one sample exceeded applicable screening levels for VOCs ethyl benzenes and total xylenes (Shannon & Wilson, Inc. 2006). While cyanide was detected in multiple sediment cores, it was not found in the bioavailable toxic free cyanide form (HCN or CN⁻).

Dioxin, a known carcinogen, was also measured in the Shannon & Wilson, Inc. (2006) study. Long-term exposure to dioxin in humans is linked to impairment of the immune system, the developing nervous system, the endocrine system and reproductive functions. In the 2004–2005 reservoir samples, measured levels were 2.48–4.83 pg/g (picograms per gram or parts per trillion [ppt] expressed as Toxic Equivalent Concentrations) and did not exceed applicable screening levels for human health and ecological receptors (Shannon & Wilson, Inc. 2006, Dillon 2008, USEPA 2010b) or estimated background dioxin concentrations (2–5 ppt) for non-source-impacted sediments throughout the U.S. and specifically in the western U.S. (USEPA 2010b) (see Appendix C for more detail). The measured levels did exceed Oregon human health and bioaccumulation thresholds; however, Oregon's human health thresholds include risk-based values for subsistence fishers as well as the general consuming public and are quite a bit lower (0.0011–1.1 pg/g dry weight (DW) Toxicity equivalency quotient [TEQ]) than many other screening levels (ODEQ 2007) (see Appendix C for more detail).

As part of the Klamath Dam Removal Secretarial Determination studies, a sediment evaluation was undertaken during 2009–2011 to evaluate potential environmental and

human health impacts of the downstream release of sediment deposits currently stored behind the dams under the Proposed Action². Sediment cores were collected during 2009–2010 at multiple sites and at various sediment depths per site in J.C. Boyle Reservoir, Copco 1 Reservoir, Iron Gate Reservoir, and the Klamath Estuary (Bureau of Reclamation 2010). A total of 501 analytes were quantified in the sediment samples, including metals, poly-cyclic aromatic hydrocarbons (PAHs), PCBs, pesticides/herbicides, phthalates, VOCs, SVOCs, dioxins, furans, and polybrominated diphenyl ethers (PBDEs) (i.e., flame retardants). Samples were analyzed for sediment chemistry and elutriate (pore water) chemistry, and bioassays were conducted on the sediment and elutriate using fish and invertebrate national benchmark toxicity species (see below for discussion of the bioaccumulation component of this study). Five exposure pathways were evaluated, which generally correspond to potential effects evaluated in this Klamath Facilities Removal EIS/EIR.

Based on comparisons of sediment chemistry to (1) screening levels (SLs) within the sediment evaluation framework (SEF) and human health criteria and (2) the relatively small number of chemicals of potential concern (COPCs) identified in sediment, reservoir sediments do not appear to be notably contaminated (for an explanation of the SEF see Section 3.2.4.1). No consistent pattern of elevated chemical composition was observed across discrete sampling locations within a reservoir; however, sediment in J.C. Boyle Reservoir does have marginally higher chemical concentrations and more detected COPCs in sediment when compared to the other reservoirs and the estuary. Also, J.C. Boyle Reservoir had more COPCs based on comparison to both freshwater ecological and human health SLs. However, in the case of J.C. Boyle Reservoir and in other instances where elevated concentrations of chemicals in sediment were found, the degree of exceedance based on comparisons of measured detected chemical concentrations to SLs was small and in several cases (i.e., arsenic, mercury, 2,3,7, 8-TCDD, total PCBs) may reflect regional background conditions (see Section C.7.1.1 for more detail). Toxicity tests generally indicated low potential for sediment toxicity to benchmark benthic indicator species; the exception to this occurred in a single sample from J.C. Boyle Reservoir, where survival of the benthic amphipod *Hyaella azteca* indicated a moderate potential for sediment toxicity. Results of the laboratory bioaccumulation tests indicated no consistent pattern of contaminant distribution among chemicals, media type, or location, although some chemicals accumulated in invertebrate tissues (i.e., acenaphthene, arsenic, benzo(a)pyrene, DDD/DDE, endosulfan I, endosulfan II, endosulfan sulfate, fluoranthene, hexachlorobenzene, lead, mercury, phenanthrene, pyrene, total PBDEs, total PCBs) (CDM 2011). In all cases the differences from one reservoir to another and between reservoirs and laboratory controls were small and not likely to be ecologically significant (see Appendix C, Section C.7.1.1 for more detail).

² There are currently 13.1 million yd³ of sediment deposits stored within J.C. Boyle, Copco 1 and 2, and Iron Gate Reservoirs (Reclamation 2012) (see also Section 2.2, text box on sediment weight and volume, of this Klamath Facilities Removal EIS/EIR). Prior estimates of the sediment deposits were 14.5 million yd³ (Eilers and Gubala 2003) and 20.4 million yd³ (GEC 2006).

3.2.3.8.3 Contaminants in Aquatic Biota

A discussion of algal toxins (i.e., microcystin) in fish tissue is presented in Section 3.2.3.7. Assessments of other contaminants in fish tissue for the Hydroelectric Reach have been undertaken by SWAMP and PacifiCorp. SWAMP data include sport fish tissue samples collected during 2007 and 2008 to evaluate accumulated contaminants in nearly 300 lakes Statewide. Sport fish were sampled to provide information on potential human exposure to selected contaminants and to represent the higher aquatic trophic levels (i.e., the top of the aquatic food web).

In the Hydroelectric Reach, fish tissue samples were collected in Copco 1 and Iron Gate Reservoirs and analyzed for total mercury, selenium, and PCBs (Iron Gate Reservoir only) (Davis et al. 2010). SWAMP data for Iron Gate and Copco reservoirs indicate mercury tissue concentrations above the USEPA criterion of 300 ng/g methylmercury (for consumers of noncommercial freshwater fish); and greater than OEHHA public health guideline levels advisory tissue levels (Klasing and Brodberg 2008) for consumption for 3 and 2 servings per week (70 and 150 ng/g wet weight, respectively) and the fish contaminant goal (220 ng/g wet weight). Measured selenium concentrations were 3–4 orders of magnitude lower than OEHHA thresholds of concern (2,500–15,000 ng/g wet weight) and PCB concentrations were below the lowest OEHHA threshold (i.e., fish contaminant goal of 3.6 ng/g wet weight) (Davis et al. 2010).

In a screening-level study of potential chemical contaminants in fish tissue in Keno, J.C. Boyle, Copco, and Iron Gate Reservoirs, and in Upper Klamath Lake, PacifiCorp analyzed metals (i.e., arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, and zinc), organochlorine (pesticide) compounds, and PCBs in largemouth bass (*Micropterus salmoides*) and black bullhead catfish (*Ameiurus melas*) (PacifiCorp 2004c). PacifiCorp reported that, in general, contaminant levels in fish tissue were below screening level values for protection of human health (USEPA 2000) and recommended guidance values for the protection of wildlife (MacDonald 1994). Exceptions to this include some tissue samples for total mercury, arsenic, total DDTs and total PCBs, when compared to screening levels for wildlife and subsistence fishers (individual comparisons are shown in Appendix C for more detail). Dioxins were not tested.

To supplement existing fish tissue data and provide additional lines of evidence in the Secretarial Determination sediment evaluation (see above and Section C.7.1.1), two species of field-caught fish were collected during late September 2010 from J.C. Boyle, Copco 1, and Iron Gate reservoirs and analyzed for contaminant levels in fish tissue (CDM 2011, see Section C.7.1.1 for more detail). Results indicate that multiple chemicals were found in fish tissue (i.e., arsenic, DDE/DDT, dieldrin, endrin, mercury, mirex, selenium, and total PCBs) under current conditions (CDM 2011). Mercury exceeded tissue-based toxicity reference values (TRVs) for perch in Iron Gate Reservoir and bullhead samples in all three reservoirs (CDM 2011). TRVs are not available for several chemicals detected in invertebrate and fish tissue (CDM 2011, see Section C.7.1.1 for more detail). TEQs for dioxin, furan, and dioxin-like PCBs in reservoir and estuary

sediment samples were within the range of local background values and suggest a potential to cause minor or limited adverse effects for fish exposed to reservoir sediments (CDM 2011).

3.2.4 Environmental Consequences

3.2.4.1 Environmental Effects Determination Methods

The Klamath Facilities Removal EIS/EIR water quality analysis includes consideration of the effects of the Proposed Action and alternatives on water temperature, suspended sediments, nutrients (TN, TP, nitrate, ammonium, ortho-phosphorus), dissolved oxygen, pH and alkalinity, chlorophyll-*a* and algal toxins, and inorganic and organic contaminants in water and reservoir sediments. For all water quality parameters, the analysis approach for water quality effects associated with facilities removal under Klamath Hydroelectric Settlement Agreement (KHSAs) is conducted at the project-level and is presented by water quality parameter. Elements of Klamath Basin Restoration Agreement (KBRA) restoration projects that would affect water quality are identified and analyzed at a program-level.

For water quality, existing conditions is generally defined as physical, chemical, and biological characteristics of water in the area of analysis at the time of the Notice of Preparation (Water Year [WY] 2010). However, while some water quality parameters to be analyzed here are well-represented by data collected during WY2010, most are represented by data collected within the past 5 to 10 years (WY2000–WY2010). Further, the start of the period of analysis for the hydrology, water temperature, and suspended sediment modeling conducted as part of Secretarial Determination studies was WY2012 (Section 1.4.1). Despite several existing regulations or agreements that may be partially implemented between WY2010 and WY2012 and that would affect water quality, in general, conditions in the Klamath River are not expected to be substantially different in WY2012 than conditions during WY2000–WY2010. Therefore, for the water quality analysis, existing conditions generally encompass the 10 to 12-year period prior to WY2012 (summarized in Section 3.2.3; additional detail provided in Appendix C).

The KHSAs presents nine water-quality-related Interim Measures (IMs) (KHSAs Section 1.2.4):

- IM 3, Iron Gate Turbine Venting
- IM 5, Iron Gate Flow Variability
- IM 7, J.C. Boyle Gravel Placement and/or Habitat Enhancement
- IM 8, J.C. Boyle Bypass Barrier Removal
- IM 10, Water Quality Conference
- IM 11, Interim Water Quality Improvements
- IM 13, Flow Releases and Ramp Rates
- IM 15, Water Quality Monitoring
- IM 16, Water Diversions

As discussed in Chapter 2, IM 3 is ongoing with pilot study data available from 2008 and 2010 and thus this interim measure is included as part of existing conditions. IM 5, Iron Gate Flow Variability, would alter flow variability, but the flows would stay within the range of historical flows. One year of IM 7, J.C. Boyle Gravel Placement and/or Habitat Enhancement is included in the No Action/No Project Alternative and was completed during November 2011. IM 8, J.C. Boyle Bypass Barrier Removal, could have construction-related water quality effects. IM 13, Flow Releases and Ramp Rates stipulates no change in the current flows from J.C. Boyle, so no water quality effects are anticipated as part of existing conditions.

Remaining IMs are included in Alternatives 2 and 3. Seven years of IM 7, J.C. Boyle Gravel Placement and/or Habitat Enhancement, could affect water quality. Planning efforts under IM 10, Water Quality Conference, and IM11, Interim Water Quality Improvements, are ongoing; however, pilot scale projects are still in the data collection or planning stage, so an assessment of water quality impacts is not yet practical. IM 16, the elimination of three screened diversions on Shovel and Negro Creeks and relocation of the points of diversion from the creeks to the Klamath River, could have construction-related water quality effects. IM 15 has been used to augment existing water quality monitoring programs in the basin by PacifiCorp, Karuk, Yurok and Reclamation. Additionally, IM 15, Water Quality Monitoring, has produced monitoring results which, as available, were incorporated into the existing conditions summary (Watercourse Engineering, Inc. 2011) that are incorporated into the existing conditions summary. Cyanobacteria monitoring reports for public health, reported by individual monitoring entities, are produced separately; these and many planning documents and reports of results from this process are posted online at: <http://www.kbmp.net/collaboration/klamath-hydroelectric-settlement-agreement-monitoring/>

Within the period of analysis (i.e., 50 years) reasonably foreseeable actions associated with water quality are anticipated to be the following:

- Ongoing restoration activities in the Klamath Basin (see Section 2.4.2).
- Implementation of TMDLs for Oregon and California (see Section 3.2.2.4)
- National Oceanic and Atmospheric Administration (NOAA) Fisheries Service 2010 Biological Opinion mandatory flows (see Section 2.3.1).
- California Department of Fish and Game (CDFG) Code Section 5937 instream flow mandate for tributaries to the mainstem Klamath River³
- Climate change (see Section 3.10.3.1).

Therefore, under the No Action/No Project Alternative, elements of ongoing restoration projects, TMDLs, and programs mandating stream flows that would affect future water quality are identified for a specific reach and/or water quality parameter and included as part of the analysis narrative in a qualitative or, if possible, a quantitative manner. Long-

³ This action is not included in the project description (Section 2) since it will occur only in tributaries to the middle and Lower Klamath River. It may increase flows to the mainstem Klamath River, thus it is briefly discussed as part of the No Action/No Project Alternative analysis for water quality.

term quantitative analyses for the No Action/No Project Alternative rely on existing models developed by PacifiCorp for the FERC relicensing process, the NCRWQCB for development of the Klamath River TMDLs, and the Secretarial Determination studies (see Appendix D for details). Multiple numeric models are used for the water quality analyses conducted in the Klamath Facilities Removal EIS/EIR because no individual existing numeric model captures all of the long-term water quality conditions anticipated for and encompassed by the No Action/No Project Alternative.

Water quality models are inherently complex, especially ones depicting a large and variable system such as the Klamath River. In the case of the California Klamath River TMDLs, a significant five-year effort was employed by the NCRWQCB in collaboration with PacifiCorp and working jointly with USEPA Region's 9 and 10, ODEQ, and USEPA's contractor Tetra Tech on the modeling work for the TMDL. That work was subject to extensive peer review and public comment before the NCRWQCB adoption. It was further reviewed and subject to additional public comment before approved unanimously by the SWRCB. It was then subsequently reviewed and approved by the USEPA. The California Klamath River TMDL models are sufficiently reliable for the purpose in which they are used in the Klamath Facilities Removal EIS/EIR.

Under the Proposed Action and remaining alternatives, the analysis of water quality effects considers both the short term (<2 years following dam removal/construction of fish passage facilities)⁴ and long term (2–50 years following dam removal/construction of fish passage facilities). While the timing of reservoir drawdown under the Proposed Action was optimally developed to minimize environmental effects, some short-term effects are anticipated and, for water quality, would be heavily influenced by the release of fine sediment deposits currently stored behind the dams to the downstream river reaches, the estuary, and the marine nearshore environment. This is because mobilization of reservoir sediment deposits would be most intense during the first year or two following dam removal, when the majority of sediments would be eroded by river flows (Reclamation 2012, Stillwater Sciences 2008). Short-term effects would also occur as a result of construction activities related to fish passage structures and restoration activities associated with dam removal and KBRA implementation. Under the Proposed Action and other dam removal alternatives, long-term effects on water quality would be primarily characterized by the shift from lacustrine to riverine environments in the Hydroelectric Reach and the concomitant changes in physical and chemical processes on water quality in this reach and downstream river reaches. Parameter-specific analysis methods are discussed below. As described for the No Action/No Project Alternative, long-term quantitative analyses for the Proposed Action rely on existing models developed by PacifiCorp for the FERC relicensing process, the NCRWQCB for development of the Klamath River TMDLs, and the Secretarial Determination studies (see Appendix D for details). Multiple numeric models are used for the water quality

⁴ Note that for the purposes of this analysis the use of “short term” as <2 years is not the same as the use of “short term (acute)” when applied to numeric water quality criteria for determining thresholds of aquatic life toxicity (i.e., 24-hr or 96-hr exposure periods).

analyses conducted in the Klamath Facilities Removal EIS/EIR because individual existing numeric model captures all of the long-term water quality conditions anticipated for and encompassed by the Proposed Action and the remaining alternatives.

3.2.4.1.1 Water Temperature

Short-term (<2 years following dam removal/construction of fish passage facilities) effects of the alternatives on water temperature are assessed based on the existing conditions understanding of the seasonal effects of the KHP reservoirs on water temperature within the Hydroelectric Reach and downstream from the dam.

For long-term (2–50 years following dam removal/construction of fish passage facilities) effects of the alternatives, quantitative Klamath River water quality model (KRWQM) results for “current conditions” and dams-out conditions are available (PacifiCorp 2004a, Dunsmoor and Huntington 2006, FERC 2007; see Appendix D for more detail), but they do not include implementation of the Oregon and California TMDLs, which are considered as reasonably foreseeable actions under the No Action/No Project Alternative (see above list). The Klamath TMDL model includes a dams-in scenario (T4BSRN) (Tetra Tech 2009), similar to the conditions for the No Action/No Project Alternative. The Klamath TMDL model T1BSR natural conditions scenario is also useful for analyzing water temperature, since this parameter relies upon a comparison to background or natural levels for regulatory water quality compliance. The Klamath TMDL TOD2RN and TCD2RN scenarios assume the removal of the Four Facilities and full TMDL implementation (Tetra Tech 2009), which is similar to the Proposed Action; to place the Proposed Action analysis in context, results of these modeling scenarios are generally interpreted in this EIS/EIR with respect to starting assumptions (i.e., model boundary conditions) about water temperature. One boundary condition that differs from the Proposed Action is that, in the T1BSR, TOD2RN, and TCD2RN scenarios (but not T4BSRN), Keno Dam is replaced by the historical natural Keno Reef, such that the Keno Reach is still partially impounded even though the reef’s elevation is two feet lower than the current full pool elevation of Keno Impoundment/Lake Ewauna (Tetra Tech 2009, Kirk et al. 2010).

Since the TMDL model scenarios do not include climate change projections or changes in future hydrology included under KBRA, one additional set of water temperature modeling results is used for the Klamath Facilities Removal EIS/EIR analysis; the RBM10 model was developed as part of the Secretarial Determination studies and includes the effects of climate change and KBRA hydrology on future water temperatures (Perry et al. 2011). RBM10 model results use climate change predictions from five Global Circulation Models (GCMs) (see Appendix D for more detail).

Appendix D, Table D-1 shows the reaches where KRWQM, Klamath TMDL, and RBM10 model results are used for the water quality analysis under each alternative. Since no one existing model captures all of the elements analyzed for water temperature in this Klamath Facilities Removal EIS/EIR, where possible, model outputs are used in combination to assess similar spatial and temporal trends in predicted water temperature.

3.2.4.1.2 Suspended Sediments

The Proposed Action was optimally developed as an alternative that allows reservoir drawdown to occur during winter months when precipitation, river flows, and turbidity are naturally highest. Results from the sediment mobility analysis conducted by Reclamation are used to provide estimates of short-term (<2 years following dam removal) suspended sediment concentrations (SSCs⁵) downstream from Iron Gate Dam under the Proposed Action and other dam removal alternatives. The sediment mobility analysis used existing suspended sediment data collected by the U. S. Geological Survey (USGS) at the Shasta River near the City of Yreka (USGS gage no. 11517500), Klamath River near Orleans (USGS gage no. 11523000), and Klamath River near Klamath (USGS gage no. 11530500) gages to estimate daily total SSCs (mg/L) as a function of flow (cfs) using the SRH-1D sediment transport model (Sedimentation and River Hydraulics–One Dimension Version 2.4) (Huang and Greimann 2010, Reclamation 2012). Daily total SSCs were modeled for existing conditions representing WY 1961–2008 (“background”) and for short-term conditions following dam removal (WY 2020–2021). SRH-1D model output representing total sediments, including both inorganic (i.e., mineral) and organic (e.g., algal-derived) sediments, is applied herein to the suspended sediment analysis. The SRH-1D model assumes a three-phase drawdown for Copco 1 Reservoir beginning on November 1, 2019, and a single-phase drawdown for J.C. Boyle and Iron Gate Reservoirs beginning on January 1, 2020 consistent with the Proposed Action. This would allow maximum SSCs to occur during winter months when flows are naturally high in the mainstem river (Stillwater Sciences 2008, Reclamation 2012). The analysis of short-term (<2 years following dam removal) effects also considers results from previous studies (e.g., Stillwater Sciences 2010) regarding anticipated sediment release from Klamath River Dam removal within the context of sediment delivery at the basin scale.

To inform long-term (2–50 years following dam removal/construction of fish passage facilities) effects determinations on suspended materials under all of the alternatives, existing data sources for TSS and turbidity sources to the Hydroelectric Reach and the Lower Klamath River (e.g., PacifiCorp 2004a, 2004b; YTEP 2005) are used. Existing analyses of the potential effects of dam removal on long-term sediment supply (Stillwater Sciences 2010) are also considered.

3.2.4.1.3 Nutrients

Under the Proposed Action, short-term (<2 years following dam removal) nutrient loads associated with high SSCs are assessed in a qualitative manner, considering the likelihood of sediment deposition in the lower river, seasonal rates of primary productivity and microbially mediated nutrient cycling, and potential light limitation of primary producers given the high sediment concentrations in the river.

To determine general long-term spatial and temporal trends of nutrients in the Hydroelectric Reach and the Lower Klamath River under all of the alternatives, results

⁵ For the purposes of this report, SSC is considered equivalent to TSS. As needed, data from multiple sources reported as either TSS or SSC are used interchangeably, despite potential differences in the numeric values reported by each method (Gray et al. 2000).

of the T4BSRN, TOD2RN and TCD2RN Klamath TMDL scenarios (Tetra Tech 2009) are presented. To place the Proposed Action analysis in context, results of the TOD2RN and TCD2RN scenarios are generally interpreted with respect to starting assumptions (i.e., model boundary conditions) about nutrient concentrations. Reaches where T4BSRN, TOD2RN and TCD2RN information is available include all reaches associated with the EIS/EIR nutrient analysis from J.C. Boyle Reservoir to the Klamath Estuary (see Appendix D, Table D-1).

Additionally, an existing analysis regarding potential nutrient dynamics under a “dams-out” scenario (i.e., Asarian et al. 2010) is used to inform the assessment of the long-term effects of the Proposed Action on nutrients. Using nutrient measurements and hydrologic data for the Klamath River, Asarian et al. (2010) constructed mass-balance nutrient budgets to evaluate nutrient dynamics in free-flowing reaches of the Klamath River, including longitudinal trends in absolute and relative retention of phosphorus and nitrogen. The analysis also compared nutrient retention rates between free-flowing river reaches and reservoir reaches and developed a range of estimates for the degree to which seasonal TP and TN concentrations downstream from Iron Gate Dam might be altered by dam removal. The analysis used hydrologic and nutrient data collected by a variety of tribal, Federal, and State agencies, and PacifiCorp, during June-October of 2005–2008. The mass balance estimates for 2005–2008 improve upon estimates for the period 1998–2002 (Asarian and Kann 2006a) by using flow- and season-based multiple regression models for predicting daily nutrient concentrations and loads and quantification of uncertainty, relatively lower laboratory reporting limits, higher sampling frequency, and nutrient speciation (i.e., not just TN and TP). The mass balance also uses improved accounting for peaking flows in the J.C. Boyle Bypass Reach and their effect on retention times and mixing dynamics in Copco 1 Reservoir. The effects of dam removal were quantified using calculated relative retention rates in river reaches and comparing them to results from a retention study of Copco 1 and Iron Gate Reservoirs by Asarian et al. (2009).

3.2.4.1.4 Dissolved Oxygen

Both short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2-50 years following dam removal/construction of fish passage facilities) dissolved oxygen effects due to the alternatives are analyzed. For short-term effects under the Proposed Action and dam removal alternatives, results of numerical modeling conducted by the Lead Agencies as part of the Klamath Dam Removal Secretarial Determination studies are used to describe predicted short-term dissolved oxygen levels in the Hydroelectric Reach and downstream from Iron Gate Dam due to oxygen demand from mobilized reservoir sediments during dam removal. In the 1-dimensional, steady-state model, the different short-term oxygen demand parameters (i.e., BOD, immediate oxygen demand [IOD], and sediment oxygen demand [SOD]) are off-set by tributary dilution and re-aeration using an approach similar in concept to Streeter and Phelps (1925) dissolved oxygen-sag. This BOD/IOD spreadsheet model also includes chemical oxygen demand generated from the conversion of ammonium and other nitrogenous

compounds in reservoir sediments to nitrate under oxic conditions. This is termed nitrogenous oxygen demand and is inherently included in the oxygen demand rate constants used in the BOD/IOD spreadsheet model (Stillwater Sciences 2011).

IOD and BOD are predicted in the spreadsheet model using empirically derived oxygen depletion rates for a particular SSC based on laboratory incubations conducted under the Secretarial Determination oxygen demand study (Stillwater Sciences 2011). Oxygen depletion rates are scaled to the level of suspended sediments expected under each of the three water year types considered for the Reclamation hydrology and sediment transport modeling assessment (i.e., typical dry, median, and typical wet water years) (see Section 3.2.4.1).

The BOD/IOD spreadsheet model assumes a three-phase drawdown for Copco 1 Reservoir beginning on November 1, 2019, and a single-phase drawdown for J.C. Boyle and Iron Gate Reservoirs beginning on January 1, 2020 consistent with the Proposed Action (Reclamation 2012). This would allow maximum SSCs to occur during winter months when flows are naturally high in the mainstem river (Stillwater Sciences 2008, Reclamation 2012). While the KHP reservoirs exhibit varying degrees of thermal stratification and hypolimnetic anoxia during summer months (see Section 3.2.3.1), all of the reservoirs tend to experience fully-mixed conditions by November/December and remain mixed through April/May. Thus, drawdown beginning in December is expected to involve a well-oxygenated water column and inflowing water and, potentially, an oxic surficial sediment layer. This is important because the spreadsheet model is highly sensitive to background concentrations of dissolved oxygen (Stillwater Sciences 2011), which are generally highest in the KHP reservoirs during winter months (see Section 3.2.3.1). The BOD/IOD spreadsheet model results encompass a 6-month period following drawdown in order to estimate potential dissolved oxygen minimums corresponding to the period of greatest sediment transport in the river under the Proposed Action.

For long-term (2–50 years following dam removal/construction of fish passage facilities) effects, existing information on water quality dynamics and physical, chemical, and biological drivers for dissolved oxygen in the river are used to inform the effects determination for all of the alternatives. Dissolved oxygen model results from PacifiCorp relicensing efforts (FERC 2007) and the California Klamath River TMDL (NCRWQCB 2010a; see Section 3.2.2.7.4) are also used for the long-term effects analysis. Where possible, the Klamath TMDL model output is used in combination with KRWQM output to assess similar spatial and temporal trends in predicted dissolved oxygen. To place the Proposed Action analysis in the context, the TOD2RN and TCD2RN model predictions (Tetra Tech 2009) are interpreted with respect to starting assumptions (i.e., model boundary conditions) about dissolved oxygen (and nutrient) concentrations. Reaches where T4BSRN, TOD2RN and TCD2RN information is available include all reaches associated with the EIS/EIR dissolved oxygen analysis from J.C. Boyle Reservoir to the Klamath Estuary (see Appendix D, Table D-1).

3.2.4.1.5 pH

Short-term (<2 years following dam removal/construction of fish passage facilities) effects of the alternatives on pH are assessed based on the existing conditions understanding of the seasonal effects of the KHP reservoirs on pH within the Hydroelectric Reach and downstream from the dam.

For long-term (2–50 years following dam removal/construction of fish passage facilities) effects, existing data on pH in the Hydroelectric Reach and the Lower Klamath Basin are used to inform the effects determination for the Proposed Action. As for water temperature, nutrients, and dissolved oxygen, T4BSRN, TOD2RN and TCD2RN Klamath TMDL scenarios (Tetra Tech 2009) are available for pH. Reaches where T4BSRN, TOD2RN and TCD2RN information is available include all reaches associated with the EIS/EIR pH analysis from J.C. Boyle Reservoir to the Klamath Estuary (see Appendix D, Table D-1).

3.2.4.1.6 *Chlorophyll-a* and Algal Toxins

Effects of the alternatives on the algal community (phytoplankton, aquatic macrophytes, riverine phytoplankton and periphyton) in the Klamath River are discussed in Section 3.4, Algae. *Chlorophyll-a* is analyzed as a separate water quality parameter in the Klamath Facilities Removal EIS/EIR because it is a surrogate measure of algal biomass and it is included as a numeric criterion associated with the Oregon nuisance algae growth water quality objective (see Table 3.2-3) and a target specific to the KHP reservoirs in the California Klamath River TMDLs (NCRWQCB 2010a). The Hoopa Valley Tribe water quality objective for *chlorophyll-a* is a measure of attached (benthic) algal growth (see Table 3.2-6) and is discussed further in Section 3.4, Algae.

Quantitative predictive tools for *chlorophyll-a* are not available for the alternatives. While the California Klamath TMDLs model includes a *chlorophyll-a* component, covering both periphyton and phytoplankton, the model appears to over predict *chlorophyll-a* under the “dams out” scenario (Tetra Tech 2008) and is therefore not used for the Klamath Facilities Removal EIS/EIR analysis. The *chlorophyll-a* target (10 ug/L) developed for the KHP reservoirs in the California Klamath TMDLs is based on a Nutrient Numeric Endpoints (NNE) analysis, which appears to be a conservative estimate of mean summer *chlorophyll-a* concentrations required to move the system toward support of beneficial uses (Creager et al. 2006, Tetra Tech 2008).

The *chlorophyll-a* effects determinations are based on a qualitative assessment of whether the alternatives would result in exceedances of the Oregon 15 ug/L water quality objective or the California 10 ug/L target for the KHP reservoirs and adversely affect beneficial uses with respect to water column concentrations of *chlorophyll-a*. Growth conditions for suspended algae (i.e., nutrient availability, impounded water) are considered as part of the qualitative analysis, where predicted changes in nutrient availability, water temperatures, and the availability of lacustrine (lake or reservoir) conditions would correspondingly affect *chlorophyll-a* concentrations.

Since algal toxins are a water quality concern and have the potential to affect designated beneficial uses of water, an analysis of project effects on algal toxins as related to water quality standards and beneficial uses is included in the water quality effects determinations. There are no quantitative models predicting algal toxin trends under a dam removal scenario, thus the effects determinations are based upon trends in the density of *M. aeruginosa* (or other toxin-producing blue-green algae) to algal toxin concentrations (see Section 3.2.3.7) discerned from data collected in the Hydroelectric Reach and the Lower Klamath Basin. This information is considered along with the potential for changes in habitat availability for *M. aeruginosa* (or other toxin-producing blue-green algae) under the alternatives.

3.2.4.1.7 Inorganic and Organic Contaminants

The determination of potential toxicity and bioaccumulation with respect to aquatic species and humans under the alternatives is based on the evaluation of existing data on inorganic and organic contaminants associated with both reservoir water quality and sediment deposits, as well as new sediment contaminant data collected as part of the ongoing Secretarial Determination studies.

The Secretarial Determination sediment evaluation process has followed screening protocols of the SEF for the Pacific Northwest, issued in 2009 by the interagency Regional Sediment Evaluation Team (RSET). The SEF is a regional guidance document that provides a framework for the assessment and characterization of freshwater and marine sediments in Idaho, Oregon, and Washington (RSET 2009). The SEF involves a data screening assessment to compare reservoir sediment data to available and appropriate sediment maximum levels, screening levels, and bioaccumulation triggers. It also provides guidance for conducting elutriate chemistry, toxicity bioassays, and bioaccumulation tests, and special evaluations such as tissue analysis and risk assessments (the latter not utilized for this evaluation). The results of the SEF-based evaluation for the 2009–2010 Klamath River sediment samples are used primarily to inform the water quality effects determinations related to inorganic and organic contaminants under the Proposed Action.

To systematically consider potential impact pathways for each of the alternatives for the Secretarial Determination process, sediment data were compared to established sediment screening values in a step-wise manner. Elutriate (sediment pore water) data were also evaluated through comparison with a suite of regional, State and Federal standards for water quality; the comparison is first performed without consideration of dilution as a conservative approach (CDM 2011).

Biological testing was also conducted, using the SEF approach, and consisted of sediment and elutriate toxicity testing and tissue analyses, or other special evaluations designed to provide more empirical evidence regarding the potential for sediment contaminant loads to have adverse effects on receptors (RSET 2009). While whole sediment toxicity tests identify potential contamination that may affect bottom-dwelling (benthic) organisms, toxicity tests using suspension/elutriates of dredged material assess potential water column toxicity. Bioaccumulation evaluation is undertaken when bioaccumulative

chemicals of concern exceed or may exceed sediment screening levels, and thus further evaluation is needed to determine whether they pose a potential risk to human health or ecological health in the aquatic environment (RSET 2009).

Results from elutriate and sediment toxicity bioassays and sediment bioaccumulation tests carried out for the Secretarial Determination studies are used to provide additional information beyond simple comparisons of sediment contaminant levels to individual-contaminant regional or national screening levels. The results of sediment and elutriate toxicity bioassays provide a direct assessment of potential toxicity that takes into account possible interactive effects of mixtures of multiple contaminants, and of potential contaminants that may be present but were not individually measured.

3.2.4.2 Significance Criteria

Significance criteria to be used for the determination of impacts on beneficial uses of water and water quality are listed below. These criteria are excerpted from the list of ten significance criteria generally applicable to hydrology and water quality environmental factors for proposed projects in California (Appendix E in California Resources Agency [2010]). The criteria also encompass elements of Oregon and California water quality standards.

Effects on beneficial uses of water and water quality will be considered significant if the Proposed Action or alternatives would do any of the following:

- Result in regular exceedances of water quality standards or waste discharge requirements.
- Result in substantial adverse effects on beneficial uses of water.

For the purposes of this EIS/EIR, substantial is defined as “of considerable importance to water quality and the support of beneficial uses”. “Substantial adverse effects” are intended to correspond to water quality parameters that are included on the CWA Section 303(d) list (see Table 3.2-8) because if a parameter is listed, it has already been determined that beneficial uses are not supported due to regular exceedances of established numeric standards or water quality objectives. Substantial adverse effects can also apply to water quality parameters that would experience degradation within the EIS/EIR short-term time from of less than 2 years.

Additional criteria related to groundwater and hydrology (i.e., drainage, runoff, stormwater, flooding, and inundation) will be addressed in Section 3.6, Flood Hydrology or Section 3.7, Groundwater.

3.2.4.2.1 Thresholds of Significance for Numeric Standards or Water Quality Objectives

Thresholds of significance for established numeric standards and water quality objectives are the numeric values themselves. The numeric values for Oregon, California, Hoopa Valley Tribe, and the Ocean Plan are presented in Tables 3.2-3 through 3.2-7.

Numeric values presented in Tables 3.2-3 through 3.2-7 are used as thresholds of significance for water temperature, dissolved oxygen, and pH. Other numeric values presented in Tables 3.2-3 through 3.2-7, including Oregon and California turbidity standards, California nitrate and nitrite standards for the support of municipal beneficial uses, the Hoopa Valley Tribe criterion for chlorophyll-*a* as periphyton, and the Hoopa Valley Tribe ammonia and nitrate standards for the support of cold freshwater habitat and municipal beneficial uses, are not used as thresholds of significance. The reasons for not using these numeric standards in the water quality effects determinations are discussed below, by parameter.

3.2.4.2.2 Thresholds of Significance for Narrative Standards or Water Quality Objectives

Suspended Sediments

Oregon has a numeric turbidity standard based upon increases relative to background levels (see Table 3.2-3), and California's water quality objective for turbidity is based upon increases relative to natural conditions (see Table 3.2-4). Turbidity levels under natural conditions are not readily available in the Klamath River data record. While a relationship between turbidity and suspended sediment can be developed on a watershed-specific basis, seasonal coincident suspended sediment and turbidity data for the Klamath Basin are not currently sufficient, either temporally or spatially, to develop a robust relationship between these two parameters for either background levels or natural conditions levels (Stillwater Sciences 2009). For these reasons, the established numeric water quality objectives for turbidity in Oregon and California are not used for the water quality effects determination; instead, the narrative sediment water quality objectives are applied to the analysis.

California's North Coast Basin Plan water quality objectives for suspended material, settleable material, and sediment are narrative and require that waters do not contain concentrations that cause nuisance or adversely affect beneficial uses (see Table 3.2-4). While the Klamath River has multiple designated beneficial uses (see Table 3.2-2), the use most sensitive to water quality is the cold freshwater habitat (COLD) associated with salmonids (NCRWQCB 2010a). In order to adequately protect this use from *short-term* (<2 years following dam removal) effects of the Proposed Action, the water quality effects determination methods focus on the suspended material water quality objective and rely upon the extensive sediment transport modeling effort undertaken for the Secretarial Determination process to quantify predicted SSCs for 1 to 2 years following dam removal (see Section 3.2.4.1). An alternative "dose-response" approach to developing a numeric suspended sediments threshold of significance for potential short-term effects has been adopted, as detailed in Appendix D, Section D.2. Based on this

approach, the water quality effects determination uses a predicted suspended sediment value of 30 mg/L over a 4-week exposure period as a general threshold of significance for analyzing the *short-term* effects of the alternatives.

A more detailed analysis of suspended sediment effects on key fish species, including consideration of specific life history stages, SSCs, and exposure period, is required for a comprehensive assessment of the impacts of the alternatives on the cold water designated beneficial use. This level of analysis is presented in Section 3.3, Aquatic Resources and appendices to this section. Further discussion of particular effects of suspended sediment on shellfish and estuarine and marine organisms is also presented in Section 3.3.4.3, Aquatic Resources.

Nutrients

Oregon does not stipulate numeric nutrient water quality standards (see Table 3.2-3). California has a narrative water quality objective for biostimulatory substances and does not stipulate numeric nutrient water quality standards for the cold water habitat beneficial use (see Table 3.2-4). California does have numeric nitrate and nitrite standards for the support of municipal beneficial uses (i.e., drinking water). However, these standards are much higher than concentrations that have been measured in the Klamath Basin, such that there is no indication that the municipal beneficial use is not being met or would not be met in the future. Hoopa Valley Tribe also has a nitrate standard for municipal beneficial uses, which is similarly high.

The California Klamath River TMDLs provide the numeric interpretation of the narrative biostimulatory substances objective for the Klamath River through numeric targets for nutrients, organic matter, chlorophyll-*a*, *M. aeruginosa* and microcystin. The numeric TMDL targets for nutrients (TP and TN) and organic matter (as carbonaceous biochemical oxygen demand [CBOD]) vary by month are established for the tailraces of Copco 2 and Iron Gate Dams. The numeric TP targets range 0.023–0.029 mg/L for May–October and 0.024–0.030 mg/L for November–April. The numeric TN targets range 0.252–0.372 mg/L for May–October and 0.304–0.395 mg/L for November–April (NCRWQCB 2010a). These targets are based on the T4BSRN scenario (Appendix D, Section D-1) and are established as the monthly mean concentrations that allow achievement of the in-reservoir chlorophyll-*a* summer mean target of 10 µg/L, the *M. aeruginosa* cell density target of 20,000 cells/mL, and the microcystin target of 4 µg/L (NCRWQCB 2010a).

For multiple locations in the Klamath River, the TMDL model results indicate large daily variability in TP and TN that exceeds the small range in the monthly TMDL targets, particularly during summer and early fall (i.e., generally June–October) (Tetra Tech 2009). Therefore, the nutrient effects analysis as part of the TMDL considers whether a general downward (or upward) trend in TP and TN toward (or away from) the numeric targets would occur and, qualitatively, whether such a trend would support or alleviate the growth of nuisance and/or noxious phytoplankton or nuisance periphyton.

Chlorophyll-*a* and Algal Toxins

Within the area of analysis, Oregon possesses a numeric criterion for chlorophyll-*a* that is associated with the nuisance algae growth water quality objective and applies to natural lakes that do not thermally stratify, reservoirs, rivers, and estuaries (see Table 3.2-3). The Klamath River TMDLs establish a chlorophyll-*a* target specific to the KHP of 10 µg/L during the growth season, based on a NNE analysis (NCRWQCB 2010a). The Hoopa Valley Tribe has a chlorophyll-*a* criterion (150 mg/m²; see Table 3.2-6) for their periphyton density water quality objective, which is applicable to a short reach (≈RM 45–46) of the Klamath River upstream of the Trinity River. However, since effects of the Proposed Action on periphyton growth are addressed in Section 3.4, Algae, chlorophyll-*a* as a measure of periphyton density is not discussed further in the water quality effects analysis.

The Oregon criterion (15 µg/L) and the California TMDL target (10 µg/L) are used as chlorophyll-*a* thresholds of significance for J.C. Boyle Reservoir and Copco 1 and Iron Gate reservoirs, respectively. Anticipated regular exceedances of these thresholds would constitute a significant impact for this analysis.

For algal toxins, both Oregon and California have narrative water quality objectives for general toxicity (see Table 3.2-3 and 3.2-4). The Hoopa Valley Tribe has numeric objectives for algal toxins (see Table 3.2-6). The WHO has set numeric thresholds for recreational exposures of microcystin toxin at 4 µg/L for a low probability of adverse health effects, and 20 µg/L for a moderate probability of adverse health effects (Falconer et al. 1999, Chorus and Cavalieri 2000). The WHO thresholds are general levels representing a variety of toxigenic cyanobacteria. Oregon has adopted public health guidelines for recreational exposures similar to the WHO values, and California uses the *Draft Voluntary Statewide Guidance for Blue-Green Algae Blooms* (SWRCB et al. 2010) developed jointly by the California Department of Public Health, SWRCB and OEHHA. To avoid conditions that lead to water quality impairments, the California Klamath River TMDLs use the WHO low probability of adverse health effects thresholds as targets specific to the California reaches of the KHP for *M. aeruginosa* and microcystin toxin (see Table 3.2-10).

Since it is common to Oregon, California, and the Hoopa Valley Tribe (see Table 3.2-10), the < 8 µg/L criterion for microcystin in recreational water is used as the threshold of significance for this Klamath Facilities Removal EIS/EIR. As is the case with chlorophyll-*a*, quantitative predictive tools for algal toxins are not available for the Proposed Action. Therefore, the algal toxin effects determinations are based on a qualitative assessment of whether the Proposed Action would result in exceedances of the criterion and adversely affect the human health recreational beneficial uses (REC-1, REC-2; Table 3.2-2). Growth conditions for toxigenic suspended algae (i.e., nutrient availability, impounded water) are considered as part of the qualitative analysis, where predicted changes in nutrient availability, water temperatures, and the availability of lacustrine (lake or reservoir) conditions would correspondingly affect algal toxin concentrations.

Table 3.2-10. Summary of Water Quality Guidance, Criteria, or Targets for Toxigenic Blue-Green Algae and Algal Toxins in the Area of Analysis

Source	Description
Oregon ¹	
Public health guidelines for recreational exposure	40,000 cells/mL <i>M. aeruginosa</i> , or 8 µg/L microcystin
California ²	
Draft Voluntary Statewide Guidance for Blue-Green Algae Blooms	>100,000 cells/mL potentially toxigenic blue-green algae, or 40,000 cells/mL <i>M. aeruginosa</i> , or 8 µg/L microcystin
California Klamath River TMDL ³	
Chl-a target for California KHP reservoirs (growth season)	< 20,000 cells/L <i>M. aeruginosa</i> , or < 4 µg/L microcystin
Hoopa Valley Tribe ⁴	
<i>Microcystis aeruginosa</i> cell density	<5,000 cells/mL for drinking water <40,000 cells/mL for recreational water
Microcystin toxin Concentration	<1µg/L total microcystin for drinking water <8 µg/L total microcystin for recreational water
Total potentially toxigenic cyanobacteria species ⁵	<100,000 cells/mL for recreational water

¹ ODEQ (2011): At these levels, water is considered impaired.

² SWRCB et al. (2010): At these levels, water is considered impaired.

³ NCRWQCB (2010a): These targets are set to avoid conditions that could lead to water quality impairments.

⁴ HVTEPA (2008): At these levels, water is considered impaired.

⁵ Includes: *Anabaena*, *Microcystis*, *Planktothrix*, *Nostoc*, *Coelosphaerium*, *Anabaenopsis*, *Aphanizomenon*, *Gloeotrichia*, and *Oscillatoria*.

Inorganic and Organic Contaminants

Both Oregon and California have water quality objectives related to inorganic and organic contaminants. Oregon’s toxicity objective has both a narrative and a numeric component (see Table 3.2-3); the numeric component has chemical-specific water-column criteria for freshwater and marine aquatic life and human health (CDM 2011). Oregon’s numeric marine aquatic life criteria are not considered further because the Proposed Action would not affect the marine environment in Oregon. California’s chemical constituents objective is numeric (listed in the Basin Plan [NCRWQCB 2011], as noted in Table 3.2-4 and has chemical-specific water-column criteria for freshwater and marine aquatic life and human health, including bioaccumulative chemicals such as PCBs, methylmercury, dioxins, and furans (CDM 2011). California’s toxicity and pesticides objectives are narrative (see Table 3.2-4). Hoopa Valley also has an ammonia toxicity objective based on pH and temperature (see Table 3.2-6). However, since available data collected to date suggests no actual ammonia toxicity events associated with the operation of the Four Facilities (NCRWQCB 2010a), and because the increased

velocity of stream flow in the Hydroelectric Reach under dam removal would increase nitrification (i.e., oxidation of ammonia), thus minimizing the potential for ammonia toxicity, this objective is not considered further.

Thresholds of significance for the Oregon and California narrative water quality objectives focus on designated beneficial uses and are applicable for contaminants in either the water column or the sediments. For this Klamath Facilities Removal EIS/EIR, establishment of toxicity and/or bioaccumulative potential for sediment contaminants relies upon thresholds developed through regional and State efforts such as the SEF for the Pacific Northwest (Appendix D, Section D.3). The SEF includes bulk sediment screening levels for standard chemicals of concern and chemicals of special occurrence in marine and freshwater sediments for Idaho, Oregon, and Washington (RSET 2009). Additionally, Oregon has developed bioaccumulation screening level values that are used for this Klamath Facilities Removal EIS/EIR analysis. Similar numeric chemical guidelines for the assessment and characterization of freshwater and marine sediments do not exist for California. Additional information regarding applicable sediment screening levels used for the Secretarial Determination sediment evaluation process is presented in CDM (2011).

Impacts on water quality would be considered significant if results of sediment and elutriate chemical analyses and biological testing indicate that at least one chemical is detected at a level with potential for significant adverse effects based on multiple lines of evidence (CDM 2011). This evaluation is not intended to be equivalent to the SEF process.

3.2.4.3 Effects Determinations

3.2.4.3.1 Alternative 1: No Action/No Project Alternative

Under this Alternative, the Klamath Hydroelectric Project would continue current operations under the terms of an annual license until a long-term license is finalized. Some restoration actions have already been initiated and would continue under the No Action alternative. These include the Williamson River Delta Project, the Agency Lake and Barnes Ranch Project, fish habitat restoration work, and ongoing climate change assessments. The TMDLs would still be implemented under this and all other alternatives as they are an unrelated regulatory action. Hydroelectric operations would continue as they have been, providing peaking power generation during the summer as demand requires and conditions allow. The No Action/No Project Alternative would leave the Four Facilities in place. In the Upper Klamath Basin, operation of the Four Facilities would only affect water quality in the Hydroelectric Reach; however, resource management actions elsewhere in the Upper Klamath Basin (i.e., Upper Klamath Lake and tributaries) are also analyzed under this alternative because they would potentially affect water quality further downstream.

Water Temperature

Upper Klamath Basin

Continued impoundment of water at the Four Facilities could result in short-term and long-term seasonal water temperatures that are shifted from the natural thermal regime of the river and do not meet applicable ODEQ and California Basin Plan water quality objectives and adversely affect beneficial uses in the Hydroelectric Reach. Under existing conditions, water temperatures (measured as 7-day-average maximum values) in much of the reach from Keno Dam to the Oregon-California State line exceed 20°C (68°F) in June through August and result in non-attainment of the designated beneficial use (Redband or Lahonton cutthroat trout habitat, see Table 3.2-3). The exception to this occurs in the approximately 4-mile long J.C. Boyle Bypass Reach where cold groundwater springs enter the river at a relatively constant 11-12°C (Kirk et al. 2010) and combine with flow releases from J.C. Boyle Dam (i.e., 100 cubic feet per second minimum flow release; FERC [2007]). Due to the constant groundwater input and temperature moderation due to the upstream thermal mass of J.C. Boyle Reservoir, there is also reduced diel variation in water temperatures in the Bypass Reach. Just downstream, in the J.C. Boyle Peaking Reach, water temperatures vary on a diel basis due to powerhouse peaking flows. When peaking flows are not occurring, water in the Peaking Reach is dominated by cooler water from the upstream groundwater springs. When peaking flows from J.C. Boyle Reservoir enter the reach, water temperatures can increase by several degrees (PacifiCorp 2006b). Further downstream in the California portions of the Klamath River, summer MWMTs regularly exceed the range of chronic effects temperature thresholds (13–20°C [55.4–68°F]) for full salmonid support in California (NCRWQCB 2010a) and result in non-attainment of designated COLD and WARM beneficial uses (see Table 3.2-4)

Under the No Action/No Project Alternative, several ongoing resource management actions in the Upper Klamath Basin represent reasonably foreseeable actions related to water temperature within the period of analysis (50 years). Underway since 2007, the Williamson River Delta Project is intended to restore wetlands for endangered fish species and improve water quality in Upper Klamath Lake (see Section 2.3.1). Thus far, the project has involved breaching over two miles of agricultural levees along the Williamson River where it flows into Upper Klamath Lake, restoring approximately 3,500 acres of wetlands in 2007 and an additional 1,400 acres in 2008. One of the project goals is to create wetlands with warmer spring water temperatures for rearing fish in the wetlands (as compared to cooler temperatures in the Williamson River or Upper Klamath Lake). The Agency Lake and Barnes Ranches Project would use historically diked and drained portions of the Barnes Ranches as interim pumped water storage areas, ultimately reconnecting them to Agency Lake (see Section 2.3.1). Breaching the dikes would convert the current 63,770 acre feet pumped storage to passive storage in Upper Klamath Lake. Specific options still need to be developed and studied as part of a separate project-level National Environmental Policy Act (NEPA) evaluation and Endangered Species Act (ESA) consultation. At a programmatic level, these activities may improve springtime water temperatures for spawning and rearing of fish in Upper Klamath Lake

and tributaries to the lake. Additional resource management actions related to spring, summer, and fall water temperatures that are ongoing in tributaries to Upper Klamath Lake (see Section 2.3.1) include the following:

- Floodplain rehabilitation
- Large woody debris replacement
- Riparian vegetation planting
- Purchase of conservation easements and/or land

Although these resource management actions may improve water temperatures in the Upper Klamath Basin under the No Action/No Project Alternative, the effects would only be local and would not measurably improve water temperatures in the Hydroelectric Reach. These resource management actions are discussed again with respect to water quality effects under the KBRA (see Section 3.2.4.3, Full Facilities Removal of Four Dams - KBRA).

In Oregon, implementation measures focused on water temperature in the Upper Klamath Lake Drainage TMDL and those in the Upper Klamath River and Lost River Sub-basins TMDLs would improve water temperatures in the Hydroelectric Reach. The Oregon TMDLs include heat load allocations for anthropogenic and background nonpoint sources, where effective shade and channel morphology targets are used as surrogate measures for controlling nonpoint source temperature loading (see Section 3.2.2.4).

To support beneficial uses in California, the North Coast Basin Plan stipulates that water temperature cannot be increased by more than 2.8°C (5°F) above natural receiving temperatures (see Table 3.2-4). The NCRWQCB has determined that natural receiving water temperatures in the Klamath River are already too warm to support designated beneficial uses. Therefore, the Klamath TMDL allocates a daily average (and daily maximum) increase in water temperatures of 0.5°C [0.9°F] for Copco 1 and 2 reservoir tailraces and 0.1°C [0.18°F] for the Iron Gate Reservoir tailrace. This allocation is designed to alleviate the late summer/fall 2–10°C (3.6–18°F) warming caused by the reservoirs immediately downstream from Iron Gate Dam under existing conditions (see Section 3.2.3.2). Additionally, a compliance lens in Copco 1 and Iron Gate Reservoirs must be maintained, such that water temperature and dissolved oxygen conditions would be suitable for cold water fish in the reservoirs during the critical summer period (see Section 3.2.2.4). To date, no Proposed Action has been identified by PacifiCorp to achieve the temperature allocations assigned to Copco 1 and Iron Gate reservoirs.

The Klamath TMDL model (see Appendix D) indicates that under the No Action/No Project Alternative (similar to the TMDL T4BSRN scenario) water temperatures in the reach from Link River Dam to just upstream of J.C. Boyle Reservoir (including Keno Impoundment/Lake Ewauna and in the Hydroelectric Reach) would be very similar to modeled natural conditions temperatures (TMDL T1BSR scenario) (NCRWQCB 2010a). While the Klamath TMDL model output also indicates that natural conditions would exceed the 20°C (68°F) numeric water quality objective for the support of Redband and Lahonton cutthroat trout in Oregon during June–August (see Table 3.2-3), the narrative

Oregon standard stipulates that the natural conditions criterion would supersede the numeric criterion. Thus, assuming eventual full attainment of the Oregon and California TMDLs, water temperature objectives in the Klamath Hydropower Reach can be met; however, the timeframes for achieving water temperature allocations required under the TMDLs will depend on the measures taken to improve water quality conditions. Full attainment could require decades to achieve.

The TMDL models do not address the potential effects of global climate change on water temperatures in the Klamath Basin (Appendix D). Within the period of analysis (i.e., 50 years), climate change models for the region suggest that as the western United States warms, air temperatures will increase, there will be a slight increase in overall precipitation, winter snowfall will likely shift to higher elevations, and snowpack will be diminished as more precipitation falls as rain (Oregon Climate Change Research Institute [OCCRI] 2010; see also Section 3.10.3.1). For the Sprague River watershed, increased flooding earlier in the spring and decreased summer baseflow would occur as a consequence of increased and decreased proportions of rainfall and snowfall, respectively, given climate change projections (Risley 2010). Bartholow (2005) predicted that in the Klamath Basin as a whole, increasing air temperatures and decreasing flows in the summer months would be expected to cause general increases in summer and fall water temperatures on the order of 2–3°C (3.6–5.4°F) (see also discussion under Lower Klamath Basin).

As part of the Klamath Dam Removal Secretarial Determination studies, the effects of climate change were included in model projections for future water temperatures under the No Action/No Project Alternative and the Proposed Action. RBM10 model results using climate change predictions from five GCMs indicate that future water temperatures under the No Action/No Project Alternative (where simulated flows are subject to the 2010 Biological Opinion mandatory flow regime [NOAA Fisheries Service 2010]) would be 1–2.3°C (1.8–4.1°F) warmer than historical temperatures in the Klamath Basin (Perry et al. 2011). While this temperature range is slightly lower than that suggested using the Bartholow (2005) historical estimates, within the general uncertainty of climate change projections, the two modeling efforts correspond reasonably well and indicate that water temperatures in the Upper Klamath Basin are expected to increase within the period of analysis on the order of 1–3°C (1.8–5.4°F).

The anticipated increases in water temperatures due to climate change would also occur over a timescale of decades and would act in opposition to improvements expected from successful TMDL implementation throughout the Upper Klamath Basin. The magnitude of the opposition would be slightly less than, but within the general range of, late summer/fall improvements (2–10°C [3.6–18°F]) expected by the TMDLs immediately downstream from Iron Gate Dam (see discussion under Lower Klamath Basin), such that climate change would partially offset the anticipated TMDL-related improvements.

Existing late summer/fall water temperatures in the Hydroelectric Reach are adverse. Full attainment of the Oregon and California TMDLs (implementation mechanisms and timing unknown) would significantly improve conditions in the

Hydroelectric Reach, but climate change would partially offset TMDL-related improvements in the late summer/fall. Continued impoundment of water in the reservoirs at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Lower Klamath Basin

Continued impoundment of water at the Four Facilities could result in short-term and long-term seasonal water temperatures and diel temperature variation that are shifted from the natural thermal regime of the river and do not meet applicable California North Coast Basin Plan water quality objectives and adversely affect beneficial uses in the Klamath River downstream from Iron Gate Dam. Under existing conditions, the Four Facilities shift the natural thermal regime of the river by approximately 18 days by cooling springtime water temperatures 1–2.5°C (1.8–4.5°F) and warming late summer/fall water temperatures 2–10°C (3.6–18°F) in the Lower Klamath River, with the largest effects occurring just downstream from Iron Gate Dam (RM 190.1) (PacifiCorp 2004a, Bartholow 2005, Dunsmoor and Huntington 2006, NCRWQCB 2010a, Perry et al. 2011). The warming effect, which can be stressful to rearing salmonids, lasts for the majority of late summer and fall months and is of larger magnitude than the cooling effect in spring (PacifiCorp 2004a). Effects diminish with distance downstream such that they are not discernable downstream from the Salmon River (RM 66) (see Section 3.2.3.2). Summer MWMTs in the Klamath River downstream from Iron Gate Dam to the Salmon River regularly exceed the range of chronic effects temperature thresholds (13–20°C [55.4–68°F]) for full salmonid support in California (NCRWQCB 2010a) and result in non-attainment of designated COLD and WARM beneficial uses (see Table 3.2-4). Although not an effect of the reservoirs at the Four Facilities, MWMTs in the mainstem from the Salmon River to the Klamath Estuary also regularly exceed these thresholds and result in non-attainment of these beneficial uses (see Section 3.2.3.2 and Appendix C for more detail).

Reservoir thermal regimes also act to reduce the magnitude of diel temperature variation in the reservoir reaches and the riverine reaches immediately downstream from Iron Gate Reservoir (RM 190.1; see Section 3.2.4.3.2, Figure 3.2-5) (Deas and Orlob 1999, PacifiCorp 2005). As discussed in Section 3.3.4.3 Alternative 1: No Action/No Project, when average temperatures are high, diel variability provides salmonids opportunities for regenerative healing and foraging during the cool hours (NRC 2004). During these periods, decreased diel temperature variation in the Klamath River downstream from Iron Gate Dam is deleterious for salmonids. As with the seasonal temperature effect, the dampening influence of the reservoirs on diel temperature variation is considerably diminished farther downstream, at the confluence with the Scott River (RM 143.9; see Section 3.2.4.3.2, Figure 3.2-6). The KRWQM indicates that the temperature influence of the Hydroelectric Reach is mostly ameliorated by RM 66 at the confluence with the Salmon River (see Section 3.2.4.3.2, Figure 3.2-7).

Within the period of analysis (i.e., 50 years), implementation of NOAA Fisheries Service 2010 Biological Opinion mandatory flows and CDFG Code Section 5937 instream flow mandate for tributaries to the mainstem Klamath River (see Section 2.3.1 and Section

3.2.4.1, No Action/No Project Alternative) would increase seasonal stream flow and may result in minor increases in water temperatures in the Klamath River downstream from Iron Gate Dam during summer and fall months⁶. The California Klamath River TMDLs were developed based on compliance with water quality objectives at the Oregon-California State line, meaning that successful implementation of water quality improvement measures under the Oregon TMDLs will improve water temperatures in the Lower Klamath Basin as well. General implementation measures under the California Klamath TMDLs associated with water temperature improvements are described in the prior section for the Upper Klamath Basin and in Section 3.2.2.4. Additionally, the Shasta, Scott, and Salmon Rivers, tributaries to the Lower Klamath River within California, have TMDLs addressing temperature (see Section 3.2.2.4).

The Klamath TMDL model indicates that as implementation of the TMDL progresses under the No Action/No Project Alternative (similar to TMDL T4BSRN scenario), water temperatures from Iron Gate Dam (RM 190.1) to the Klamath Estuary (RM 0-2) would improve towards modeled natural conditions (similar to the TMDL T1BSR scenario) (NCRWQCB 2010a). Some delayed warming of springtime water temperatures (February-March) and delayed cooling of late summer/fall (August-November) water temperatures would still occur under the No Action/No Project Alternative due to the large thermal mass of Copco 1 and Iron Gate reservoirs. This temporal shift may continue to occur under the No Action/No Project Alternative from downstream from Iron Gate Dam to approximately the Salmon River (RM 66) because while full attainment of the California Klamath TMDLs would improve water temperature, the model is unable to demonstrate full temperature compliance in the spring and fall downstream from Iron Gate Dam to the Salmon River with the Four Facilities in place. The model-predicted lack of compliance from Iron Gate Dam to the Salmon River underlies the TMDL requirement for PacifiCorp to address water temperature and dissolved oxygen improvements (NCRWQCB 2010a). The timeframes for achieving water temperature allocations required under these TMDLs will depend on the measures taken to improve water quality conditions. It is anticipated that full attainment of the TMDLs would require decades to achieve.

The Klamath TMDL model also predicts that, with full implementation, reduced diel variation in water temperature would continue to occur under the No Action/No Project Alternative immediately downstream from Iron Gate Dam due to the thermal mass of the upstream reservoirs, with the magnitude of diel variation increasing with distance downstream from Iron Gate Dam as the river approaches equilibrium with ambient air temperatures (NCRWQCB 2010a, Dunsmoor and Huntington 2006). As discussed in Section 3.3.4.3 Alternative 1: No Action/No Project – Key Ecological Attributes – Water Temperature, the decrease in diel temperature variation compared with historical conditions in the Klamath River downstream from Iron Gate Dam is deleterious for

⁶ The effects of increased tributary flows on Lower Klamath River temperatures were evaluated as part of the analyses conducted for the California Klamath River TMDL development. The evaluation indicated little temperature effect on the Klamath River, and only when the tributaries were assumed to have full natural flows (see Section 4.2.4 of NCRWQCB 2010a).

salmonids. General climate change effects are discussed in Section 3.10.3.1. With respect to water temperatures in the Lower Klamath Basin, the historical data record indicates that mainstem water temperatures have increased approximately 0.05°C (0.09°F) per year between 1962 and 2001 (Bartholow 2005) such that climate change may already be affecting Klamath River water temperatures. Projecting the Bartholow (2005) estimate of an average annual temperature increase 50 years into the future, water temperatures would increase 2–3°C (3.6–5.4°F) by the end of the analysis period. As part of the Klamath Dam Removal Secretarial Determination studies, the effects of climate change were included in model projections for future water temperatures under the No Action/No Project Alternative and the Proposed Action. RBM10 model results using climate change predictions from five GCMs indicate that future water temperatures under the No Action/No Project Alternative (where simulated flows are subject to the 2010 Biological Opinion mandatory flow regime [NOAA Fisheries Service 2010]) would be 1–2.3 °C (1.8–4.1 °F) warmer than historical temperatures at the end of the analysis period (Perry et al. 2011). While this temperature range is slightly lower than that suggested using the Bartholow (2005) historical estimates, within the general uncertainty of climate change projections, the two projections correspond reasonably well. Considering together the available sources for climate change predictions, annual average water temperatures in the Lower Klamath Basin are expected to increase within the period of analysis on the order of 1–3 °C (1.8–5.4 °F).

The anticipated increases in water temperatures due to climate change would also occur over a timescale of decades and would act in opposition to improvements expected from successful TMDL implementation throughout the Lower Klamath Basin. Within the range of late summer/fall improvements expected by the TMDLs (2–10 °C [3.6–18 °F] immediately downstream from Iron Gate Dam and 2–5 °C [3.6–9 °F] just upstream of the Scott River), climate change would partially offset the anticipated TMDL-related improvements. Climate change would also completely offset the existing 1–2 °C springtime cooling effect of the reservoirs; see Section 3.3.4.3. Water Temperature for a discussion of the effect of the spring cooling on fish in the Lower Klamath River.

Existing late summer/fall water temperatures and reduced diel temperature variation in the Klamath River from immediately downstream from Iron Gate Dam to the Salmon River (RM 66) are adverse.⁷ Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly improve conditions but water temperatures from Iron Gate Dam to approximately Seiad Valley (RM 129.4) would remain adverse. Climate change would partially offset TMDL-related improvements in the late summer/fall. Continued impoundment of water in the reservoirs at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

⁷ Water temperatures from the Salmon River to the Klamath Estuary are also adverse but this condition is not a result of the impoundment of water in the reservoirs at the Four Facilities.

Suspended Sediments

Upper Klamath Basin

Continued impoundment of water at the Four Facilities could result in short-term and long-term interception and retention of mineral (inorganic) suspended material by the KHP dams. Under existing conditions, peak concentrations of mineral (inorganic) suspended material occur during winter and spring (November through April) due to runoff and tributary flows to the Hydroelectric Reach associated with high-flow events. The KHP dams mostly intercept and trap suspended materials (silts, clays with diameters < 0.063 mm) such that water column concentrations generally decrease with distance downstream in the Hydroelectric Reach (see Section 3.2.3.3 and Appendix C, Section C.2.1). Likewise, the reservoirs trap bedload or fluvial sediment (coarse sand, gravels, and larger materials with diameters > 0.063 mm) from the tributaries in the Hydroelectric Reach. While trapping of the suspended materials may be potentially beneficial for downstream reaches by decreasing TSS concentrations and turbidity, trapping of bedload may reduce habitat suitability below Iron Gate Dam for anadromous fish (see Section 3.3.3.3.2 Bedload for discussion of the effect of this trapping of bedload under existing conditions).

On the scale of the entire Klamath Basin, the trapping of fine sediments and suspended materials does not appear to be a critical function with respect to the overall cumulative sediment delivery including downstream tributaries (see also Section 3.11.3.3 for a discussion of basin sediment supply and transport), since a relatively small (3.4 percent) fraction of total sediment supplied to the Klamath River on an annual basis originates from the upper and middle Klamath River (i.e., from Keno Dam to the Shasta River) (see Section 3.2.3.3). Beneficial uses in the upper Klamath River are currently not impaired due to mineral (inorganic) suspended material (see Table 3.2-8).

Under the No Action/No Project Alternative, the ongoing Williamson River Delta Project and Agency Lake and Barnes Ranches Project would contribute to reduced mineral (inorganic) fine sediment inputs to Upper Klamath Lake. In the tributaries to Upper Klamath Lake, additional resource management actions for fish habitat restoration (see Section 2.4.2) related to mineral (inorganic) sediment are ongoing, including the following:

- Floodplain rehabilitation
- Large woody debris replacement
- Cattle exclusion [fencing]
- Riparian vegetation planting
- Mechanical thinning of upland areas and fire treatment
- Purchase of conservation easements/land
- Road decommissioning
- Reduction of fine sediment sources

These resource management actions are also discussed with respect to water quality effects under the KBRA (see Section 3.2.4.3, Full Facilities Removal of Four Dams - KBRA).

Anticipated climate change effects within the period of analysis (i.e., 50 years) include increased fine sediment delivery to streams due to more intense and frequent precipitation events and elevated stormwater runoff (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections). The anticipated increases would occur over a timescale of decades and may reduce anticipated improvements expected from successful implementation of the aforementioned resource management actions; however, the magnitude of the increased sediment delivery relative to the currently low levels of fine sediment production has not been assessed.

Existing interception and retention of mineral (inorganic) suspended material in the reservoirs in the Hydroelectric Reach is potentially beneficial. Continued impoundment of water at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Implementation of IM 7, J.C. Boyle Gravel Placement and/or Habitat Enhancement, could result in short-term (1 year) increases in mineral (inorganic) suspended material in the Hydroelectric Reach. Under this IM, suitable spawning gravel would be placed in the J.C. Boyle Bypass and Peaking reaches in the fall of 2011 using a passive approach before high flow periods, or to provide for other habitat enhancement in the Klamath River upstream of Copco 1 Reservoir. These actions would provide improvements in habitat quality for resident fish prior to dam removal, and for resident and anadromous species following dam removal (for effects on aquatic species, see Section 3.3.4.3.2.3). Work on IM 7 began in fall 2010 with the contracting, planning, and permitting phase. Passive gravel placement is specified by IM 7, which would avoid in-stream placement of gravel and would limit turbidity increases to periods of high river flow when turbidity is naturally elevated. Under the *No Action/No Project Alternative*, the duration of IM 7 would only be one year and the amount of gravel to be added is therefore limited. The potential for sediments to enter the water during gravel placement along the river banks can be minimized or eliminated downstream from the enhancement sites through the implementation of BMPs for construction activities (Appendix B) (BLM 2011). Any disturbed sediments would be trapped by Iron Gate Reservoir and not transferred downstream to the Klamath River, particularly given implementation of BMPs. **Under the *No Action/No Project Alternative*, the effect of IM 7, J.C. Boyle Gravel Placement and/or Habitat Enhancement, on SSCs in the Hydroelectric Reach would be a less-than-significant impact.**

Implementation of IM 8, J.C. Boyle Bypass Barrier Removal, could result in short-term increases in mineral (inorganic) suspended material in the Hydroelectric Reach due to deconstruction activities. Under this IM, the sidecast rock barrier located approximately three miles upstream of the J.C. Boyle Powerhouse in the J.C. Boyle Bypass Reach would be removed. The objective of IM 8 is to provide for the safe, timely, and effective upstream passage of Chinook and coho salmon, steelhead, Pacific lamprey, and redband

trout. The potential for sediments to enter the water during in-stream work associated with barrier removal and from construction site runoff could be minimized or eliminated through the implementation of BMPs for construction activities (Appendix B). Any disturbed sediments would be trapped by Copco 1 Reservoir and not transferred downstream to the Klamath River, particularly given implementation of BMPs. **Under the No Action/No Project Alternative, the effect of IM 8, J.C. Boyle Bypass Barrier Removal, on SSCs in the Hydroelectric Reach in the J.C. Boyle Bypass Reach would be a less-than-significant impact.**

Continued impoundment of water at the Four Facilities could result in short-term and long-term seasonal (April through October) increases in algal-derived (organic) suspended material in the Hydroelectric Reach due to in-situ algal blooms. Under existing conditions, episodic increases in suspended material occur in the KHP reservoirs during summer months as a result of *in-situ* algal productivity. These concentrations typically range 10–20 mg/L, but can be greater than 200 mg/L (see Section 3.2.3.3) and cause nuisance or adversely affect beneficial uses during intense blooms. While some settling of algal-derived (organic) suspended materials from Upper Klamath Lake may occur in the reservoirs at the Four Facilities, the majority of removal occurs further upstream in the Keno Impoundment/Lake Ewauna, with some additional decreases in concentration due to mechanical breakdown of algal remains in the turbulent river reaches between Keno Dam and Copco 1 Reservoir, and dilution from the springs downstream from J.C. Boyle Dam (see Appendix C for more detail). The high levels of seasonal suspended material caused by algal blooms in the reservoirs in the Hydroelectric Reach would continue to occur under the No Action/No Project Alternative.

Also under this alternative, the ongoing Williamson River Delta Project and Agency Lake and Barnes Ranches Project would contribute to reduced fine sediment inputs to Upper Klamath Lake. At a programmatic level, the fine sediment reductions may decrease overall sediment-associated phosphorus inputs to the lake and downstream reaches. The effects would be mostly local, but may indirectly reduce nutrient concentrations in the Hydroelectric Reach by decreasing concentrations in upstream Upper Klamath Lake. In the tributaries to Upper Klamath Lake, additional resource management actions for fish habitat restoration (see Section 2.4.2) related to sediment-associated phosphorus are ongoing, including the following:

- Floodplain rehabilitation
- Cattle exclusion [fencing]
- Riparian vegetation planting
- Mechanical thinning of upland areas and fire treatment
- Purchase of conservation easements/land
- Road decommissioning

These resource management actions are also discussed with respect to water quality effects under the KBRA (see Section 3.2.4.3, Full Facilities Removal of Four Dams - KBRA).

Full attainment of the measures in Oregon's Upper Klamath River and Lost River TMDLs may indirectly decrease algal-derived suspended material in the Link River and Klamath River upstream of the Oregon-California State line within the period of analysis (i.e., 50 years). The Oregon draft TMDLs require reductions in phosphorus and nitrogen loading from both point sources and nonpoint sources in the Upper Klamath River to address chlorophyll-*a* impairments (see Section 3.2.2.4, Upper Klamath River and Lost River TMDLs). Decreases in nutrient inputs to the upper Klamath River would decrease algal blooms and decrease algal-derived suspended material in this reach. Full attainment of the California Lower Lost River for pH and nutrients and the Klamath River TMDLs for organic enrichment/low dissolved oxygen, nutrients, and microcystin water quality impairments would decrease algal-derived suspended material in the Klamath River downstream from the Oregon-California State line to Iron Gate Reservoir and would, in the long term, be beneficial to water quality. It is anticipated that full attainment of the Oregon and California TMDLs would require decades to achieve.

Anticipated climate change effects within the period of analysis (i.e., 50 years) include longer and more intense algal blooms due to increased air temperatures (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections) and higher overall rates of photosynthesis during summer months. This may increase levels of algal-derived (organic) suspended material. The anticipated increases in suspended material due to climate change would also occur over a timescale of decades and may reduce anticipated improvements expected from successful TMDL implementation throughout the Upper Klamath Basin; however, the magnitude of the increased algal productivity with increasing temperature has not been assessed.

Existing seasonal increases in algal-derived (organic) suspended material in the reservoirs in the Hydroelectric Reach are adverse. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly decrease algal blooms and associated suspended material in the reservoirs in this reach. Continued impoundment of water in the reservoirs at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Lower Klamath Basin

Continued impoundment of water at the Four Facilities could result in short-term and long-term interception and retention of mineral (inorganic) sediments by the dams and correspondingly low levels of suspended material immediately downstream from Iron Gate Dam. Under existing conditions, during November–April, mineral (inorganic) suspended sediments tend to be <100 mg/L in the Klamath River immediately downstream from Iron Gate Dam, increasing to levels greater than 150 mg/L in the mainstem downstream from the confluence with the Trinity River during storm events (see Section 3.2.3.3). While the interception and retention of mineral (inorganic) suspended sediments may be moderately beneficial for the Klamath River immediately downstream from Iron Gate Dam, this represents a very minor portion of the load with respect to overall sediment delivery for the Klamath Basin. A relatively small (3.4 percent) fraction of total sediment supplied to the Klamath River on an annual basis,

originates from the upper and middle Klamath River (i.e., from Keno Dam to the Shasta River) (see Section 3.2.3.3) and beneficial uses in the Klamath River immediately downstream from Iron Gate Dam are currently not impaired due to mineral (inorganic) suspended material (see Table 3.2-8).

The Klamath River from the Trinity River (RM 42.5) to the mouth (RM 0) is listed as sediment impaired (see Table 3.2-8), and while the California Klamath River TMDLs do not explicitly address sediment impairments, they do identify allocations to address temperature impairments caused by excessive (primarily inorganic) sedimentation (see Section 3.2.2.4, Klamath River TMDLs). Additionally, the Trinity River and South Fork Trinity River TMDLs, which are outside of the area of analysis for the Proposed Action and alternatives, are expected to affect water quality in the Lower Klamath River. These TMDLs include a specific focus on sediment improvements. Further, the Scott River TMDL addresses sediment. General measures under the Trinity, South Fork Trinity, and Scott Rivers' TMDLs that can be associated with (primarily mineral) suspended sediment loads are described briefly in Section 3.2.2.4.

Full attainment of the measures in the Trinity River, South Fork Trinity River, and Scott River TMDLs would decrease (primarily mineral) suspended sediment loads in the sediment impaired reach of the Lower Klamath River from the Trinity River (RM 40) to the mouth (RM 0) and would, in the long term, be beneficial to water quality. Full attainment could require decades to achieve. These implementation measures would occur downstream from the Four Facilities and are not related to the KHP reservoirs under the No Action/No Project Alternative.

Anticipated climate change effects within the period of analysis (i.e., 50 years) include increased fine sediment delivery to streams due to more intense and frequent precipitation events and elevated stormwater runoff (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections). The anticipated increases would occur over a timescale of decades and may reduce improvements expected from successful implementation of the aforementioned TMDL implementation actions; however, the magnitude of the increased sediment delivery relative to the currently low levels of fine sediment production has not been assessed.

Existing interception and retention of mineral (inorganic) sediments by the dams is potentially beneficial. Continued impoundment of water in the reservoirs at the Four Facilities under the No Action/No Project Alternative would result in no change from existing conditions.

Continued impoundment of water at the Four Facilities could result in short-term and long-term seasonal (April through October) increases in algal-derived (organic) suspended material in the reservoirs in the Hydroelectric Reach and transport into the Klamath River downstream from Iron Gate Dam. Under existing conditions, concentrations of summer and fall (June–October) algal-derived (organic) suspended material in the Klamath immediately downstream from Iron Gate Dam tend to be less than 5–8 mg/L, reflecting the dams' capacity to intercept and retain suspended material.

Much of the algal-derived (organic) suspended material retained behind the Project dams is a result of in-reservoir algal production, as the majority of the algal material transported downstream from Upper Klamath Lake appears to be intercepted in the Keno Impoundment/Lake Ewauna (see Appendix C for more detail). However, some of the seasonal algal production that occurs in Copco 1 and Iron Gate Reservoirs is transported downstream to the Klamath River, as evidenced by chlorophyll-*a* patterns, and to a lesser degree TSS patterns, in the river from Iron Gate Dam to the Klamath Estuary (see Appendix C for more detail). While the transport occurs, TSS levels are still relatively low. This pattern would continue to occur under the No Action/No Project Alternative.

Full attainment of the measures in Oregon's Upper Klamath River and Lost River TMDLs would decrease algal blooms and decrease algal-derived suspended material in the KHP reservoirs due to decreased nutrient availability. Full attainment of the measures in California's Lower Lost River TMDLs and Klamath River TMDLs for organic enrichment/low dissolved oxygen, nutrients, and microcystin water quality impairments, would also decrease algal-derived suspended material KHP reservoirs and would, in the long term, be beneficial to water quality. It is anticipated that full attainment of the Oregon and California TMDLs would require decades to achieve.

Anticipated climate change effects within the period of analysis (i.e., 50 years) include increased fine sediment delivery to streams and earlier, longer, and more intense algal blooms (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections), which may increase levels of both mineral (inorganic) and algal-derived (organic) suspended material, the latter due to higher overall rates of photosynthesis during summer months. The anticipated increases in suspended sediments due to climate change would also occur over a timescale of decades and may offset improvements expected from successful TMDL implementation throughout the Lower Klamath Basin; however, the magnitude of the offset is unknown.

Existing transport of seasonally high algal-derived (organic) suspended material from the reservoirs to the Klamath River downstream from Iron Gate Dam is adverse. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly improve conditions. Continued impoundment of water in the reservoirs at the Four Facilities under the No Action/No Project Alternative would result in no change from existing conditions.

Nutrients

Upper Klamath Basin

Continued impoundment of water at the Four Facilities could result in long-term interception and retention of TN and TP in the Hydroelectric Reach on an annual basis but release of TP and, to a lesser degree, TN from reservoir sediments on a seasonal basis. Under existing conditions, TN and TP decrease longitudinally through the Hydroelectric Reach on an annual basis due to dilution from the springs downstream from J.C. Boyle Dam and the settling of algal-derived (organic) material and associated nutrients in Copco 1 and Iron Gate reservoirs. On a seasonal basis, reservoir sediments can release bioavailable TP (as ortho-phosphorus), and to a lesser degree, bioavailable

TN (as ammonium), to the water column during periods of seasonal hypolimnetic anoxia (see Section 3.2.3.4). While much of the TP released from anoxic reservoir sediments appears to remain within the hypolimnion until the reservoirs begin to turn over in the fall, some release can occur during late summer and fall months when it could stimulate in-reservoir algal blooms. Nutrients infrequently meet narrative California North Coast Basin Plan water quality objective for biostimulatory substances (see Table 3.2-4) in the Hydroelectric Reach.

Under the No Action/No Project Alternative, the ongoing Williamson River Delta Project and Agency Lake and Barnes Ranches Project (see above water temperature and suspended sediment discussions) would provide long-term reductions in nutrients transported from the Agency Lake subbasin to Upper Klamath Lake. While short-term releases of nutrients are possible during the establishment of project equilibrium, at a programmatic level, these activities may decrease overall nutrient inputs to Upper Klamath Lake by inundating wetland (peat) soils and creating anaerobic conditions that support nutrient retention, particularly in the case of phosphorus (Snyder and Morace 1997). The effects would be mostly local, but may indirectly reduce nutrient concentrations in the Hydroelectric Reach by decreasing upstream nutrient concentrations in Upper Klamath Lake. These resource management actions are discussed again with respect to water quality effects under the KBRA (see Section 3.2.4.3.2, Full Facilities Removal of Four Dams - KBRA).

In Oregon, implementation of water quality improvement measures addressing nutrients in the Upper Klamath Lake Drainage TMDL and Water Quality Management Plan (WQMP) (ODEQ 2002) and the Upper Klamath River and Lost River Sub-basins TMDL and WQMP (see Section 3.2.2.4), include the following:

- Achievement of TMDL targets for TP loading as the primary method of improving dissolved oxygen (and pH) conditions in Upper Klamath and Agency lakes
- Reductions in phosphorus, nitrogen, and BOD loading from both point and nonpoint (e.g., agricultural returns) sources in the Upper Klamath River

In addition to the Oregon upstream improvements, California has promulgated load allocations for the Lower Lost River TMDLs for pH and nutrients and specific TMDL load allocations for TN and TP assigned to the KHP facilities for the Klamath River TMDLs. The California Klamath River TMDL also indicates that “alternative pollutant load reductions and/or management measures or offsets that achieve the in-reservoir targets” are possible (NCRWQCB 2010a).

The Oregon and California TMDLs in the Upper Klamath Basin are designed to meet water quality objectives; however, the timeframes for achieving nutrient allocations required under these TMDLs will depend on the measures taken to improve water quality conditions. Klamath TMDL model results for nutrient species (i.e., ortho-phosphorus, nitrate, and ammonium) are highly variable depending on location and season, likely due to rapid uptake and release of these chemical species during and following seasonal algal

blooms (see Section 3.2.3.1) and potentially due to peaking operations at the J.C. Boyle Powerhouse. Nonetheless, TMDL modeling results tend to suggest that concentrations under the No Action/No Project Alternative would be similar to modeled natural conditions in the Hydroelectric Reach in spring and summer assuming full attainment of the TMDLs. Full attainment could require decades to achieve and is highly dependent on reducing nutrient loads exiting Upper Klamath Lake and the agricultural return flows (including the Klamath Straits Drain) along the Keno Reach.

In summary, despite beneficial annual decreases in TP and TN through the Hydroelectric Reach, on a seasonal basis, internal release of TP, and to a lesser degree TN, from anoxic reservoir sediments during the summer and late fall may contribute to large blooms of toxigenic algae in the reservoirs.

Existing interception and retention of nutrients in the reservoirs on an annual basis is beneficial, but the release (export) of nutrients (particularly TP) from reservoir sediments on a seasonal basis is adverse for the Hydroelectric Reach. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly decrease nutrients. Continued impoundment of water in the reservoirs at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Lower Klamath Basin

Continued impoundment of water at the Four Facilities could result in long-term interception and retention of TP and TN in the KHP reservoirs on an annual basis and release (export) of TP to the Klamath River downstream from Iron Gate Dam on a seasonal basis. On an annual basis, nutrients in the Klamath River downstream from Iron Gate Dam currently tend to be lower than those in upstream reaches, due to dilution from the natural springs downstream from J.C. Boyle Dam and settling of particulate matter and associated nutrients in Copco 1 and Iron Gate Reservoirs (see Section 3.2.3.4). Further decreases in nutrient levels occur with distance downstream from Iron Gate Dam due to a combination of tributary dilution and in-river nutrient removal processes (see Section 3.2.3.4). Although interception and retention of nutrients in Copco 1 and Iron Gate Reservoirs on an annual basis may be beneficial to the Klamath River downstream from Iron Gate Dam, under existing conditions TP and TN concentrations from the dam to the Klamath Estuary during late summer/early fall do not meet the narrative California Basin Plan water quality objective for biostimulatory substances due to the promotion of algal growth at levels that cause nuisance effects or adversely affect beneficial uses (see Table 3.2-4), nor do they meet the Hoopa Valley Tribe numeric criteria for TP (0.035 mg/L) and TN (0.2 mg/L) (see Table 3.2-6). In late-summer and fall (i.e., August-November), TP concentrations can increase downstream from the KHP reservoirs due to release of TP (as ortho-phosphorus) which is formed during periods of seasonal hypolimnetic anoxia in Copco 1 and Iron Gate Reservoirs. This seasonal release during late summer and fall periods may stimulate periphyton growth in the Klamath River downstream from Iron Gate Dam (see Appendix C, Sections C.3.1.4 and C.3.2.1). This pattern would continue under the No Action/No Project Alternative.

In the Lower Klamath Basin, the California Klamath TMDLs include a specific focus on nutrient (TN and TP) improvements through specific load allocations assigned to the KHP facilities in California – Copco and Iron Gate reservoirs (see Section 3.2.2.4). Although specific nutrient allocations are only assigned to the KHP, the California Klamath TMDLs were developed based on compliance with water quality objectives at the Oregon-California State line, meaning that successful implementation of water quality improvement measures under the Oregon TMDLs will improve nutrients in the Lower Klamath Basin as well. General measures under the California Klamath River TMDLs that are associated with nutrients include the following:

- Developing a conditional waiver by 2012 to control discharges from agricultural activities (e.g., grazing, irrigated agriculture)
- Prohibiting the unauthorized discharge of waste that is in violation of water quality standards

Full attainment of the measures in the Oregon and California TMDLs would result in waters meeting water quality standards; however, the timeframes for achieving nutrient allocations required under these TMDLs will depend on the measures taken to improve water quality conditions. Modeling conducted for development of the California Klamath River TMDLs indicates that under the No Action/No Project Alternative (similar to the T4BSRN scenario) TN and TP in the Klamath River downstream from Iron Gate Dam would meet or be lower than modeled natural conditions due to the trapping efficiency of sediment- and algal-associated nutrients behind the dams. Nutrient levels would also meet Hoopa Valley Tribe criteria for TP (0.035 mg/L) and TN (0.2 mg/L) (NCRWQCB 2010a). Given full attainment of the measures in the Oregon and California TMDLs, actual TN concentrations under the No Action/No Project Alternative and natural conditions might be slightly lower than the model predicted concentrations, because denitrification is not included as a possible nitrogen removal term in the riverine segments of the Klamath TMDL model (Tetra Tech 2009). In contrast, dissolved nutrient species (i.e., ortho-phosphorus, nitrate, ammonium) concentrations are variable depending on location and season, with particularly high daily variation during summer months, but Klamath TMDL model results tend to suggest that concentrations under the No Action/No Project Alternative would be somewhat higher than modeled natural conditions in the Lower Klamath Basin. Use of adaptive management will be employed to refine efforts toward achieving water quality standards and TMDL targets. It is anticipated that full attainment of the TMDLs would require decades to achieve.

Existing interception and retention of nutrients in the reservoirs on an annual basis is beneficial, but the release (export) of nutrients (particularly TP) on a seasonal basis is adverse for the Klamath River downstream from Iron Gate Dam. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly decrease nutrients. Continued impoundment of water in the reservoirs at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Dissolved Oxygen

Upper Klamath Basin

Continued impoundment of water at the Four Facilities could result in long-term seasonal and daily variability in dissolved oxygen concentrations in the Hydroelectric Reach, such that levels do not meet ODEQ and California North Coast Basin Plan water quality objectives and adversely affect beneficial uses. Under existing conditions, dissolved oxygen concentrations in summer and fall are substantially below (i.e., do not meet) water quality objectives and infrequently support designated beneficial uses in Oregon for cool water aquatic life and redband or Lahonton cutthroat trout; see Table 3.2-3), and in California for COLD, WARM, and SPWN beneficial uses (see Table 3.2-4). Dissolved oxygen levels are particularly low during the summer in the reach from Link River Dam to upstream of J.C. Boyle Reservoir (including Keno Impoundment/Lake Ewauna), with typical levels ranging from <1 mg/L to 5 mg/L. The primary cause of low summertime dissolved oxygen in the Keno Impoundment/Lake Ewauna is settling and decomposition of algae exported from Upper Klamath Lake (see Section 3.2.3.5), in combination with warm water temperatures that support lower dissolved oxygen concentrations than cold water, including when saturated. Organic matter and nutrient inputs from the Lost River Basin via Klamath Straits Drain and the Lost River Diversion Channel also contribute to low dissolved oxygen levels in this reach (see Appendix C, Section C.4.1.3 for additional detail). In the Hydroelectric Reach, the seasonal variability in dissolved oxygen concentrations in J.C. Boyle Reservoir can be highly influenced by the high oxygen demand of water flowing downstream from the upstream Keno Impoundment/Lake Ewauna. Dissolved oxygen in hypolimnetic waters of Copco 1 and Iron Gate reservoirs reach minimum values near 0 mg/L during the summer (see Section 3.2.3.5).

Under the No Action/No Project Alternative, the ongoing Williamson River Delta Project and Agency Lake and Barnes Ranches Project may contribute to long-term improvements in seasonally low dissolved oxygen in Upper Klamath Lake. These resource management actions may decrease overall suspended sediment and nutrient inputs to Upper Klamath Lake and downstream reaches. These resource management actions are discussed again with respect to water quality effects under the KBRA (see Section 3.2.4.3.2.11).

In Oregon, implementation of TMDL water quality improvement measures focus on dissolved oxygen through reductions in water temperature and nutrient concentrations. The Upper Klamath Lake Drainage TMDL (see Section 3.2.2.4) include the following recommended measures for working toward achievement of TMDL targets for TP loading as the primary method of improving dissolved oxygen (and pH) conditions in Upper Klamath River along with Upper Klamath Lake and Agency lakes:

- Implementation of BMPs for improving dissolved oxygen in the Sprague River
- Reductions in phosphorus, nitrogen, and BOD loading from both point and nonpoint sources in the Upper Klamath River

Additionally, the Upper Klamath River and Lost River Sub-basins TMDLs require dissolved oxygen augmentation to J.C. Boyle Reservoir and several impoundments on the Lost River (the latter is not included in the area of analysis). The Lower Lost River pH and nutrient TMDLs were designed to ensure that California's numeric dissolved oxygen water quality standard would be attained. In California, one of the three TMDL load allocations assigned to the KHP is to create sufficient dissolved oxygen in Copco 1 and Iron Gate Reservoirs through a compliance lens, such that water temperature and dissolved oxygen conditions would be suitable for cold water fish during the critical summer period (see Section 3.2.2.4).

Full attainment of the measures in the Oregon and California TMDLs would result in waters meeting water quality standards; however, the timeframes for achieving dissolved oxygen (DO) allocations required under these TMDLs will depend on the measures taken to improve water quality conditions, especially reductions in nutrients. Based on Oregon numeric water quality standards, dissolved oxygen levels in the Upper Klamath Basin would need to meet natural conditions or attain 5.5 mg/L (year-round minimum for warm water aquatic life), 6.5 mg/L (year-round minimum for cool water aquatic life), 8.0 mg/L (year-round minimum for coldwater aquatic life), or 11.0 mg/L (January 1–April 15 minimum for spawning) (see Table 3.2-3). As with water temperature, the narrative Oregon standard stipulates that the natural conditions criterion supersedes the numeric criterion and is the standard for that water body (see Table 3.2-3). For California, dissolved oxygen would need to achieve 90 percent saturation based on natural receiving water temperatures during October–March and 85 percent saturation during April–September (see Table 3.2-4). The Klamath TMDL model (see Appendix D) indicates that under the No Action/No Project Alternative with full attainment of the TMDLs (similar to the T4BSRN scenario) dissolved oxygen in the riverine portions of the reach from Link River Dam to the Oregon-California State line would meet Oregon's 6.5 mg/L numeric objective for supporting the cool water aquatic life beneficial use. Dissolved oxygen predicted levels would be similar to the modeled natural conditions baseline (TMDL T1BSR scenario) (NCRWQCB 2010a).

Klamath TMDL model results for riverine conditions at the Oregon-California State line indicate a similar pattern, whereby predicted dissolved oxygen concentrations meet the 6.5 mg/L objective year round and achieve the modeled natural conditions baseline during the warm summer and fall months (Figure 3.2-17). Under full TMDL compliant conditions, the California 85 percent saturation objective (based on natural receiving water temperatures) is met at State line under the No Action/No Project Alternative (Figure 3.2-17). Thus, full attainment of the Oregon and California TMDLs would eventually be beneficial for dissolved oxygen in the Hydroelectric Reach. Full attainment could require decades to achieve and is highly dependent on improvements in dissolved oxygen, nutrients, and organic matter export from Upper Klamath Lake and the upstream reach from Link River Dam to J.C. Boyle Dam (particularly Keno Impoundment/Lake Ewauna).

Climate change is expected to cause a small decrease in dissolved oxygen due to general increases in water temperature in the Klamath Basin on the order of 2–3 °C (3.6–5.4 °F)

over the period of analysis (i.e., 50 years) (Bartholow 2005; see also the subsection, Upper Klamath Basin, in Section 3.2.4.3.1). This would decrease the 100 percent saturation level for dissolved oxygen by an estimated 0.3–0.4 mg/L, using general assumptions for water temperature (20–24 °C [68–75.2 °F]), salinity (0 ppt) and elevation (1,433 m [4,700 ft]), where the elevation of Upper Klamath Lake is used as a simplifying assumption for the calculation. Climate change would also occur over a timescale of decades and would act in opposition to improvements expected from successful TMDL implementation throughout the Upper Klamath Basin. Alternately, increased levels of algal growth and photosynthesis anticipated under climate change (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections) may increase daytime dissolved oxygen concentrations during summer months, along with the severity of bloom crashes and their negative effect on dissolved oxygen. The magnitude of these changes is unknown.

Existing seasonal dissolved oxygen levels in the Hydroelectric Reach are adverse. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly increase dissolved oxygen. Continued impoundment of water at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Lower Klamath Basin

Continued impoundment of water at the Four Facilities could result in the continued release of seasonally low dissolved oxygen concentrations from Iron Gate Reservoir into the Klamath River, such that levels immediately downstream from the dam do not meet California North Coast Basin Plan water quality objectives and adversely affect beneficial uses. Under existing conditions, dissolved oxygen in the Klamath River exhibits seasonal low levels immediately downstream from Iron Gate Reservoir with frequent violations of the California water quality objective (expressed as percent saturation, see Table 3.2-5) during late summer/early fall (July–September) (see Section 3.2.3.5). Dissolved oxygen levels generally recover with distance downstream, but they still exhibit occasional minimum values below objectives during late summer/early fall downstream from the confluence with the Trinity River (RM 40). The Hoopa Valley Tribe (8 mg/L) water quality objective for dissolved oxygen, which applies at ≈RM 45–46, is also infrequently met during late summer/early fall months (see Section 3.2.3.5). Thus, dissolved oxygen conditions currently do not fully support designated beneficial uses COLD and WARM beneficial uses (see Table 3.2-4) in the Klamath River downstream from Iron Gate Dam.

Under the No Action/No Project Alternative, IM 3, Iron Gate Turbine Venting, as part of ongoing KHSa IM studies (see also Section 3.2.4.1), may be used to augment dissolved oxygen in the river downstream from the dam prior to 2020. Pilot study results from 2008 indicated that dissolved oxygen levels immediately downstream from Iron Gate Dam can be increased through the mechanical introduction of oxygen as water passes through the turbines (i.e., turbine venting). PacifiCorp reported an increase of approximately 0.5 to 2 mg/L dissolved oxygen (approximately 7 to 20 percent saturation) observed across separate tests in August and October 2008 (Carlson and Foster 2008,

PacifiCorp 2008). However, during the October 2008 test, when the upstream reservoirs were de-stratifying and dissolved oxygen concentrations in the river immediately downstream from Iron Gate Powerhouse were decreasing to levels of approximately 6.5 mg/L, turbine venting only increased concentrations at this location by approximately 0.5 mg/L and 7 percent saturation (Carlson and Foster 2008). As part of their review of PacifiCorp's requested "Authorization for Incidental Take and Implementation of KHP Interim Operations Habitat Conservation Plan for Coho Salmon", USEPA indicated that the 2008 study did not demonstrate the efficacy of the proposed turbine venting to significantly improve dissolved oxygen downstream from Iron Gate Dam (USEPA 2011). Further testing conducted in 2010 indicated that turbine venting in combination with a forced air blower was the most effective of three methods tested (i.e., turbine venting, blower, turbine venting plus blower), resulting in an initial increase in dissolved oxygen percent saturation from approximately 50 percent to just over 70 percent immediately downstream from the Iron Gate Powerhouse (PacifiCorp 2011). Throughout the 6-mile test reach downstream from the powerhouse, dissolved oxygen concentrations continued to increase for all tested methods, as well as for ambient (i.e., no treatment) conditions, due to river re-aeration. For the turbine venting plus blower treatment, dissolved oxygen concentrations achieved the reach-specific Basin Plan water quality objective of 90 percent saturation (i.e., October 1 through March 31 from Stateline to Scott River) at the end of the 6-mile test reach. Ambient conditions (i.e., no treatment) achieved approximately 88 percent saturation at the end of the 6-mile reach (PacifiCorp 2011). Although turbine venting treatments considerably improved dissolved oxygen concentrations in the 6-mile test reach, particularly in the first 1 to 3 miles downstream from the dam, the full compliance point in the river with turbine venting did not shift considerably further upstream as compared with that of ambient conditions (i.e., no treatment). Thus, although there have been improvements from the initial tests, turbine venting efforts have not yet been demonstrated to be a viable long-term solution for dissolved oxygen impairment from the reservoirs

In the Lower Klamath Basin, the California Klamath River TMDLs include a specific focus on dissolved oxygen improvements. Full attainment of water quality improvement measures under the Oregon TMDLs would improve dissolved oxygen in the California portions of the Klamath River as well, particularly since California Klamath River TMDLs were developed based on compliance with water quality objectives at the Oregon-California State line. Specific dissolved oxygen allocations are assigned to the KHP and TN, TP, and CBOD allocations are assigned to the mainstem river and tributaries to support improvement toward dissolved oxygen targets (i.e., water quality objectives for dissolved oxygen). Specific monthly dissolved oxygen numeric targets are also assigned to the Copco and Iron Gate tailraces, based on percent saturation (see Section 3.2.2.4). General measures under the California Klamath River TMDLs associated with dissolved oxygen in the Klamath River include the following:

- A conditional waiver (developed by 2012) for discharges from agricultural activities (e.g., grazing, irrigated agriculture)

- Prohibiting the unauthorized discharge of waste that is in violation of water quality standards

The Shasta River TMDLs also address dissolved oxygen. Dissolved oxygen improvements in the Shasta River would be expected to improve concentrations in the Klamath River mainstem at or downstream from the confluence with the Shasta River (RM 176.7). Multiple water quality improvement measures in the Shasta River TMDL focus on dissolved oxygen (see Section 3.2.2.4).

Full attainment of the measures in the Oregon and California TMDLs would result in waters meeting water quality standards; however, the timeframes for achieving dissolved oxygen allocations and targets required under these TMDLs will depend on the measures taken to improve water quality conditions, especially reductions in nutrients in upstream reaches. The Oregon and California with-dam TMDL scenario (T4BSRN - see Appendix D) was run in order to quantify the impacts of the dams on water quality and to determine appropriate allocations and targets. The Klamath with-dam TMDL modeling scenario indicates that, with full compliance of the TMDLs, under the No Action/No Project Alternative (similar to the TMDL T4BSRN scenario), dissolved oxygen concentrations immediately downstream from Iron Gate Dam, without additional mitigation, would not meet the North Coast Basin Plan water quality objective of 85 percent saturation (see Tables 3.2-4 and 3.2-5) during August–September, and the 90 percent saturation objective would not be met from October–November (Figure 3.2-18). Further downstream, near the confluence with the Shasta River, dissolved oxygen concentrations under the No Action/No Project Alternative would not meet the 90 percent saturation objective from October–November (Figure 3.2-19). In the Klamath River at Seiad Valley, concentrations would be mostly in compliance with the exception of modeled values in November that are just above the 90 percent saturation objective (Figure 3.2-20). The inability to achieve the water quality objectives under TMDL compliance conditions immediately downstream from Iron Gate Dam is due to the release of low dissolved oxygen water from the hypolimnion of the reservoir. This result indicates that while full attainment of the California Klamath TMDLs would result in dramatic improvements in dissolved oxygen both upstream and downstream from Iron Gate Dam, release of low dissolved oxygen water from the hypolimnion (i.e., the bottom layer within stratified reservoir) inhibits compliance immediately downstream from Iron Gate Dam with the dams in place. The TMDL does include dissolved oxygen targets for the Iron Gate Dam tailrace that meet water quality objectives. It is possible that there are management practices that PacifiCorp could use to meet the TMDL dissolved oxygen targets. However, these practices have not been demonstrated to date and the NCRWQCB could not make presumptions regarding what these practices might be. Therefore, these enhancements were not included in the with-dams TMDL modeling scenario. The TMDL Action Plan includes a requirement for PacifiCorp to submit a proposed Implementation Plan that incorporates timelines and contingencies pursuant to the KHSA. PacifiCorp may propose the use of off-site pollutant reduction measures (i.e., offsets or “trades”) to meet the allocations and targets in the context of the Interim Measures 10 and 11 of the KHSA (NCRWQCB 2010a).

By the Salmon River (RM 66.0) confluence, with full attainment of TMDL allocations, predicted dissolved oxygen concentrations would remain at or above the 85 percent saturation objective (as well as the 90 percent saturation objective, where applicable), meeting the North Coast Region Basin Plan requirements. Predicted dissolved oxygen would infrequently meet the Hoopa Valley Tribe numeric dissolved oxygen objective of 8 mg/L (see Table 3.2-6), which applies at \approx RM 45–46, because warm water temperatures during July–October would decrease the saturation level of oxygen in the water column to less than 8 mg/L (see Figure 3.2-20 and 3.2-21). However, Hoopa Valley Tribe has a natural conditions clause requiring dissolved oxygen to achieve 90% saturation if numeric values are not met; predicted dissolved oxygen concentrations would meet this natural condition clause. The Hoopa Valley Tribe's Water Quality Control Plan (HVTEPA 2008) has been approved by USEPA; however, this natural conditions clause has not yet been approved (as of July 2012). USEPA requires that a method be developed for determining that the dissolved oxygen objectives are not achievable due to natural conditions and presented for approval. Throughout the Lower Klamath River, daily fluctuations in dissolved oxygen during July–October would occur due to colonization of periphyton mats in the river and the associated photosynthesis.

As described for the Upper Klamath Basin, climate change would decrease the 100 percent saturation level for dissolved oxygen in the lower basin by increasing water temperatures. In the lower basin, this would result in an estimated 0.3–0.5 mg/L decrease in dissolved oxygen, using general assumptions for water temperature (20–24°C [68–75.2°F]), salinity (0 ppt) and elevation at sea level as a simplifying assumption for the calculation. The small anticipated decreases in dissolved oxygen due to climate change would also occur over a timescale of decades and would act in opposition to improvements expected from successful TMDL implementation throughout the Lower Klamath Basin. As with the Upper Basin, increased levels of algal growth and photosynthesis anticipated under climate change (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections) may increase daytime dissolved oxygen concentrations during summer months but could increase the severity of subsequent bloom crashes and their negative effect on dissolved oxygen. The magnitude of these changes is unknown.

Existing seasonal dissolved oxygen levels immediately downstream from Iron Gate Dam are adverse. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly increase dissolved oxygen, although seasonal concentrations from Iron Gate Dam to the Shasta River would remain adverse. Continued impoundment of water at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

pH

Upper Klamath Basin

Continued impoundment of water at the Four Facilities could result in long-term seasonal and daily variability in pH in the Hydroelectric Reach. Under existing

conditions, pH values in the Hydroelectric Reach range from just above neutral to greater than 9, with large (0.5–1.5 pH units) daily fluctuations occurring in reservoir surface waters during periods of intense algal blooms (see Section 3.2.6). During these periods, pH levels infrequently meet applicable ODEQ and California North Coast Basin Plan water quality objectives (see Table 3.2-3 and Table 3.2-4), and adversely affect beneficial uses.

Several ongoing resource management actions represent reasonably foreseeable actions within the period of analysis that may affect pH. Although initially resulting in increased nutrient release, the ongoing Williamson River Delta Project and Wood River Wetland Restoration are expected to eventually reduce nutrient inputs to Upper Klamath Lake which may decrease algal bloom populations and rates of photosynthesis, and correspondingly decreasing observed pH maximums in the lake and its tributaries. Additional resource management actions such as floodplain rehabilitation, riparian vegetation planting, and purchase of conservation easements/land, and which could affect nutrients, are currently ongoing in the Upper Klamath Basin (see Section 2.3.1) and are expected to continue to improve long-term pH in the Upper Klamath Lake. This may indirectly decrease pH maximums in the Hydroelectric Reach. These resource management actions are discussed again with respect to water quality effects under the KBRA (see Section 3.2.4.3, Full Facilities Removal of Four Dams - KBRA).

In Oregon, implementation of TMDL measures focused on pH in the Upper Klamath Lake Drainage TMDL and WQMP and those in the draft Upper Klamath River and Lost River Sub-basins TMDL and WQMP (see Section 3.2.2.4) include decreased loading of total phosphorous as the primary method for decreasing pH in Upper Klamath and Agency lakes and in the Sprague River. While the California Klamath River TMDLs do not include specific allocations or targets for pH, load allocations and targets for TN and TP, which include pH under the allocations for nutrients as biostimulatory substances (NCRWQCB, 2010a), are assigned to the KHP and are designed to limit algal photosynthesis. This will decrease maximum pH levels and daily variability in the Hydroelectric Reach. The California Lower Lost River TMDLs also include pH allocations.

The Oregon and California TMDLs in the Upper Klamath Basin are designed to achieve water quality objectives; however, the timeframes for achieving pH objectives will depend on the measures taken to improve water quality conditions, especially reductions in nutrients. To consistently support beneficial uses, pH cannot be below 6.5 units or above 9.0 units in Oregon (see Table 3.2-3) and cannot be depressed below 7.0 units nor raised above 8.5 units in California upstream or downstream from Iron Gate Dam (see Table 3.2-4). The pH in the reach from Link River Dam to just upstream of J.C. Boyle Reservoir, and to the Oregon-California State line in the Hydroelectric Reach, would meet water quality objectives for Oregon. Similarly, in California from the State line to Iron Gate Dam, pH is expected to trend toward achievement of water quality objectives given full attainment of the TMDLs within the period of analysis (NCRWQCB 2010a). Full attainment could require decades to achieve.

Anticipated climate change effects on pH include earlier, longer, and more intense algal blooms (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections), which may increase pH maximums due to higher overall rates of photosynthesis during summer months. The anticipated increases in pH due to climate change would also occur over a timescale of decades and would act in opposition to improvements expected from successful TMDL implementation throughout the Upper Klamath Basin; however, the magnitude of the opposition is unknown.

Existing seasonal fluctuations in pH occurring during periods of intense algal blooms in the Hydroelectric Reach are adverse. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly improve pH. Continued impoundment of water at the Four Facilities under the No Action/No Project Alternative would result in no change from existing conditions.

Lower Klamath Basin

Continued impoundment of water at the Four Facilities could result in long-term seasonal and daily variability in pH in the Klamath River downstream from Iron Gate Dam. Under existing conditions, pH during late-summer and early-fall months (August–September) in the Klamath River downstream from Iron Gate Dam ranges from just above neutral to greater than 9, with large (0.5–1.5 pH units) daily fluctuations occurring in the river during periods of high photosynthesis (see Section 3.2.3.6). In California, to consistently support beneficial uses in the Klamath, pH cannot be depressed below 7.0 units nor raised above 8.5 units (see Table 3.2-4).

While the California Klamath River TMDLs do not include specific allocations or targets for pH, load allocations and targets for TN and TP, which include pH under the allocations for nutrients as biostimulatory substances (NCRWQCB, 2010a), are assigned to the KHP and are designed to limit algal photosynthesis, which will decrease maximum pH levels and daily variability in the Klamath River downstream from Iron Gate Dam.

The timeframes for achieving pH objectives will depend on the measures taken to improve water quality conditions, especially reductions in nutrients. The Klamath TMDL model (see Appendix D) indicates that under the No Action/No Project Alternative (similar to TMDL T4BSRN scenario) pH in the reach from Seiad Valley (RM 129.4) to downstream from the mainstem confluence with Indian Creek (RM 108) would meet water quality objectives. While model results indicate that daily maximum values in some stretches of the Klamath River downstream from Iron Gate Dam may not meet the Basin Plan water quality objective of 8.5 pH units (see Table 3.2-4), within the resolution of the Klamath TMDL model these potentially occasional exceedances of the pH objective would not be expected to substantially adversely affect beneficial uses. The Hoopa Valley Tribe water quality objective for pH (7.0–8.5) (see Table 3.2-6) is met at the location that it is applicable (≈RM 45–6) (NCRWQCB 2010a). Therefore, pH under the No Action/No Project Alternative would meet pH water quality objectives for

California within the period of analysis due to full attainment of the California TMDLs (NCRWQCB 2010a). It is anticipated that full attainment of the TMDLs would require decades to achieve.

Anticipated climate change effects on pH include earlier, longer, and more intense algal blooms (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections), which may increase pH maximums due to higher overall rates of photosynthesis during summer months. The anticipated increases in pH due to climate change would also occur over a timescale of decades and would act in opposition to improvements expected from successful TMDL implementation throughout the Lower Klamath Basin; however, the magnitude of the opposition is unknown.

Existing seasonal fluctuations in pH downstream from Iron Gate Dam, which occur during periods of intense algal blooms in the upstream reservoirs, are adverse. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly improve pH. Continued impoundment of water at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Chlorophyll-a and Algal Toxins

Upper Klamath Basin

*Continued impoundment of water at the Four Facilities could support long-term growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa*, resulting in high seasonal concentrations of chlorophyll-a and algal toxins in the Hydroelectric Reach.* Under existing conditions, chlorophyll-a samples during summer and fall in Upper Klamath Lake and the two largest reservoirs at the Four Facilities (Copco 1 and Iron Gate Reservoirs) exhibit annual mean values >10 µg/L (measured May through October) with the highest values (> 100 µg/L) occurring in surface waters during late summer periods of intense algal blooms (see Section 3.2.3.7). High (>8 µg/L) seasonal levels of algal toxins (microcystin) are linked to intense blue-green algae blooms and exceed applicable ODEQ water quality objectives for toxic substances (see Table 3.2-3) and the North Coast Basin Plan water quality objectives for toxicity (see Table 3.2-4). This adversely affects beneficial uses, particularly the human health water contact recreational use (REC-1) and the cultural use (CUL).

As with other water quality parameters analyzed in this EIS/EIR (i.e., water temperature, sediment, nutrients, dissolved oxygen, pH), several ongoing resource management actions represent reasonably foreseeable actions within the period of analysis that may affect algal toxins and chlorophyll-a concentrations in the Upper Klamath Basin. The ongoing Williamson River Delta Project and Wood River Wetland Restoration are intended to eventually reduce nutrient inputs to Upper Klamath Lake, which may help decrease the incidence of toxic cyanobacterial algal blooms and high chlorophyll-a levels and algal toxins in Upper Klamath Lake and reduce those transported downstream to the Hydroelectric Reach. Additional resource management actions such as floodplain rehabilitation, riparian vegetation planting, and purchase of conservation easements/land, and which could affect nutrients, are ongoing in the Upper Klamath Basin (see

Section 2.3.1) and are expected to continue to decrease long-term levels of algal toxins and chlorophyll-*a* in Upper Klamath Lake. This may slightly decrease concentrations in the Hydroelectric Reach. These resource management actions are discussed again with respect to water quality effects under the KBRA (see Section 3.2.4.3, Full Facilities Removal of Four Dams - KBRA).

In Oregon, implementation of measures related to chlorophyll-*a* and algal toxins in the Upper Klamath Lake Drainage TMDL and WQMP and those in the Upper Klamath River and Lost River Sub-basins TMDL and WQMP (see Section 3.2.2.4) include decreased loading of TP as the primary method for decreasing the magnitude of algal productivity (blooms) affecting the high rates of photosynthesis and the related water quality problems (e.g., pH, dissolved oxygen) in the Sprague River, Upper Klamath and Agency lakes, and the Keno Reach. Decreases in upstream algal blooms would result in corresponding decreases in chlorophyll-*a* concentrations and, for toxin-producing algal species, levels of microcystin in the Hydroelectric Reach.

Additionally, the Oregon and California TMDLs include specific load allocations for TN and TP upstream of the Klamath Hydropower Facilities (see Section 3.2.2.4), which are intended to eventually limit the extensive algal blooms in Copco 1 and Iron Gate Reservoirs and thus decrease chlorophyll-*a* and algal toxin levels toward the TMDL targets of 10 µg/L chlorophyll-*a* (growing season average), *M. aeruginosa* cell density ≤20,000 cells/L, and microcystin toxin <4 µg/L (see Table 3.2-10). Full attainment of the measures in the Oregon and California TMDLs would result in waters meeting water quality standards; however, the timeframes for achieving water quality objectives with respect to algal toxins and chlorophyll-*a* will depend on the measures taken to improve water quality conditions. This would require decades to achieve and it is highly dependent on nutrient improvements in Upper Klamath Lake, Link River, and the Keno Impoundment/Lake Ewauna.

Anticipated climate change effects include earlier, longer, and more intense algal blooms (Barr et al. 2010) (see Section 3.10.3.1, Existing Conditions – Climate Change Projections), which may increase algal toxin and chlorophyll-*a* concentrations due to higher overall rates of photosynthesis and algal primary production during summer months. The anticipated effects of climate change would also occur over a timescale of decades and may slightly offset improvements expected from successful TMDL implementation throughout the Upper Klamath Basin.

Existing seasonal blooms of toxin-producing nuisance algal species and corresponding levels of chlorophyll-*a* and algal toxins in the Hydroelectric Reach are adverse. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly decrease chlorophyll-*a* and algal toxins. Continued impoundment of water at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Lower Klamath Basin

*Continued impoundment of water at the Four Facilities could support long-term growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa*, resulting in high seasonal concentrations of chlorophyll-*a* and algal toxins (i.e., microcystin) transported into the Lower Klamath River and likely the Klamath Estuary and the marine nearshore environment.* Under existing conditions, chlorophyll-*a* concentrations during summer through fall in the Klamath River downstream from Iron Gate Dam can be greater than those in the river directly upstream of Copco 1 Reservoir due to in-reservoir algal blooms that are transported into the lower river (see Appendix C, Section C.4.1.4 and Figure C-28). These algal blooms can be toxic and can exceed numeric thresholds for microcystin (i.e., SWRCB/OEHHA Public Health Threshold of 8 µg/L, WHO guidelines of 4 µg/L) posing a human health risk and substantially adversely affecting recreational beneficial uses, particularly water contact (REC-1) and CUL uses. The CUL beneficial use is applicable in the Klamath River from State line to the Klamath River Estuary (see Table 3.2-2). Known or perceived risks of exposure to degraded water quality conditions due to algal toxins during ceremonial bathing and traditional cultural activities have resulted in impairment of this beneficial use (see also Section 3.12.3). Additionally, Hoopa Valley Tribe water quality objectives for toxigenic cyanobacteria species and cyanobacterial scums are not consistently met during summer months (see Section 3.2.3.7 and Appendix C for more detail). Microcystin can also bioaccumulate in aquatic biota in the Lower Klamath River, including filter feeders and fish. A discussion of algal toxins as related to fish health is presented in Section 3.3.3.2, Physical Habitat Descriptions - Water Quality - Algal Toxins.

Existing information indicates that instances of elevated levels of *M. aeruginosa* and microcystin toxin in the Klamath Estuary correspond with elevated levels measured at upstream locations in the Lower Klamath River (see also Section 3.4.3.6). Continued occurrence of *M. aeruginosa* and microcystin toxin in the Lower Klamath River under the No Action/No Project Alternative would also likely result in the continued occurrence of this toxic blue-green algae and the associated toxin in the Klamath Estuary. Lastly, there is emerging evidence that cyanotoxins flushing from coastal rivers into Monterey Bay, California were responsible for numerous sea otter deaths in 2007 (Miller et al. 2010). While it is not known if conditions in Monterey Bay are similar to those in the Klamath River marine nearshore environment, there may be potential for microcystin to adversely impact marine organisms under the No Action/No Project Alternative.

Additionally, the Oregon and California TMDLs include specific load allocations for TN and TP upstream of the Klamath Hydropower Facilities (see Section 3.2.2.4), which are intended to eventually limit the extensive algal blooms in Copco 1 and Iron Gate Reservoirs and thus decrease chlorophyll-*a* and algal toxin levels toward the TMDL targets of 10 µg/L chlorophyll-*a* (growing season average), *M. aeruginosa* cell density 20,000 cells/L, and microcystin toxin <4 µg/L (see Table 3.2-10). This would subsequently decrease levels of chlorophyll-*a* and algal toxins transported into the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment. This would require decades to achieve and it is highly dependent on upstream nutrient improvements.

As with the Upper Klamath Basin, anticipated effects of climate change on chlorophyll-*a* and algal toxins would occur over a timescale of decades and would act in opposition to improvements expected from successful TMDL implementation throughout the Lower Klamath Basin; however, the magnitude of the opposition is unknown.

Existing transport of seasonal blooms of toxin-producing nuisance algal species, chlorophyll-*a*, and algal toxins into the Lower Klamath River and likely the Klamath Estuary are adverse. Transport to the marine nearshore environment is potentially adverse. Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly decrease chlorophyll-*a* and algal toxins. Continued impoundment of water at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Inorganic and Organic Contaminants

Upper Klamath Basin

Freshwater Aquatic Life Toxicity and/or Bioaccumulation

Effects of the No Action/No Project Alternative on potential inorganic and organic contaminants in Upper Klamath Lake and its major tributaries cannot be assessed directly due to a lack of information for these parameters (see Section 3.2.3.8, Upper Klamath Lake – Inorganic and Organic Contaminants). However, under the No Action/No Project Alternative, ongoing resource management actions (i.e., Williamson River Delta Project, Agency Lake and Barnes Ranches Project) may reduce transport of inorganic and organic contaminants into Upper Klamath Lake and downstream reaches. While Oregon and California TMDLs do not address inorganic and organic contaminants, under the No Action/No Project Alternative TMDL implementation may indirectly limit transport of inorganic and organic contaminants through mechanisms expected to reduce suspended sediments and nutrients.

Low levels of organic and inorganic contaminants have been identified in the sediment deposits trapped behind the dams in the Hydroelectric Reach (see Section 3.2.3.8). Benthic uptake and subsequent transfer through the food web is one potential pathway of contaminant exposure for aquatic organisms in the Hydroelectric Reach; exposure to water column contaminants is also a possible pathway. Sediment contaminants influenced by pH or dissolved oxygen, such as methylmercury, may flux into the water column via the low redox conditions supported by reservoir stratification and seasonal anoxia. Human exposure to methylmercury, inorganic contaminants (e.g., arsenic), and organic contaminants (e.g., pesticides, PCBs, PAHs) associated with reservoir sediments may occur through consumption of contaminated reservoir fish or shellfish. Potential effects of the No Action/No Project Alternative are further discussed below using available water column, sediment, and aquatic biota contaminant data.

Continued impoundment of water at the Four Facilities and associated interception and retention of sediments behind the dams could result in long-term low-level exposure to inorganic and organic contaminants for freshwater aquatic species in the Hydroelectric Reach.

Water Column Contaminants Water quality data collected during in Copco 1 and Iron Gate reservoirs during 2001–2005 under the SWAMP indicate that concentrations of numerous inorganic compounds (i.e., arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, and zinc) and organic compounds (i.e., pesticides, PCBs, phenols) were in compliance with water quality objectives (NCRWQCB 2008; see Section 3.2.3.1 and Appendix C, Section C.7.1.1 for more detail).

Sediment Contaminants Two studies provide data for the evaluation of sediment toxicity and bioaccumulation potential under the No Action/No Project Alternative:

- Sediment chemistry data collected during 2004–2005 from 26 cores in J.C. Boyle, Copco 1, and Iron Gate Reservoirs (Shannon & Wilson, Inc. 2006). The 2004–2005 sediment chemistry data indicate generally low levels of metals, pesticides, chlorinated acid herbicides, PCBs, VOCs, SVOCs, cyanide, and dioxins (Shannon & Wilson, Inc. 2006; see Section 3.2.3.1).
- Sediment chemistry and toxicity data collected during 2009–2010 as part of the Secretarial Determination process, including samples from J.C. Boyle, Copco 1, and Iron Gate Reservoirs, and the Klamath Estuary (Department of the Interior 2010a and “Exposure Pathway 1” in CDM [2011]). Based on comparison to appropriate freshwater sediment screening levels (see Section 3.2.3.8 and Appendix C for more detail), a limited number of COPCs were detected in reservoir sediment samples (i.e., nickel, iron, dieldrin, 4,4’-DDT, 4,4’-DDD, 4,4’-DDE, 2,3,4,7,8-PECDF, and 2,3,7,8-TCDD; see Appendix C, Section C.7.1.1 and Table 2 in CDM [2011]), indicating a low risk of toxicity to or bioaccumulation in freshwater sediment-dwelling organisms in the Hydroelectric Reach under the No Action/No Project Alternative. Based on additional lines of evidence (i.e., toxicity tests, calculation of TEQs), there does not appear to be a substantial sediment toxicity concern for national benchmark benthic indicator species from Copco 1 and Iron Gate Reservoir under the No Action/No Project Alternative. The exception to this occurred in a single sample from J.C. Boyle Reservoir, where survival of the benthic amphipod *Hyalella azteca* indicated a moderate potential for toxicity. TEQs for dioxin, furan, and dioxin-like PCBs in reservoir and estuary sediment samples were within the range of local background values and suggest a limited potential for adverse effects for fish exposed to reservoir sediments under the No Action/No Project Alternative (CDM 2011). Similarly, based on comparison to appropriate human health sediment screening levels, a limited number of COPCs were detected in reservoir sediment samples (i.e., arsenic, nickel, dieldrin, 4,4’-DDT, 4,4’-DDD, 4,4’-DDE, dioxin-like compounds, and pentachlorophenol) (see Appendix C, Section C.7.1.1 and Table 3 in CDM [2011]).

Contaminants in Aquatic Biota The potential for bioaccumulation under the No Action/No Project Alternative can also be evaluated using fish tissue concentrations. Two studies provide data for the evaluation of bioaccumulation potential in freshwater fish:

- PacifiCorp (2004c) conducted a screening-level analysis looking at metals (i.e., arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, and zinc), organochlorine pesticides, and PCBs in the Hydroelectric Reach and Upper Klamath Lake. The PacifiCorp data suggest that, with two exceptions, fish in the KHP reservoirs do not appear to be exposed to levels of contaminants that may adversely affect beneficial uses or that are toxic or detrimental to aquatic life. The exceptions include exceedances of the total mercury wildlife screening level (0.00227 ug/g) for all tissue samples in Keno, J.C. Boyle, Copco 1, and Iron Gate Reservoirs (see Appendix C for more detail), suggesting that localized mercury methylation may be occurring during periods of stratification and anoxia in the reservoirs (see Table C-1). Another exception is that exceedances of recommended wildlife screening levels for total DDTs based on p,p'-DDE found in fish tissue samples from Upper Klamath Lake, the Keno Impoundment/Lake Ewauna, J.C. Boyle Reservoir, and Copco 1 Reservoir (see Section 3.2.3.1, Inorganic and Organic Contaminants – Hydroelectric Reach), may suggest a possible broader-scale bioaccumulation effect (see Appendix C, Table C-7).
- Results from the 2009-2010 Secretarial Determination fish tissue sampling (“Exposure Pathway 1” in CDM [2011]) indicate that mercury is present in fish tissue at levels with potential to cause minor or limited adverse effects to fish; multiple other chemicals are not present at such levels, or they are present but do not possess tissue-based TRVs for comparison (see Section 3.2.3.8 and Appendix C for more detail). Fish tissue results were also below dioxin, furan, and dioxin-like PCB TEQs, indicating no adverse effect (CDM 2011). Combined with the sediment contaminant data (see above), inorganic and organic contaminants are present in reservoir sediments at levels that have the potential to cause minor or limited adverse effects (i.e., toxicity or bioaccumulation) to freshwater aquatic species (Figure 3.2-2).

Existing inorganic and organic contaminant data characterizing reservoir sediments at the Four Facilities indicate that a relatively small number of chemicals (i.e., mercury, DDTs, and possibly dioxin-like chemicals) are present in reservoir sediments at levels that have the potential to cause minor or limited adverse effects (i.e., toxicity or bioaccumulation) to freshwater aquatic species in the Hydroelectric Reach. Continued impoundment of water at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Exposure Pathway		Freshwater biota	Marine biota	Terrestrial biota	Humans
Pathway 1	Short-term exposure to sediments flushed downstream	●	●	--	--
Pathway 2	Long-term exposure to exposed reservoir terrace and or river bank deposits	--	--	● ⁽¹⁾	● ⁽²⁾
Pathway 3	Long-term exposure to new river channels and river bed deposits	●	--	--	●
Pathway 4	Long-term exposure to marine / near shore deposits	--	●	--	--
Pathway 5	Long-term exposure to reservoir sediments	●	--	--	●

●	No adverse effects based on lines of evidence
●	One or more chemicals present, but at levels unlikely to cause adverse effects based on the lines of evidence
●	One or more chemicals present at levels with potential to cause minor or limited adverse effects based on the lines of evidence
●	At least one chemical detected at a level with potential for significant adverse effects based on the lines of evidence
--	This exposure pathway is incomplete ⁽³⁾ or insignificant ⁽⁴⁾ for this receptor group

Note:

This does not include an evaluation of the physical effects (e.g., dissolved oxygen in the water, suspended sediment)

(1) Qualitative evaluation conducted for this exposure pathway

(2) Limited quantitative, along with qualitative evaluations conducted for this exposure pathway

(3) Incomplete - receptor group is unlikely to come in contact with sediment-associated contaminants under this exposure pathway

(4) Insignificant - exposure pathway not considered a major contributor to adverse effects in humans based on best professional judgment

Figure 3.2-2. Summary of Anticipated Effects of Inorganic and Organic Contaminants in Klamath Reservoir and Estuary Sediments Under the No Action/No Project Alternative and the Proposed Action, for Five Exposure Pathways . Source: CDM 2011.

Continued impoundment of water at the Four Facilities and associated interception and retention of sediments behind the dams could result in long-term low-level exposure to inorganic and organic contaminants in the Hydroelectric Reach for humans through the consumption of resident fish tissue. Human health exposure to inorganic or organic chemicals in reservoir sediments under the No Action/No Project Alternative is primarily through consumption of resident fish. Under the No Action/No Project Alternative, direct human exposure to sediments is not considered a reasonable exposure pathway. Three studies provide data for the evaluation of human health exposure through consumption of resident fish:

- Results from California SWAMP fish tissue sampling in Copco 1 and Iron Gate Reservoirs indicate mercury tissue concentrations of 310 and 330 ng/g wet weight, respectively (Davis et al. 2010). These data are greater than the advisory tissue levels for 3 and 2 servings per week (70 and 150 ng/g wet weight, respectively) and the fish contaminant goal (220 ng/g wet weight) (see Appendix C, Section C.7), suggesting low-level bioaccumulation potential in the two largest KHP reservoirs.
- PacifiCorp (2004c) reported that, in general, fish in the reservoirs at the Four Facilities are not exposed to levels of contaminants that may adversely affect human health via fish consumption. Exceptions to this include arsenic and total PCBs, which may equal or exceed the toxicity screening level for subsistence fishers (see Appendix C, Section C.7; PacifiCorp 2004c). Additionally, a subsequent review of the PacifiCorp data and conversion to wet weight values found that mercury levels exceeded the screening level for subsistence fishers (0.049 ug/g) for samples from Keno, J.C. Boyle, Copco 1, and Iron Gate Reservoirs, and exceeded the screening level for recreational fishers (0.4 ug/g) for samples from Copco 1 and Iron Gate Reservoirs (see Appendix C for more detail).
- Results from the 2010 Secretarial Determination fish tissue sampling indicate that a relatively small number of chemicals are present in fish tissue at levels with potential to cause minor or limited adverse effects to humans through fish consumption (Figure 3.2-2). These include arsenic, total PCBs, and dioxins in yellow perch at J.C. Boyle, Copco 1, and Iron Gate reservoirs (CDM 2011). In bullhead, the same chemicals are present, with the addition of mercury for Copco 1 Reservoir (see Section 3.2.3.8.3 and Appendix C for more details).

In summary, existing fish tissue, bioassay, and sediment chemistry data indicate that continued retention of sediments behind the KHP dams under the No Action/No Project Alternative may result in concentrations of inorganic and organic contaminants at levels that adversely affect beneficial uses or are toxic to humans in the Hydroelectric Reach. This includes possible exposure to low-level bioaccumulation of arsenic (which may be naturally elevated in the Upper Klamath Basin [see Section 3.2.3.8]) and mercury in fish residing in the lacustrine environment of the Keno Impoundment/Lake Ewauna and J.C. Boyle, Iron Gate, and Copco 1 Reservoirs.

Existing inorganic and organic contaminant data characterizing fish tissue in the reservoirs at the Four Facilities indicate that a relatively small number of chemicals (i.e., mercury, arsenic, total PCBs, and dioxins) are present at levels that have the potential to cause minor or limited adverse effects to humans through fish consumption in the Hydroelectric Reach. Continued impoundment of water at the Four Facilities under the *No Action/No Project Alternative* would result in no change from existing conditions.

Lower Klamath Basin

With the possible exception of compounds (i.e., mercury) that can be released (exported) from reservoir bottom waters under seasonally anoxic conditions, continued impoundment of water at the Four Facilities is not anticipated to result in increased exposure to inorganic and organic contaminants for freshwater aquatic species in the Klamath River downstream from Iron Gate Dam. This is because contaminants that may be present in reservoir sediments at the Four Facilities would remain in place under the No Action/No Project Alternative. There is currently insufficient information to assess whether the No Action/No Project Alternative would expose downstream aquatic biota to methylmercury released from bottom waters. Bioaccumulation of algal toxins (i.e., microcystin) has been documented in fish and mussel tissue in the Klamath River downstream from Iron Gate Dam (Kann et al. 2010) and is discussed further in Section 3.3, Aquatic Resources. Potential for the Proposed Action and alternatives to affect production and toxicity of algal toxins is discussed in Section 3.4, Algae.

3.2.4.3.2 Alternative 2: Full Facilities Removal of Four Dams (Proposed Action)

The Full Facilities Removal of Four Dams (Proposed Action) is the removal of four major dams in the Klamath Hydroelectric Project (J.C. Boyle, Copco 1, Copco 2, and Iron Gate) along with the ancillary facilities of each installation in a 20-month period which includes an 8-month period of site preparation and partial drawdown at Copco 1 and a 12-month period for full drawdown and removal of facilities. This includes the entire dam, the powerhouses, spillways, and other infrastructure associated with the power generating facilities, as well as the transfer of the Keno Dam facilities to Reclamation and the implementation of the KBRA. Removal of the Four Facilities would not affect water quality in the following reaches in the Upper Klamath Basin: Wood, Williamson, and Sprague Rivers, Upper Klamath Lake, and Link River to the upstream end of J.C. Boyle Reservoir. In the Hydroelectric Reach of the Upper Klamath Basin, removal of the Four Facilities would result in the release of sediments currently trapped behind the dams. This release would have short-term (<2 years following dam removal) effects on suspended sediments, dissolved oxygen, nutrients, and inorganic and organic contaminant concentrations in the Klamath River. Under the Proposed Action, interception and retention of sediments behind the dams at the Four Facilities would no longer occur; this would have long-term (2–50 years following dam removal) effects on suspended sediments. Additionally, elimination of the lacustrine environment of the reservoirs under the Proposed Action would have long-term effects on water temperature, dissolved oxygen, nutrients, pH, algal toxins and chlorophyll-*a* in the river. The following sections provide detail regarding the anticipated effects. KBRA under the Proposed Action is addressed at a programmatic level in the last subsection of the Proposed Action.

Water Temperature

Upper Klamath Basin

Removal of the Four Facilities under the Proposed Action and elimination of hydropower peaking operations at J.C. Boyle Powerhouse could result in short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) alterations in overall water temperatures and diel water temperature variation in the J.C. Boyle Bypass and Peaking Reaches. Klamath TMDL model (see Appendix D) results indicate that under the Proposed Action (similar to the TMDL TOD2RN scenario, which includes Oregon TMDL allocations), water temperatures in the Bypass Reach immediately downstream from J.C. Boyle Dam would be similar to those under the No Action/No Project Alternative, but there would be relatively *greater* diel water temperature variation during June through September (similar to the TMDL T4BSRN scenario) due to the absence of the thermal mass in J.C. Boyle Reservoir, which tends to moderate diel water temperature variation immediately downstream from the dam under existing conditions (NCRWQCB 2010a). Greater diel variation would also occur further downstream in the J.C. Boyle Bypass Reach because it would no longer be dominated by cold groundwater inputs at a relatively constant temperature of 11–12 °C (Kirk et al. 2010, data from electronic appendices of Asarian and Kann 2006b). Water temperatures in this short river reach (i.e., downstream from the cold springs) would increase during summer months due to the elimination of bypass operations and associated increase in streamflows; however, areas adjacent to the coldwater springs in the Bypass Reach would continue to serve as thermal refugia for aquatic species because the springs themselves would not be affected by the Proposed Action. Further, as described in Section 3.3.4.3 Alternative 2: Proposed Action – Key Ecological Attributes – Water Temperature, a shift in water temperatures toward natural diel variation would increase daily maximum temperatures, but would also increase nighttime cooling providing regular thermal relief, time for repair of proteins damaged by thermal stress, and significant bioenergetic benefits for salmonids.

In the J.C. Boyle Peaking Reach model results indicate that water temperatures under the Proposed Action would exhibit slightly lower daily maximum values (0.0–2 °C [0–3.6 °F]) as compared to those predicted under the No Action/No Project and would exhibit *lower* diel water temperature variation during June through September, moving toward the natural thermal regime (Figure 3.2-3) (NCRWQCB 2010a, data from electronic appendices of Asarian and Kann 2006b). At these locations the relative difference in diel water temperature variation between the Proposed Action and the No Action/No Project Alternative is due to the elimination of peaking operations and the associated large artificial temperature swings. Overall, the TMDL model results indicate that June through October riverine water temperatures from J.C. Boyle Reservoir to the Oregon-California State line would meet the Oregon narrative natural conditions criterion that supersedes the numeric objective (i.e., 20 °C [68 °F], see Table 3.2-3) for support of coolwater habitat.

Figure 3.2-3. Predicted Water Temperature at the California-Oregon State line (RM 208.5) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario). Source: NCRWQCB 2010a.

Under the *Proposed Action*, the short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) increases in summer/fall water temperatures and diel temperature variation in the J.C. Boyle Bypass Reach due to the removal of J.C. Boyle Reservoir and elimination of bypass operations would be a less than significant impact. Slight decreases in long-term maximum summer/fall water temperatures and less artificial water temperature swings in the J.C. Boyle Peaking Reach would be beneficial.

Removal of the Four Facilities under the Proposed Action and conversion of the reservoir areas to a free-flowing river could result in short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) increases in spring water temperatures and decreases in late summer/fall water temperatures in the Hydroelectric Reach downstream from Copco 1 Reservoir.

In the California portion of the Hydroelectric Reach, the TMDL model indicates that removal of the Four Facilities under the Proposed Action would eliminate the seasonal temperature shift caused by the Four Facilities in the Hydroelectric Reach, returning the river to a more natural thermal regime. Removal of the Project reservoirs would also result in a slight increase in flow as the evaporative losses would be reduced. Evaporation from the surface of the reservoirs is currently about 11,000 acre-feet/year and after dam removal the evapotranspiration in the same reaches is expected to be approximately 4,800 acre-feet/year, resulting in a gain in flow to the Klamath River of approximately 6,200 acre-feet/year (Reclamation 2012).

The TMDL model indicates that just downstream from Copco 1 and Copco 2 Reservoirs (≈RM 198), removal of the Four Facilities would increase daily maximum temperatures that are currently up to 7°C (13°F) lower than modeled natural conditions in spring (May and June) and decrease temperatures that are up to roughly 4°C (7°F) greater than modeled natural conditions in late summer/fall (August through October), due to the presence of the reservoirs (Figure 3.2-4) (NCRWQCB 2010a). Water temperature modeling conducted for the Klamath Dam Removal Secretarial Determination Studies provides generally similar results, with RBM10 model results showing a projected shift in the annual temperature cycle that would slightly increase river temperatures in the spring, and decrease temperatures in the late summer/fall in the Hydroelectric Reach under the Proposed Action (Perry et al. 2011). Further discussion of RBM10 results is presented below for the Lower Klamath Basin.

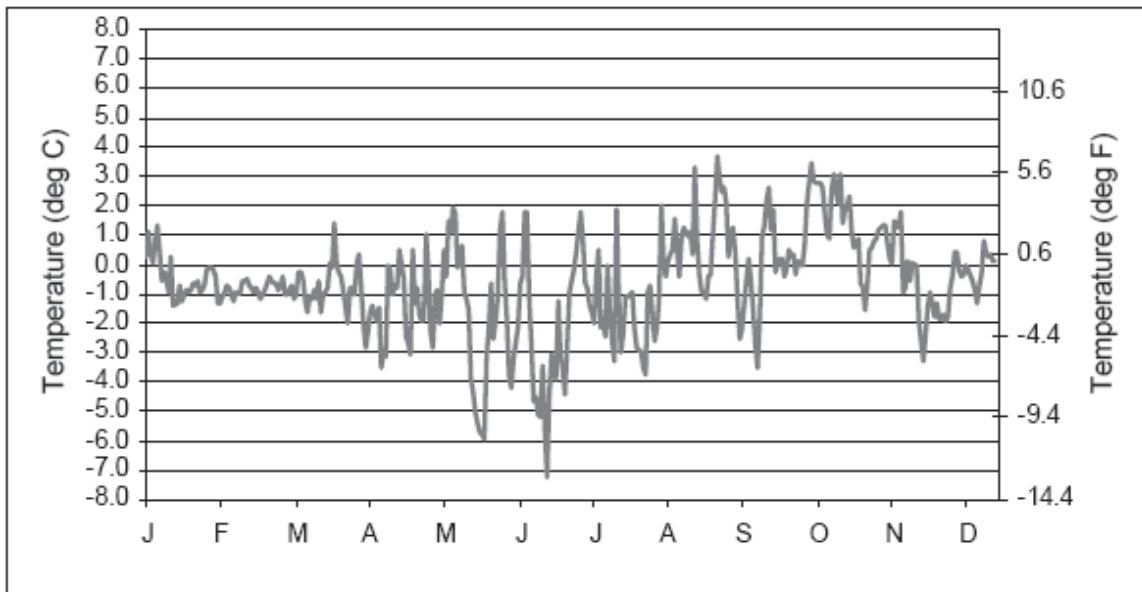

Figure 3.2-4. Estimated Changes in Daily Maximum Klamath River Water Temperatures at ≈RM 198 due to the Presence of Copco 1 and 2 Reservoirs for the 2000 Calendar Year. Positive Values Represent an Increase above Modeled Natural Conditions. Source: NCRWQCB 2010a.

Prior evaluations of the cooling effect of the Project reservoirs in spring have indicated that cooler spring water is potentially beneficial to rearing salmonids because it can reduce stress and disease for late outmigrants (PacifiCorp 2004a). However, as discussed in Section 3.3.4.3 (Alternative 2: Proposed Action), warming of spring water temperatures could lead to earlier fall-run Chinook spawning in the mainstem (reducing pre-spawn mortality) more in sync with historical spawning timing. In addition to earlier spawning, warmer spring temperatures would result in fry emerging earlier and growing

faster, which could encourage earlier emigration downstream, reducing stress and disease (Bartholow 2005, FERC 2007). Thus, the projected increase in spring water temperatures under the Proposed Action would be a less than significant effect.

The timing of reservoir drawdown under the Proposed Action was optimally developed to minimize environmental effects. Because drawdown of the reservoirs would begin in winter and would be largely complete by March/April of 2020 (i.e., prior to thermal stratification in the reservoirs), the aforementioned water temperature effects of the Proposed Action in the Hydroelectric Reach would occur, either partially or fully, within the first 1 to 2 years following dam removal and would, therefore, also be short-term effects.

The Klamath TMDL model does not address the potential long-term effects of global climate change on water temperatures in the Klamath Basin (Appendix D). As described for the No Action/No Project Alternative, climate change is expected to increase summer and fall water temperatures in the Klamath Basin on the order of 1–3 °C (1.8–5.4 °F) (Bartholow 2005, Perry et al. 2011). The Proposed Action would decrease long-term late summer/fall water temperatures and would therefore increase the likelihood that beneficial uses would be supported under climate change.

Under the *Proposed Action*, the short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) increases in springtime water temperatures and diel temperature variation in the Hydroelectric Reach would be less than significant while decreases in late summer/fall water temperatures would be beneficial.

Lower Klamath Basin

Removal of the Four Facilities under the Proposed Action and conversion of the reservoir areas to a free-flowing river could result in short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) increases in spring water temperatures, decreases in late summer/fall water temperatures, and increased diel temperature variation in the Lower Klamath River. Water temperature modeling results are available for the Lower Klamath Basin from three separate modeling efforts: the PacifiCorp relicensing efforts (KRWQM; see Appendix D); development of the California Klamath River TMDLs (see Appendix D); and, water temperature modeling conducted for the Secretarial Determination studies (RBM10; see Appendix D). KRWQM results comparing the current condition (all KHP dams in place) to four without-project scenarios (i.e., no KHP dams including Keno Dam; without Iron Gate Dam; without Copco 1, Copco 2, and Iron Gate; and without J.C. Boyle, Copco 1, Copco 2, and Iron Gate Dams) for 2001–2004 indicate that the reservoirs create a temporal shift by releasing generally cooler water from mid-January to April, variably cooler or warmer water from April through early August, and warmer water from August through November (PacifiCorp 2004a, Dunsmoor and Huntington 2006). Just downstream from Iron Gate Dam (RM 190.1), this translates to a 1–2.5°C (1.8–4.5 °F) cooling during spring and a 2–10 °C (3.6–18 °F) warming during summer and fall (Figure 3.2-5). Immediately upstream of the confluence with the Scott River

(RM 143.9), the difference between existing conditions and without-project scenarios indicates a lesser, albeit still measurable, warming of 2–5 °C (3.6–9 °F) for most of October and November (Figure 3.2-6). Because patterns in reservoir thermal structure for Iron Gate and Copco 1 indicate that stratification generally commences in April and ends in November, the effect of reservoir thermal regime on downstream water temperatures appears to be cooling during non-stratified periods and warming during stratified periods. The cooling effect in spring is potentially beneficial to rearing salmonids by reducing stress and disease for late outmigrants, although it may also have adverse effects such as a delay in emergence or outmigration (see Section 3.3.4.3.2.1.4 Water Temperature). The fall warming effect, which can be stressful to rearing salmonids, lasts for the majority of late summer and fall months and is of larger magnitude (PacifiCorp 2004a).

Reservoir thermal regimes also act to reduce the magnitude of diel temperature variation in the reservoir reaches and the riverine reaches immediately downstream from Iron Gate Reservoir (RM 190.1; see Figure 3.2-5) (Deas and Orlob 1999, PacifiCorp 2005). As with the seasonal temperature effect, the dampening influence on diel temperature variation is considerably diminished farther downstream, at the confluence with the Scott River (RM 143.9; see Figure 3.2-6). The KRWQM indicates that the temperature influence of the Hydroelectric Reach is mostly ameliorated by RM 66 at the confluence with the Salmon River (see Figure 3.2-7).

Figure 3.2-5. Simulated Hourly Water Temperature Downstream from Iron Gate Dam (RM 190.1) Based on Year 2004 for Existing Conditions Compared to Hypothetical Conditions without J.C. Boyle (JCB), Copco 1, Copco 2, and Iron Gate (IG) Dams. Source: PacifiCorp 2005.

In agreement with KRWQM results, Klamath TMDL model (see Appendix D) results also indicate that under the Proposed Action (similar to the TMDL TCD2RN scenario), water temperature in the Klamath River downstream from Iron Gate Dam (RM 190.1) would be 2–10 °C (3.6–18 °F) lower during August through November and 2–5 °C (3.6–9°F) higher during January through March than those under the No Action/No Project (similar to the TMDL T4BSRN scenario), due to removal of the large thermal mass created by the reservoirs (NCRWQCB 2010a). The Klamath TMDL model also predicts that diel variation in water temperature at this location during this same period would be greater under the Proposed Action (TCD2RN) than the No Action/No Project Alternative (T4BSRN) as water temperatures would be in equilibrium with (and would reflect) diel variation in ambient air temperatures. As with KRWQM, these impacts of removal of the Four Facilities would decrease in magnitude with distance downstream from Iron Gate Dam, and they would not be evident in the reach downstream from the Salmon River confluence (≈RM 66) (NCRWQCB 2010a, Dunsmoor and Huntington 2006). Therefore, under the Proposed Action, water temperatures would not be directly affected in the lower river downstream from the confluence with the Salmon River, including the Klamath Estuary and the marine nearshore environment.

As part of the Klamath Dam Removal Secretarial Determination studies, the effects of climate change were included in model projections for future water temperatures under the No Action/No Project Alternative and the Proposed Action. RBM10 model results using climate change predictions from five GCMs indicate that future water temperatures under the Proposed Action (where simulated flows are subject to KBRA flows) and climate change would be 1–2.3 °C (1.8–4.1 °F) warmer than historical temperatures (Perry et al. 2011). This temperature range is slightly lower than that suggested by projecting Bartholow (2005) historical (1962–2001) estimates of 0.05 °C (0.09 °F) per year, or 2–3 °C (3.6–5.4 °F) over 50 years. However, within the general uncertainty of climate change projections, results from the two models correspond reasonably well and indicate that water temperatures in the Upper Klamath Basin are expected to increase within the period of analysis on the order of 1–3 °C (1.8–5.4 °F).

RBM10 results also indicate that, despite warming of water temperatures under climate change, the primary effect of dam removal is still anticipated to be the return of approximately 160 miles of the Klamath River, from J.C. Boyle Reservoir (RM 224.7) to the Salmon River (RM 66), to a natural thermal regime (Perry et al. 2011). Model results indicate that the annual temperature cycle downstream from Iron Gate Dam would shift forward in time by approximately 18 days under the Proposed Action, with warmer temperatures in spring and early summer and cooler temperatures in late summer and fall immediately downstream from the dam. Just downstream from Iron Gate Dam, water temperatures under the Proposed Action including climate change would average 2 °C greater in May than those under the No Action/No Project Alternative, while during October water temperatures would average 4 °C cooler. At the confluence with the Scott River, the differences would be diminished, but there would still be a slight warming (<1 °C) in the spring and cooling (1–2 °C) in the late summer and fall (Perry et al. 2011). Thus, despite the anticipated warming under climate change, water temperature improvements under the Proposed Action would still help to achieve the Oregon and California temperature TMDLs for the mainstem Klamath River.

Although all of the existing water temperature model projections (KRWQM, TMDL, RBM10) indicate that spring water temperatures would increase under the Proposed Action, as discussed in Section 3.3.4.3 (Alternative 2: Proposed Action) this effect could lead to earlier spawning of natural fall-run Chinook salmon, a longer incubation period, earlier emergence and growth, and would encourage earlier emigration, thus reducing stress and disease for this species (Hamilton et al. 2011). Overall, the increase in spring water temperatures under the Proposed Action would be a less than significant.

The timing of reservoir drawdown under the Proposed Action was optimally developed to minimize environmental effects. Because drawdown of the reservoirs would begin in winter and would be largely complete by March/April of 2020 (i.e., prior to reservoir thermal stratification), water temperature effects of the Proposed Action in the Klamath River downstream from Iron Gate Dam would occur, either partially or fully, within the first 1 to 2 years following dam removal and would be a short-term effect as well as a long-term effect.

Under the *Proposed Action*, the short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) increases in spring water temperatures and increased diel temperature variation for the reach from Iron Gate Dam to the confluence with the Salmon River would be less than significant. Decreases in late summer/fall water temperatures would be beneficial. There would be no change from existing conditions on water temperatures for Klamath River downstream from the Salmon River, the Klamath Estuary, and the marine nearshore environment.

Sediment release associated with the removal of the Four Facilities under the Proposed Action could cause short-term (<2 years following dam removal) and/or long-term (2-50 years following dam removal) increases in sediment deposition in the Klamath River or Estuary that could alter morphological characteristics and indirectly affect seasonal water temperatures. Increased sediment deposition in the estuary under the Proposed Action may decrease the size of the salt wedge, either by increasing the frequency of mouth closure, or by elevating the bottom of the estuary above portions of the tidal range when the mouth is open. Alternately, scouring of current estuarine sediment deposits may occur during the short-term high sediment transport predicted to occur following dam removal, which may sufficiently change morphology as to effect mouth closure, salt wedge formation, and associated seasonal water temperatures. However, because little short-term settling, sedimentation, or scouring is expected to occur in the Klamath River or the estuary as a result of the Proposed Action (see Section 3.11.4.3), and estimates of baseline sediment delivery for the Klamath Basin indicate that long-term sediment delivery rates will not change substantially under the Proposed Action (Stillwater Sciences 2010), **there would be no indirect effect on water temperatures in the Klamath Estuary under the *Proposed Action*.**

Suspended Sediments

Upper Klamath Basin

Sediment release associated with the Proposed Action could cause short-term (<2 years following dam removal) increases in suspended material in the Hydroelectric Reach

downstream from J.C. Boyle Dam due to the release of sediments currently trapped behind the dams at the Four Facilities. Results of sediment transport modeling of the impacts of dam removal on suspended sediment in the Lower Klamath River indicate high short-term loads immediately downstream from Iron Gate Dam under the Proposed Action (Reclamation 2012, Stillwater Sciences 2008). Modeled SSCs⁸ downstream from J.C. Boyle Reservoir are similarly high in the short term, although due to the relatively small volume of the sediment deposits behind J.C. Boyle Dam (i.e., 15 percent of total volume for the Four Facilities, see also Figure 3.3-8), concentrations would be considerably less than those anticipated to occur downstream from Iron Gate Reservoir. Overall, and within the general uncertainty of the model predictions, SSCs at J.C. Boyle Reservoir across the three water year types would have peak values of 2,000–3,000 mg/L and occurring within 1–2 months of reservoir drawdown. Predicted SSCs quickly decrease to less than 100 mg/L for 5–7 months following drawdown, and concentrations less than 10 mg/L for 6–10 months following drawdown (Figures 3.2-8 through 3.2-10). **Under the Proposed Action, the short-term (<2 years following dam removal) increases in SSCs in the Hydroelectric Reach downstream from J.C. Boyle Dam would be a significant impact.**

Figure 3.2-8. Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Action Assuming Typical Dry Hydrology (WY2001).

⁸ For the purposes of this report, SSC is considered equivalent to TSS. As needed, data from multiple sources reported as either TSS or SSC are used interchangeably, despite potential differences in the numeric values reported by each method. (Gray et al. 2000).

Figure 3.2-9. Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Action Assuming Median Hydrology (WY1976).

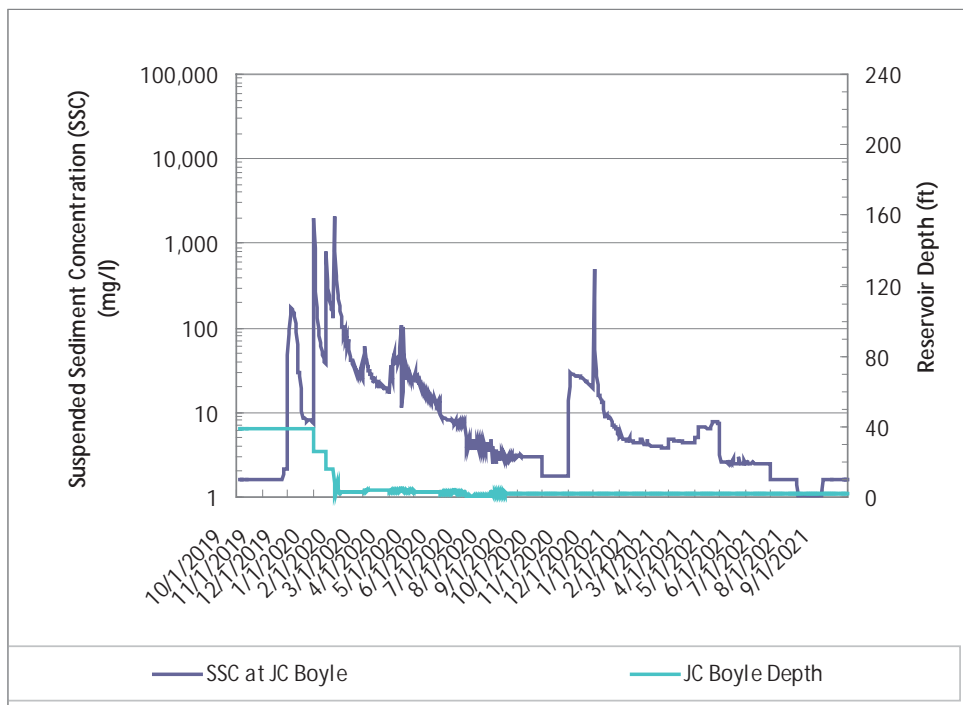

Figure 3.2-10. Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Action Assuming Typical Wet Hydrology (WY1984).

Stormwater runoff from deconstruction activities under the Proposed Action could cause short-term increases in suspended material in the Hydroelectric Reach during the deconstruction period. Deconstruction activities under the Proposed Action would include demolition of the dams and their associated structures, power generation facilities, transmission lines, installation of temporary cofferdams, road upgrading, hauling, reservoir restoration, and other activities (as described in Section 2.4.3.1). Deconstruction activities are scheduled to occur between January 10 and June 26, with cofferdam installation scheduled to occur between 2 January 2020 and 6 February 2020. Therefore, cofferdam installation would occur during the first month of reservoir drawdown and the period of peak SSCs associated with mobilization of reservoir sediment deposits during drawdown. While the magnitude of short-term effects on SSCs due to erosion of the large volume of reservoir sediment deposits trapped behind the dams would be substantially greater than those due to dam deconstruction activities, this does not alleviate the requirement to reduce impacts from deconstruction-related activities. The potential for sediments to enter the Hydroelectric Reach from deconstruction site runoff, cofferdam installation, or in-water deconstruction work can be minimized or eliminated through the implementation of BMPs for deconstruction activities that would occur in or adjacent to the Klamath River (Appendix B). **Under the Proposed Action, the effect of stormwater runoff from deconstruction activities on SSCs in the Hydroelectric Reach downstream from J.C. Boyle Dam would be a less-than-significant impact.**

Implementation of IM 7, J.C. Boyle Gravel Placement and/or Habitat Enhancement, could result in short-term increases in mineral (inorganic) suspended material in the Hydroelectric Reach. The Proposed Action includes seven out of the eight years of gravel placement under IM 7; the first year would be before the Secretary makes a determination, and would therefore be included in the No Action/No Project Alternative. The following seven years would be part of the Proposed Action. Under this IM, suitable spawning gravel would be placed in the J.C. Boyle Bypass and Peaking reaches. The spawning gravel would be placed using a passive approach before high flow periods, or to provide for other habitat enhancement in the Klamath River upstream of Copco 1 Reservoir. These actions would provide improvements in habitat quality for resident fish prior to dam removal, and for resident and anadromous species following dam removal (for effects on aquatic species, see Section 3.3.4.3.2). Passive gravel placement is specified by IM 7, which would avoid in-stream placement of gravel and would limit turbidity increases to periods of high river flow when turbidity is naturally elevated. The potential for sediments to enter the water during gravel placement along the river banks could be minimized or eliminated downstream from the enhancement sites through the implementation of BMPs for construction activities (Appendix B) (BLM 2011). Any disturbed sediments would be trapped by Copco 1 Reservoir and not transferred downstream to the Klamath River prior to dam removal, particularly given implementation of BMPs. **Under the Proposed Action, the short-term effect of IM 7, J.C. Boyle Gravel Placement and/or Habitat Enhancement, on SSCs in the Hydroelectric Reach would be a less-than-significant impact.**

Implementation of IM 16, Water Diversions, could result in short-term increases in mineral (inorganic) suspended material in the Hydroelectric Reach due to diversion screening deconstruction and construction activities. Under IM 16, PacifiCorp would seek to eliminate three screened diversions (the Lower Shovel Creek Diversion [7.5 cfs], Upper Shovel Creek Diversion [2.5 cfs], and Negro Creek Diversion [5 cfs]) from Shovel and Negro Creeks and would seek to modify its water rights to move the points of diversion from Shovel and Negro creeks to the mainstem Klamath River. If this were successful the screened diversions would be removed prior to dam removal in 2020. The intent of this measure is to provide additional water to Shovel and Negro creeks, thus increasing the quality and amount of suitable habitat for aquatic species within these tributaries, while not diminishing PacifiCorp's water rights. The potential for sediments to enter the water during screen removal activities is minimal if the diversions are individual pump intakes. If the diversions are larger concrete structures, the impacts would be of greater magnitude and longer duration, albeit still short-term and due to construction/deconstruction activities. In this case, impacts to SSCs can be minimized or eliminated through the implementation of BMPs for construction activities (Appendix B) stipulated during permitting of IM 16. Since IM 16 would be undertaken prior to dam removal, any disturbed sediments would be trapped by Copco 1 Reservoir and not transferred downstream to the Klamath River prior to dam removal, particularly given implementation of BMPs. The diversions would not be likely to affect other aspects of short-term or long-term water quality in the mainstem Klamath River since the water rights are relatively small (7.5 cfs, 2.5 cfs, and 5 cfs) compared to seasonal low flows in the mainstem upstream of Copco 1 Reservoir (typically >800 cfs). **Under the Proposed Action, the effect of IM 16, Water Diversions, on SSCs in the Hydroelectric Reach in the J.C. Boyle Bypass Reach would be a less-than-significant impact.**

Under the Proposed Action, recreational facilities currently located on the banks of the existing reservoirs will be removed following drawdown, and could release suspended sediment into the Klamath River. The existing recreational facilities provide camping and boating access for recreational users of the reservoirs. Once the reservoirs are drawn down, these facilities will be removed. The potential for sediments to enter the water during the facilities removal will be minimized or eliminated through the implementation of BMPs for construction activities (Appendix B). Implementation of BMPs would ensure that impacts are constrained to the individual sites and their immediate area, and not transferred downstream in the Klamath River. **Under the Proposed Action, the short-term impacts on SSCs from the deconstruction of the recreational facilities would be less-than-significant.**

Under the Proposed Action, revegetation associated with management of the reservoir footprint area could decrease the erosion of fine sediments from exposed reservoir terraces in the Hydroelectric Reach. Based on the reservoir area management planning currently underway, establishment of herbaceous vegetation in drained reservoir areas will be undertaken to stabilize the surface of the sediment and minimize erosion from exposed terrace surfaces following drawdown (O'Meara et al. 2010). Hydroseeding of herbaceous vegetation (i.e., grass) would be used, which typically entails applying a

mixture of wood fiber, seed, fertilizer, and stabilizing emulsion to exposed slopes. Hydroseeding would be undertaken using a barge in spring 2020 while reservoir levels are high enough to operate and access the barge. Later in spring and summer 2020, aerial application would be necessary for precision applications of material near the newly established river channel, as well as in the remaining areas (see Section 2.3.4.5). Some aerial fall seeding in 2020 might be necessary to supplement areas where spring hydroseeding was unsuccessful.

Hydroseeding would be undertaken using standard BMPs for reducing water quality impacts during deconstruction and/or construction activities and restoration projects (Appendix B). Additional BMPs specific to hydroseeding, such as avoiding over-spray onto roads, trails, existing vegetation, and the stream channel, would also be implemented so that the hydroseed mixture itself would not easily runoff or be directly sprayed into the Klamath River. **Under the Proposed Action, hydroseeding would decrease the short-term (<2 years following dam removal) erosion of fine sediments from exposed reservoir terraces into the river channel in the Hydroelectric Reach and would be beneficial.**

Under the Proposed Action, the lack of continued interception and retention of mineral (inorganic) suspended material by the dams at the Four Facilities could result in long-term (2–50 years following dam removal) increases in suspended material in the Hydroelectric Reach. Peak concentrations of mineral (inorganic) suspended material (silts and clays with diameter < 0.063 mm) in the Hydroelectric Reach during the winter/early spring (November through April) would likely remain associated with high-flow events and any increases due to the lack of interception by the dams would not be large; estimates of baseline sediment delivery for the Klamath Basin indicate that a relatively small fraction of total sediment (199,300 tons per year or 3.4 percent of the cumulative average annual delivery from the basin) is supplied to the Klamath River on an annual basis from the upper and middle Klamath River (i.e., from Keno Dam to the Shasta River) due to the generally lower rates of precipitation and runoff, more resistant and permeable geologic terrain, and relatively low topographic relief and drainage density of the Upper Klamath Basin as compared with the lower basin. (Stillwater Sciences 2010). **Under the Proposed Action, the long-term (2–50 years following dam removal) increase in mineral (inorganic) suspended material in the Hydroelectric Reach would be a less-than-significant impact.**

Under the Proposed Action, the lack of continued interception and retention of algal-derived (organic) suspended material by the dams at the Four Facilities could result in slight long-term (2–50 years following dam removal) increases in suspended material in the Hydroelectric Reach. Episodic increases (10–20 mg/L) in algal-derived (organic) suspended material resulting from in-reservoir algal productivity are not expected to

occur in the Hydroelectric Reach following dam removal. SSCs in the Hydroelectric Reach may attain levels similar to those observed upstream of J.C. Boyle Dam under existing conditions during May through October (>15 mg/L; see Appendix C), as algal-dominated suspended material is transported downstream from Upper Klamath Lake. However, similar to the No Action/No Project Alternative, interception and retention of suspended material from upstream sources would still occur to a large degree in the Keno Impoundment/Lake Ewauna, as would additional decreases in concentration due to mechanical breakdown of algal remains in the turbulent river reaches between Keno Dam and Copco 1 Reservoir, and dilution from the springs downstream from J.C. Boyle Dam. If slight long-term increases in suspended materials did occur, they would likely be offset by the loss of algal-derived suspended material previously produced in Copco 1 and Iron Gate Reservoirs and would not exceed levels that would substantially adversely affect the cold freshwater habitat (COLD) beneficial use (see discussion under Alternative 2 – Suspended Sediments – Lower Klamath Basin). **Under the Proposed Action, the long-term (2–50 years following dam removal) changes in algal-derived (organic) suspended material in the Hydroelectric Reach would be a less-than-significant impact.**

Lower Klamath Basin

Sediment release associated with the removal of the Four Facilities under the Proposed Action could cause short-term (<2 years following dam removal) increases in suspended material in the Lower Klamath River and the Klamath Estuary. Sediment transport modeling of the impacts of dam removal on suspended sediment in the Lower Klamath River indicates high short-term loads immediately downstream from Iron Gate Dam under the Proposed Action (Reclamation 2012, Stillwater Sciences 2008). The Proposed Action involves a three-phase drawdown for Copco 1 Reservoir beginning on November 1, 2019, and a single-phase drawdown for J.C. Boyle and Iron Gate Reservoirs beginning on January 1, 2020 (Reclamation 2012), which allows maximum SSCs⁹ to occur during winter months when flows and SSCs are naturally high in the mainstem river (e.g., see Appendix C, Figure C-9). Suspended sediment model predictions downstream from Iron Gate Dam for the Proposed Action are presented in Figure 3.2-11 through 3.2-13 for the three water year types (dry, median, wet) considered as part of the Secretarial Determination process. Model predictions are discussed below and summarized in Table 3.2-11.

⁹ For the purposes of this report, SSC is considered equivalent to TSS. As needed, data from multiple sources reported as either TSS or SSC are used interchangeably, despite potential differences in the numeric values reported by each method. (Gray et al. 2000).

Figure 3.2-11. SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Action Assuming Typical Dry Hydrology (WY2001).

Figure 3.2-12. SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Action Assuming Median Hydrology (WY1976).

Figure 3.2-13. SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Action Assuming Typical Wet Hydrology (WY1984).

Table 3.2-11. Summary of Model Predictions for SSCs in the Klamath River Downstream from Iron Gate Dam for the Proposed Action

Water Year Type	Peak SSC (mg/L)	SSC ≥ 1,000 mg/L		SSC ≥ 100 mg/L		SSC ≥ 30 mg/L	
		Duration (Months)	Time Period	Duration (Months)	Time Period	Duration (Months)	Time Period
Dry (WY2001)	13,600	3	January–March 2020	6	January–June 2020	10	January–October 2020
Median (WY1976)	9,900	2	January–February 2020	5	January–May 2020	6	January–June 2020
Wet (WY1984)	7,100	2	January–February 2020 and April–July 2020	7	November 2019–February 2020 and April–June 2020	9	November 2019–July 2020

For typical dry year (WY2001) hydrologic conditions, predicted SSCs in the Klamath River immediately downstream from Iron Gate Dam (RM 190.1) experience a relatively small increase to near 100 mg/L in mid-November 2019 as Copco 1 undergoes the first phase of drawdown. A second, relatively large increase (>1,000 mg/L) would occur in early January 2020 when Iron Gate and J.C. Boyle begin drawdown and Copco 1 enters phase 2 of drawdown. Concentrations remain very high (>1,000 mg/L) for approximately 3 months from January through April 2020 (see Figure 3.2-11), with peak values exceeding 10,000 mg/L to reach approximately 13,600 mg/L for a short period (4–5 days) in mid-February 2020. SSCs generally return to less than 100 mg/L by July 2020, and to concentrations near 30 mg/L by October 2020. Predicted SSCs increase again to levels between 200–400 mg/L during winter and spring of 2021 due to flushing of sediments that were not removed during the first year following drawdown.

Model predictions for median year (WY1976) hydrologic conditions follow a pattern similar to that of a typical dry year (WY2001), with a relatively small increase in SSCs (i.e., to near 200 mg/L) in mid-December 2019, and a large (>1,000 mg/L) increase again in early January 2020. Peak SSCs downstream from Iron Gate Dam are predicted to be lower for the median year condition, reaching levels just under 10,000 mg/L. Relative to the typical dry year, the lower median year peak SSCs are a result of greater flows flushing the same volume of sediment out of the reservoir and downstream. Peak concentrations also occur in mid-February 2020 for the median year hydrologic condition (see Figure 3.2-12). Predicted SSCs downstream from Iron Gate Dam (RM 190.1) remain very high (>1,000 mg/L) for approximately 2 months following the inception of drawdown in Iron Gate and Copco 1 Reservoirs, from January through February 2020. There is a slightly earlier return to SSCs less than 100 mg/L for the median year (WY1976), with concentrations decreasing by May 2020. SSCs decrease to less than 30 mg/L by June 2020, and fluctuate between 10 mg/L and 100 mg/L through the remainder of 2020. The increases above 100 mg/L are not predicted for the typical median water year condition in the year following dam removal (2021), but fluctuating SSCs may occur in the second year following dam removal due to erosion of sediment deposits remaining in the reservoir footprint area.

Model predictions for typical wet year (WY1984) hydrologic conditions indicate a higher initial pulse of fine sediments following the first phase of Copco 1 drawdown in early to mid-December 2019, with concentrations at or near 400 mg/L. Model predictions indicate that for typical wet year conditions, the outlet capacity at Copco 1 Dam is exceeded during the same timeframe and the reservoir fills slightly (see Figure 3.2-13). Very high (>1,000 mg/L) SSCs are experienced for approximately 2 months following the inception of drawdown in the reservoirs, from January through February 2020 (see Figure 3.2-13). SSCs reach approximately 7,100 mg/L, with peak values occurring in mid-February 2020. Secondary peaks (\approx 1,000 mg/L) in SSCs occur in mid-April and June 2020 for wet year (WY1984) hydrologic conditions. SSCs generally return to less than 100 mg/L during the month of March 2020 and then again by July 2020. Concentrations return to less than 30 mg/L by July 2020.

For all three water year types, predicted SSCs in the Lower Klamath River decrease to 60–70 percent of their value at Iron Gate Dam by Seiad Valley (RM 129.4) and to 40 percent of their value at Iron Gate Dam by about RM 59, downstream from Orleans (Reclamation 2012).

Overall, and within the general uncertainty of the model predictions, SSCs across the three water year types would have peak values of 7,000–14,000 mg/L and would occur within 2–3 months of reservoir drawdown. SSCs in excess of 1,000 mg/L would occur on a timescale of weeks to months (see Table 3.2-11), as compared to SSCs greater than 1,000 mg/L that can occur during winter storm events on a timescale of days to weeks under existing conditions in the Klamath River downstream from Iron Gate Dam (see Appendix C, Section C.2.2.2). Predicted SSCs would remain greater than or equal to 100 mg/L for 5–7 months following drawdown, and concentrations would remain greater than or equal to 30 mg/L for 6–10 months following drawdown (Table 3.2-11). Model results also indicate that while dilution in the lower river would decrease SSCs to 60–70 percent of their initial value downstream from Seiad Valley (RM 129.4) and to 40 percent of their initial value downstream from Orleans (\approx RM 59), within a factor of 2 uncertainty for the model results it can be conservatively assumed that SSCs in the Lower Klamath River would be sufficient (≥ 30 mg/L) to substantially adversely affect beneficial uses throughout the lower River and the Klamath Estuary for 6–10 months following drawdown (Reclamation 2012). A more detailed analysis of the anticipated suspended sediment effects on key fish species in the lower river is presented in Section 3.3.4.3.

Overall, sediment release associated with the Proposed Action would cause short-term increases in suspended material (≥ 30 mg/L for 6–10 months following drawdown) that would result in non-attainment of applicable North Coast Basin Plan water quality objectives for suspended material in the Lower Klamath River and the Klamath Estuary and would substantially adversely affect the cold freshwater habitat (COLD) beneficial use. **Under the Proposed Action, the short-term (<2 years following dam removal) increases in SSCs in the Lower Klamath River and the Klamath Estuary would be a significant impact.**

Sediment release associated with the removal of the Four Facilities under the Proposed Action could cause short-term (<2 years following dam removal) increases in sediment loads from the Klamath River to the Pacific Ocean and corresponding increases in concentrations of suspended material and rates of deposition in the marine nearshore environment. Sediment transport modeling predicted that 1.2 to 2.3 million tons of sediment (5.4 to 8.6 million yd³, or 36 to 57 % of the total sediments deposited behind the dams by 2020) would be eroded from the reservoir areas upon dam removal (Reclamation 2012) (see also Section 2.2, text box on sediment weight and volume). The range of potential erosion volumes is due to the range in potential water year types that could occur during the year of dam removal.

To put the anticipated erosion volume due to dam removal in the context of annual basin-wide sediment discharge, Stillwater Sciences (2010) estimated that Klamath River annual

total sediment discharge to the estuary is approximately 5.8 million tons (4 million tons/yr of fine sediment and 1.8 million tons/yr of sand and larger sediment). Farnsworth and Warrick (2007) estimate that the annual average silt and clay discharge is 1.2 million tons/yr. There is considerable uncertainty in the annual average sediment load estimates because there is large variation in the measurement of suspended sediment concentrations (SSCs) and there is not a unique relationship between flow and SSCs. In addition, the annual variation in sediment loads in the Klamath River is large. A single storm in 1964-1965 is estimated to have contributed more than 15 million tons of sediment to the Pacific Ocean (Reclamation 2012; Stillwater Sciences 2010). However, in dry years the supply of sediment to the ocean could be much less than 1 million tons/yr (see Figure 3.2-14). Given these estimates, it is expected that the amount of sediment released as a result of dam removal would be similar to that transported by the Klamath River to the Pacific Ocean in year with average flow, much less than that transported by the Klamath River in a wet year, and significantly greater than that transported by the Klamath River in a dry year.

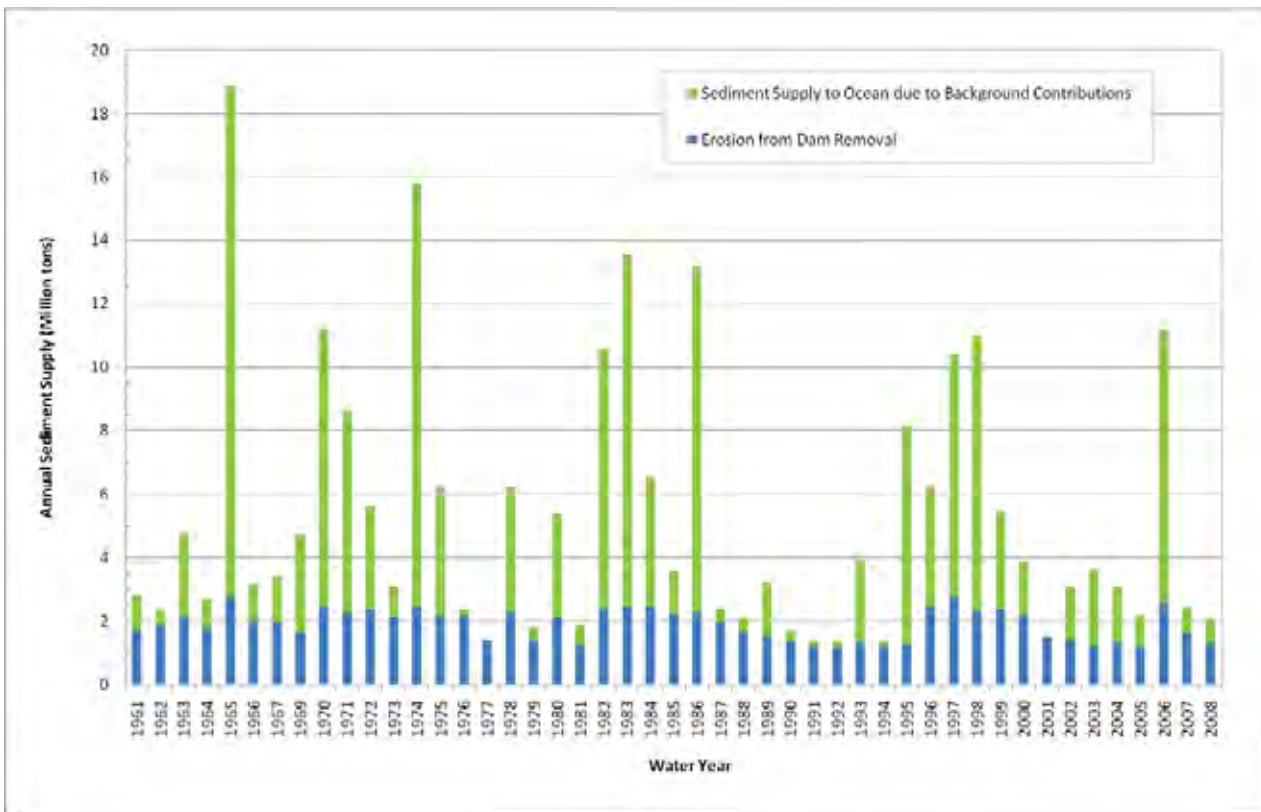

Figure 3.2-14. Annual predicted sediment delivery to the Pacific Ocean under the Proposed Action and the No Action (background conditions) by Water Year. Note: model results are only valid for the year of dam removal. No significant increase in sediment loads is predicted in years following dam removal (Source: Reclamation 2012).

After exiting the river mouth, the high SSCs (>1,000 mg/L) transported by the Lower Klamath River would form a surface plume of less dense, turbid, surface water floating on more dense, salty ocean water (Mulder and Syvitski 1995). No detailed investigations of the likely size and dynamics of the Klamath River plume have been conducted. Thus, it is not possible to predict accurately the sediment deposition pattern and location in the nearshore environment. However, the general dynamics and transport mechanisms of fine sediment can be surmised based upon regional oceanographic and sediment plume studies.

The California Marine Life Protection Act (MLPA) 2008 Draft Master Plan identifies freshwater plumes as one of three prominent habitats with demonstrated importance to coastal species (California Marine Life Protection Act 2008). The California MLPA Master Plan Science Advisory Team (2011) Methods Report designates river plumes as a key habitat to be included in marine protected areas because they harbor a particular set of species or life stages, have special physical characteristics, or are used in ways that differ from other habitats.

A recent USGS overview report on the sources, dispersal, and fate of fine sediment delivered to California's coastal waters (Farnsworth and Warrick 2007) found the following:

- Rivers dominate the supply of fine sediment to the California coastal waters, with an average annual flux of 34 million metric tons.
- All California coastal rivers discharge episodically, with large proportions of their annual sediment loads delivered over the course of only a few winter days.
- After heavy loading of fine sediment onto the continental shelf during river floods, there is increasing evidence that fluid-mud gravity flows occur within a layer 10 to 50 cm above the seabed and efficiently transport fine sediment offshore.
- Although fine sediment dominates the mid-shelf mud belts offshore of California river mouths, these mud belts are not the dominant sink of fine sediment, much of which is deposited across the inner shelf and deeper water off the continental shelf.
- Accumulation rates of fine sediment, which can exceed several millimeters per year, are generally highest near river sources of sediment and along the inner shelf and midshelf.

Farnsworth and Warrick (2007) conclude that fine sediment is a natural and dynamic element of the California coastal system because of large, natural sediment sources and dynamic transport processes.

In northern California, plume zones are primarily north of river mouths because alongshore currents and prevailing winds are northward during periods of strong runoff (Geyer et al. 2000, Pullen and Allen 2000, Farnsworth and Warrick 2007, California MLPA Master Plan Science Advisory Team 2011). Surface plumes occurring during periods of northerly (upwelling favorable) winds will thin and stretch offshore, while in

the presence of southern downwelling-favorable winds, the plume may hug the coastline and mix extensively (Geyer et al. 2000, Pullen and Allen 2000, Borgeld et al. 2008). River plume area, location, and dynamics are also affected by the magnitude of river discharge, SSCs, tides, the magnitude of winter storms, and regional climatic and oceanographic conditions such as El Niño-Southern Oscillation (ENSO) and Pacific Decadal Oscillation (PDO) climate cycles (Curran et al. 2002).

During several large flood events on the geographically proximal Eel River in the winter of 1997 and 1998, Geyer et al. (2000) found the following: flood conditions were usually accompanied by strong winds from the southern quadrant. The structure of the river plume was strongly influenced by the wind-forcing conditions. During periods of strong southerly (i.e., downwelling favorable) winds, the plume was confined inside the 50-m isobath (i.e., sea floor contour at 50-m below the water surface), within about 7 km of shore. Occasional northerly (upwelling favorable) winds arrested the northward motion of the plume and caused it to spread across the shelf. Transport of the sediment plume was confined to the inner shelf (water depths less than 50 m), during both southerly and northerly wind conditions. During southerly wind periods, fine, un-aggregated sediment was rapidly transported northward to at least 30 km from the river mouth, but flocculated sediment was deposited within 1–10 km of the river mouth. During northerly (upwelling-favorable) winds, most of the sediment fell out within 5 km of the mouth, and negligible sediment was carried offshore. The Eel River mouth is 120 km (75 miles) to the south of the Klamath River mouth and thus serves as a reasonable system for comparison.

Based upon Eel River plume studies and current knowledge of northern California oceanographic patterns, the fine sediment discharged to the marine nearshore environment under the Proposed Action would likely be delivered to the ocean in a buoyant river plume that hugs the shoreline as it is transported northward. However, since the flushing of sediments from behind the dams will occur over a number of weeks to months (and perhaps to some degree over 1-2 years), the plume carrying reservoir sediments would likely be influenced by a range of meteorological and ocean conditions (e.g., storm and non-storm periods, differing storm directions). Therefore, some of the time the plume would likely be constrained to shallower nearshore waters, while at other times it would likely extend further offshore and spread more widely. While elevated SSCs (i.e., 10–100 mg/L) created in the nearshore plume would affect physical water quality characteristics specified in the Ocean Plan (i.e., visible floating particulates, natural light attenuation, the deposition rate of inert solids [Table 3.2-7]), the effects are likely to be within the range caused by historical storm events.

A 1995 Eel River flood with a 30-yr return period delivered an estimated 25 ± 3 million metric tons of fine-grained ($<62 \mu\text{m}$) sediment to the ocean (Wheatcroft et al. 1997). Transported sediments formed a distinct layer on the sea bed that was centered on the 70-m isobath, extended for 30 km along shelf and 8 km across shelf, and was as thick as 8.5 cm. Wheatcroft et al. (1997), estimated that 75% of the flood-derived sediment did not form a recognizable sea-floor deposit, but was instead rapidly and widely dispersed over the continental margin.

A considerable amount of fine sediment in the plume is anticipated to initially deposit on the seafloor shoreward of the 60-m isobath along the coast, with greater quantities depositing in close proximity to the mouth of the Klamath River. After this initial deposition, as described by Farnsworth and Warrick (2007), resuspension during the typical winter storms would likely occur before final deposition and burial. Much of this sediment will eventually be transported further offshore to the mid-shelf and into deeper water depths off-shelf through progressive resuspension and fluid-mud gravity flows.

Because of the complexities of the transport processes, the area and depth of the deposition of fine sediment from the Proposed Action cannot be precisely predicted. However, the short-term (< 2 years following dam removal) plume effects and long-term (2–50 years following dam removal) sediment deposit effects would be less-than-significant given the relatively small amount of total sediment input, in comparison to the total annual sediment inputs to the nearshore environment, and the fact that river plume sediment inputs are a naturally occurring process. As a result, net deposition of reservoir sediments to the marine nearshore bottom substrates should be relatively less concentrated (i.e., thinner deposits in any one spot) and more widespread.

In summary, due to the relatively small magnitude of SSCs released to the nearshore environment, the anticipated rapid dilution of the sediment plume as it expands in the ocean, and the relatively low rate of deposition of sediments to the marine nearshore bottom substrates, **the short-term (< 2 years following dam removal) increases in SSCs and fine sediment deposition in the marine nearshore environment under the Proposed Action would be a less-than-significant impact.**

Stormwater runoff from deconstruction activities under the Proposed Action could cause short-term increases in suspended material in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment during the deconstruction period.

Deconstruction activities under the Proposed Action would include demolition of the dams and their associated structures, power generation facilities, transmission lines, installation of temporary cofferdams, road upgrading, hauling, reservoir restoration, and other activities (as described in Section 2.4.3.1). Deconstruction activities are scheduled to occur between January 10 and June 26, with cofferdam installation scheduled to occur between 2 January 2020 and 6 February 2020. Therefore, cofferdam installation would occur during the first month of reservoir drawdown and the period of peak SSCs associated with mobilization of reservoir sediment deposits during drawdown. While the magnitude of short-term effects on SSCs due to erosion of the large volume of reservoir sediment deposits trapped behind the dams would be substantially greater than those due to dam deconstruction activities, this does not alleviate the requirement to reduce impacts from deconstruction-related activities. Although suspended materials from deconstruction would not likely reach the Klamath Estuary or marine nearshore environment, the potential for sediments to enter the water from deconstruction site runoff or in-water deconstruction work can be minimized or eliminated through the implementation of BMPs for deconstruction activities that would occur in or adjacent to the Klamath River. **Under the Proposed Action, the effect of stormwater runoff from deconstruction activities on SSCs in the Lower Klamath River and the Klamath**

Estuary would be a less-than-significant impact. There would be no change from existing conditions on the marine nearshore environment.

Under the Proposed Action, revegetation associated with management of the reservoir footprint area could decrease the transport of fine sediments eroded from exposed reservoir terraces into the Lower Klamath River and Klamath Estuary. As described for the Upper Klamath Basin, establishment of herbaceous vegetation in drained reservoir areas will be undertaken to stabilize the surface of the sediment and minimize erosion from exposed terrace surfaces following drawdown (O’Meara et al. 2010). Hydroseeding would be undertaken using standard BMPs for reducing water quality impacts during deconstruction and/or construction activities and restoration projects (Appendix B). Additional BMPs specific to hydroseeding, such as avoiding over-spray onto roads, trails, existing vegetation, and the stream channel, would also be implemented so that the hydroseed mixture itself would not easily runoff or be directly sprayed into the Klamath River. **Under the Proposed Action, hydroseeding would decrease the short-term (<2 years following dam removal) transport of fine sediments eroded from exposed reservoir terraces into the Lower Klamath River and Klamath Estuary and would be beneficial. There would be no change from existing conditions on the marine nearshore environment.**

Under the Proposed Action, the lack of continued interception and retention of mineral (inorganic) suspended material behind the dams at the Four Facilities could result in long-term (2–50 years following dam removal) increases in suspended material in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment. As would be the case for the Upper Klamath Basin, peak concentrations of mineral (inorganic) suspended materials in the Lower Klamath Basin during the winter/early spring (November through April) would likely remain associated with high-flow events and any increases due to the lack of interception by the KHP dams would not be large; estimates of baseline sediment delivery for the Klamath Basin indicate that a relatively small fraction of total sediment (199,300 tons/yr or 3.4 percent of the cumulative average annual delivery from the basin) is supplied to the Klamath River on an annual basis from the upper and middle Klamath River (i.e., from Keno Dam to the Shasta River) (Stillwater Sciences 2010).

Under the Proposed Action, the long-term (2–50 years following dam removal) increases in mineral (inorganic) suspended material in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment would be a less-than-significant impact.

Under the Proposed Action, the lack of continued interception and retention of algal-derived (organic) suspended material by the dams at the Four Facilities could result in slight long-term (2–50 years following dam removal) increases in suspended material in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment. While removal of the Four Facilities would eliminate the potential for downstream increases in suspended material due to seasonal algal blooms occurring within the reservoirs at the Four Facilities, overall sediment (both suspended and fluvial or bedload)

trapping in the Hydroelectric Reach would no longer occur, such that, in the long term, summertime algal-derived suspended material originating from Upper Klamath Lake may move farther downstream into the lower basin and cause a relative increase in suspended material. However, similar to the No Action/No Project Alternative, interception and retention of suspended material from upstream sources would still occur to a large degree in the Keno Impoundment/Lake Ewauna, as would additional decreases in concentration due to mechanical breakdown of algal remains in the turbulent river reaches between Keno Dam and Copco 1 Reservoir, and dilution from the springs downstream from J.C. Boyle Dam.

Because existing conditions indicate that average June–October suspended sediment values decrease from over 16 mg/L at the mouth of Link River to 6 mg/L in the Klamath River downstream from J.C. Boyle Reservoir (2001–2003), with median turbidity values following a similar pattern over the long-term historical record (1950–2001) (see Section 3.2.3.1 and Appendix C, Section C.2), it is likely that the suspended sediment signal would not increase beyond typical existing conditions concentrations of 10–15 mg/L. Therefore, summertime suspended sediment in the Lower Klamath River is unlikely to increase beyond a sustained 30 mg/L for four weeks, the water quality criterion adopted for significant adverse impacts on the cold freshwater habitat (COLD) beneficial use for the Klamath Facilities Removal EIS/EIR analysis (see Section 3.2.4.2.2.1). If slight long-term increases in suspended materials did occur, they would likely be offset by the loss of algal-derived suspended material previously produced in Copco 1 and Iron Gate Reservoirs and would not exceed levels that would substantially adversely affect the cold freshwater habitat (COLD) beneficial use.

Under the *Proposed Action*, the long-term (2–50 years following dam removal) increases algal-derived (organic) suspended material in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment would be a less-than-significant impact.

Nutrients

Upper Klamath Basin

Sediment release associated with the removal of the Four Facilities under the Proposed Action could cause short-term (<2 years following dam removal) increases in sediment-associated nutrients. Short-term increases in TN and TP concentrations in the Hydroelectric Reach would occur because particulate (primarily organic) nutrients contained in reservoir sediment deposits would be transported along with the sediments themselves. However, minimal deposition of fine suspended sediments, including associated nutrients, would occur in the river channel (Reclamation 2012, Stillwater Sciences 2008). Further, reservoir drawdown under the Proposed Action would occur during winter months when rates of primary productivity and microbially mediated nutrient cycling (e.g., nitrification, denitrification) are also expected to be low. Light limitation for primary producers that do persist during winter months is also likely to occur, further decreasing the potential for uptake of TN and TP released along with reservoir sediment deposits. Therefore, particulate nutrients released along with sediment

deposits are not expected to be bioavailable and should be well-conserved during transport through the Hydroelectric Reach. **Under the Proposed Action, the short-term (<2 years following dam removal) increase in nutrients in the Hydroelectric Reach would be a less-than-significant impact.**

Removal of the Four Facilities under the Proposed Action and conversion of the reservoir areas to a free-flowing river could cause long-term (2–50 years following dam removal) increases in nutrient levels in the Hydroelectric Reach. The Four Facilities, and primarily the two largest reservoirs (Copco 1 and Iron Gate Reservoirs), intercept and retain suspended material behind the dams, including phosphorus and nitrogen originating from Upper Klamath Lake (see Section 3.2.3.1). Under the Proposed Action, these nutrients would be transported downstream and potentially be available for uptake (e.g., by nuisance algae species). Analyses of the effects of dam removal on nutrients have been conducted by PacifiCorp for its relicensing efforts (FERC 2007), NCRWQCB for development of the California Klamath River TMDLs (NCRWQCB 2010a), and the Yurok Tribe as part of an evaluation to improve previous mass-balance estimates of nutrients in the Klamath River and increase understanding of retention rates in free-flowing river reaches (Asarian et al. 2010). While the results of all of the evaluations recognize the trapping efficiency of Copco 1 and Iron Gate Reservoirs with respect to TP and TN, such that under the Proposed Action total nutrient concentrations in the Klamath River downstream from Iron Gate Dam would increase on an annual basis, the majority of the results are focused on the Klamath Basin downstream from Iron Gate Dam.

However, modeling conducted for development of the California Klamath River TMDLs (NCRWQCB 2010a) provides some information applicable to the assessment of long-term (2–50 years following dam removal) effects of the Proposed Action on nutrients at locations in the Upper Klamath Basin (i.e., upstream of Iron Gate Dam) (Kirk et al. 2010). Klamath TMDL model results indicate that under the Proposed Action (similar to the TMDL TOD2RN scenario, which includes Oregon TMDL allocations), TP and TN in the Hydroelectric Reach immediately downstream from J.C. Boyle Dam would increase slightly (<0.015 mg/L and <0.05 mg/L, respectively) during summer months compared to those of the No Action/No Project Alternative (similar to the TMDL T4BSRN scenario) due to the absence of nutrient interception and retention in both Keno Impoundment/Lake Ewauna and J.C. Boyle Reservoir (the former because the TMDL model TOD2RN scenario includes the historic Keno Reef instead of Keno Dam [Appendix D]). At the Oregon-California State line, the situation would be much the same, although the lack of hydropower peaking operations under the Proposed Action may result in decreased daily variation in TP and ortho-phosphorus, as well as nitrate and ammonium (NCRWQCB 2010a). Overall however, the predicted increases would be very small and these increases may be at least partially due to the assumption that the historic Keno Reef exists rather than Keno Dam. Further, the TMDL model predictions generally agree with empirical data regarding J.C. Boyle Reservoir; with its shallow depth and short residence time, this reservoir does not retain high amounts of nutrients (PacifiCorp 2006a) (see Appendix C for more detail) and its removal would not be expected to increase nutrient transport further downstream in the Hydroelectric Reach.

Based on available information, the slight nutrient increases in the Hydroelectric Reach would not be expected to result in exceedances of either Oregon water quality objectives for nuisance algae growth, or California North Coast Basin Plan water quality objectives for biostimulatory substances, beyond levels experienced under the No Action/No Project Alternative. While periphyton colonization would likely increase in this reach under the Proposed Action, the increases would be due to habitat increases rather than nutrient increases (see Section 3.4.4.3.2 Algae). Further, the lacustrine environment that supports the growth of nuisance algae blooms of such as *M. aeruginosa* or other cyanobacteria would be eliminated under the Proposed Action (see Section 3.4, Algae), reducing the likelihood of uptake of the slightly increased nutrient concentrations by nuisance species of phytoplankton algae. This is mainly relevant for Copco 1 and Iron Gate Reservoirs, where the longer residence times support seasonal nuisance algae blooms (see Section 3.4, Algae). **Under the Proposed Action, the long-term (2–50 years following dam removal) increase in nutrients in the Hydroelectric Reach would be a less-than-significant impact.**

Lower Klamath Basin

Sediment release associated with the removal of the Four Facilities under the Proposed Action could cause short-term (<2 years following dam removal) increases in sediment-associated nutrients in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment. **Under the Proposed Action, the short-term (<2 years following dam removal) increase in nutrients in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment would be the same as in the Hydroelectric Reach and would be a less-than-significant impact.**

Removal of the Four Facilities under the Proposed Action and conversion of the reservoir areas to a free-flowing river could cause long-term (2–50 years following dam removal) increases in nutrient levels in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment. The reservoirs at the Four Facilities currently intercept and retain suspended material behind the dams, including phosphorus and nitrogen originating from Upper Klamath Lake (see Section 3.2.3.1). Under the Proposed Action, these nutrients would be transported downstream and potentially be available for uptake by algae, including nuisance algae species. Analyses of the effects of dam removal on nutrients have been conducted by PacifiCorp for its relicensing efforts (FERC 2007), NCRWQCB for development of the California Klamath River TMDLs (NCRWQCB 2010a), and the Yurok Tribe as part of an evaluation to improve previous mass-balance estimates of nutrients in the Klamath River and increase understanding of retention rates in free-flowing river reaches (Asarian et al. 2010). Results of all of the evaluations recognize the trapping efficiency of the reservoirs with respect to TP and TN, such that under the Proposed Action total nutrient concentrations in the Klamath River downstream from Iron Gate Dam would increase on an annual basis.

Based on the Yurok Tribe analysis, TP concentrations would increase approximately 2-12 percent for the June–October period under the Proposed Action, while increases in TN concentrations would be relatively larger, at an estimated 37-42 percent for June–October and 48-55 percent for July–September (see Figure 3.2-15). Asarian et al. (2010) conducted their analysis using two different approaches; 1) calculated reach-specific nutrient retention rates based on measured nutrient concentration data, and 2) predicted retention rates using an empirical relationship between observed retention rates and measured concentrations developed for the river from Iron Gate Dam to Turwar (this approach was only applicable to TN because TP data demonstrated a weak relationship between retention rate and measured TP concentrations). This calculation implicitly includes nutrient recycling processes such as assimilative uptake for algal growth and subsequent downstream release, as these processes were ongoing and inherently included in the retention estimates determined for existing conditions. Both approaches yield similar results, indicating small increases in TP and relatively larger increases in TN concentrations downstream from the Hydroelectric Reach under the Proposed Action, which diminish with distance downstream due to both tributary dilution and nutrient retention (i.e., uptake of nutrients).

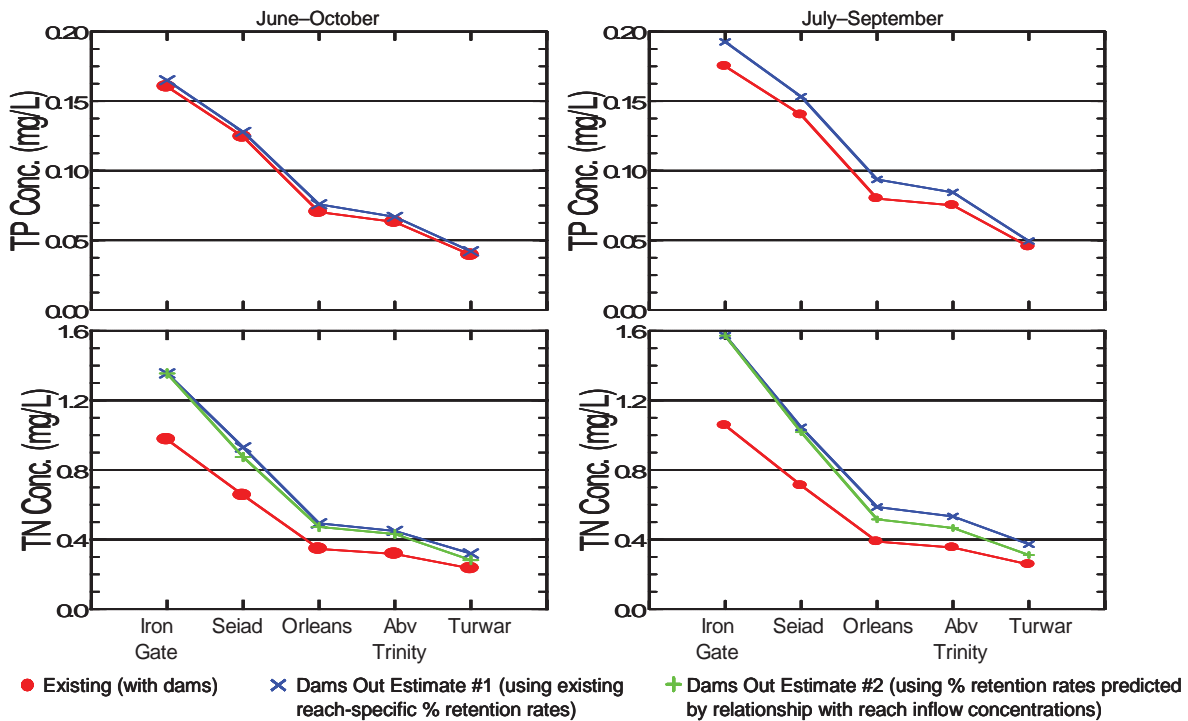

Figure 3.2-15. Comparison of TP and TN Concentrations from Iron Gate Dam to Turwar (RM 5.8) for June–October and July–September 2007–2008: (a) Measured Current Conditions (Red Circle), (b) Dams-Out Estimate using Calculated Percent Retention Rates by Reach (Blue Cross), and (c) Dams-Out Estimate using Percent Retention Rates Predicted by the Empirical Relationship between Reach Inflow Concentration and Retention (Green Cross). Source: Asarian et al. 2010.

Due to a lack of available data, the Yurok Tribe analysis does not consider other possible factors that may decrease nutrients upstream of Copco 1 Reservoir under the Proposed Action, such as TMDL implementation or elimination of peaking flows from hydropower operations (Asarian et al. 2010). If reductions in nutrient concentrations do occur upstream of Copco 1, then less nutrients would be available for removal in the reservoirs and dam removal would likely result in smaller long-term increases in nutrient concentration than predicted by the Yurok Tribe analysis (Asarian et al. 2010) analysis.

Klamath TMDL modeling efforts include an assumption of compliance with upstream TP and TN load allocations for both Oregon and California (NCRWQCB 2010a). Results are in general agreement with PacifiCorp (FERC 2007) and Yurok Tribe (Asarian et al. 2010) analyses regarding dam removal effects on nutrients, with very small annual increases in TP (0.01–0.015 mg/L) and relatively larger annual increases in TN (0.1–0.125 mg/L) immediately downstream from Iron Gate Dam (RM 190.1). Increases in nutrients would diminish with distance downstream. Note that while following the same relative trend as the Yurok Tribe analysis, the absolute increases predicted by TMDL model are much lower (e.g., 0.1–0.125 mg/L TN increase for the TMDL model vs. 0.1–0.5 mg/L TN increase for the Yurok Tribe analysis).

Continuing increased variability in TP and TN are predicted by the Klamath TMDL model (see Appendix D) during summer months, presumably due to nutrient uptake dynamics by periphyton and macrophytes. The TMDL model does not include denitrification as a possible nitrogen removal term in riverine segments (Tetra Tech 2009), meaning that TN concentrations under the Proposed Action (but also the No Action/No Project Alternative) may be overpredicted. The magnitude of this potential over-prediction would be expected to increase with distance downstream (i.e., relatively lower over-prediction at Iron Gate Dam and the Upper Klamath Basin, but relatively higher over-prediction at sites in the lowest portion of the river such as Orleans), due to a longer distance of river within which denitrification and other nitrogen removal processes would operate. Corresponding small differences in ortho-phosphorus, nitrate, and ammonium concentrations under the Proposed Action (as compared with the No Action/No Project Alternative, including TMDL compliance) are predicted by the model; however, within the uncertainty of future nutrient dynamics these differences are not clearly discernable as increases or decreases. TMDL model results indicate that while resulting TP levels would meet the existing Hoopa Valley Tribe numeric water quality objective (0.035 mg/L TP) at the Hoopa reach (≈RM 45–46) of the Klamath River, TN levels would continue to be in excess of the existing objective (0.2 mg/L TN) in some months (NCRWQCB 2010a). However, as noted previously, TN concentrations in the model may be over-predicted and therefore the Hoopa Valley Tribe objective may in fact be met.

Despite the overall increases in absolute nutrient concentrations anticipated under the Proposed Action, the relatively greater increases in TN may not result in significant biostimulatory effects on periphyton growth because it will be accompanied by only a relatively minor increase in TP. Existing data regarding TN:TP ratios suggest the potential for the Klamath River to be generally N-limited (TN:TP). However,

concentrations of both nutrients are high enough in the river from Iron Gate Dam (RM 190.1) to approximately Seiad Valley (RM 129.4) (and potentially further downstream) that nutrients are not likely to be limiting primary productivity (i.e., periphyton growth) in this portion of the Klamath River (FERC 2007, HVTEPA 2008, Asarian et al. 2010). In addition, N-fixing species dominate the periphyton communities in the lower reaches of the Klamath River where inorganic nitrogen concentrations are low (Asarian et al. 2010). Since these species can fix their own nitrogen from the atmosphere, increases in TN due to dam removal may not significantly increase algal biomass (see also Section 3.4, Algae), particularly if overall TN increases are less than those predicted by existing models due to implementation of TMDLs and general nutrient reductions in the Klamath Basin. **Under the *Proposed Action*, the long-term (2–50 years following dam removal) increase in nutrients in the Lower Klamath River and the Klamath Estuary would be a less-than-significant impact.**

Dissolved Oxygen

Upper Klamath Basin

Sediment release associated with the Proposed Action could cause short-term (<2 years following dam removal) increases in oxygen demand and reductions in dissolved oxygen in the Hydroelectric Reach downstream from J.C. Boyle Reservoir. While modeled oxygen demand is not available downstream from J.C. Boyle Reservoir, model results are available downstream from Iron Gate Dam as a function of SSC (see Section 3.2.4.3.2.4, Lower Klamath Basin) and can be applied to the Hydroelectric Reach downstream from J.C. Boyle Reservoir. This assumes as a worst case scenario that the effects of sediment release on short-term oxygen demand (and reductions in dissolved oxygen) in the Hydroelectric Reach downstream from J.C. Boyle Dam would be the same as those for the Lower Klamath River. This is a conservative assumption because peak SSCs downstream from J.C. Boyle Reservoir would be much lower and of shorter duration (i.e., 2,000–3,000 mg/L occurring within 1–2 months of reservoir drawdown) than those predicted downstream from Iron Gate Dam (i.e., 7,000–14,000 mg/L occurring within 2–3 months of reservoir drawdown) (see Section 3.2.4.3.2.2 and Figures 3.2-8 through 3.2-10). Like the effect determination for the Klamath River downstream from Iron Gate Dam, this would be a significant impact (see detailed analysis for Lower Klamath Basin, below).

Under the *Proposed Action*, the short-term (<2 years following dam removal) decrease in dissolved oxygen concentrations would be a significant impact on the riverine reaches of the Klamath River downstream from J.C. Boyle Dam to the Oregon-California State line.

Removal of the Four Facilities under the Proposed Action could cause long-term (2–50 years following dam removal) increases in dissolved oxygen, as well as increased daily variability in dissolved oxygen, in the Hydroelectric Reach. Modeling conducted for development of the Oregon and California Klamath River TMDLs indicates that under the Proposed Action (similar to the TMDL TOD2RN scenario), dissolved oxygen concentrations in the Hydroelectric Reach downstream from J.C. Boyle Dam and at the Oregon-California State line would be slightly greater during July through October than

those under the No Action/No Project (similar to the TMDL T4BSRN scenario), due to the removal of J.C. Boyle Reservoir (see Figure 3.2-16 and Figure 3.2-17; NCRWQCB 2010a). The same pattern is predicted for 30-day mean minimum and 7-day mean minimum dissolved oxygen criteria. The Klamath TMDL model (see Appendix D) also predicts that daily fluctuations in dissolved oxygen immediately downstream from J.C. Boyle Dam during this same period would be greater under the Proposed Action (TCD2RN) than the No Action/No Project Alternative (T4BSRN) (Figure 3.2-16) While the model-predicted increases in daily dissolved oxygen fluctuations may be linked to greater periphyton biomass and associated daily swings in photosynthetic oxygen production and respiratory consumption in the free-flowing river, the results are not entirely certain. The role of photosynthesis and community respiration from periphyton growth in the free-flowing reaches of the river replacing the reservoirs at the Four Facilities is unknown because nutrient cycling and resulting rates of primary productivity under the No Action/No Project Alternative are uncertain (see Section 3.2.1.1). Further, scouring in the free-flowing river from increased bed mobility and variable streamflows (see Section 3.4.4.3.2) may also limit primary productivity under the Proposed Action, which would decrease daily dissolved oxygen variability.

Further downstream at State line (i.e., in the Peaking Reach), the TMDL model predicts somewhat reduced daily fluctuations in dissolved oxygen under the Proposed Action (TCD2RN) as compared to the No Action/No Project Alternative (T4BSRN) (Figure 3.2-17). The predicted decreases in daily variability at State line may be due to elimination of hydropower peaking operations; however, since daily variability in dissolved oxygen is not currently an issue in the Peaking Reach, nor would the predicted reduced fluctuations result in an inability to meet water quality objectives (see below paragraph), this potential effect would be less than significant.

For the river downstream from J.C. Boyle Dam and at State line, modeling predictions are generally in compliance with the Oregon water quality objectives for supporting warm water (5.5 mg/L) and cool water (6.5 mg/L) fish beneficial uses, where lower dissolved oxygen concentrations in June–August would meet the Oregon narrative natural conditions criterion that supersedes the numeric objectives for the cold water beneficial use (8.0 mg/L). The same would occur for predicted concentrations in mid-February–May as related to the spawning (11 mg/L) beneficial use (Figure 3.2-16 and Figure 3.2-17; NCRWQCB 2010a).

For the free-flowing reaches of the river replacing the reservoirs, long-term dissolved oxygen levels would differ substantially from the super-saturation (i.e., >100% saturation) that currently occurs in surface waters and the hypolimnetic oxygen depletion in that occurs in bottom waters of Copco 1 and Iron Gate Reservoirs during the April/May through October/November period (see Section 3.2.3.5). Dissolved oxygen in the free-flowing reaches of the river replacing the reservoirs would not exhibit such extremes, instead possessing the riverine signal characteristic of primary production in lotic (flowing) ecosystems described above. Relative changes in dissolved oxygen under the Proposed Action would be less pronounced in the reach currently occupied by J.C. Boyle Reservoir, due to the lack of persistent thermal stratification in that reservoir.

Figure 3.2-16. Predicted Dissolved Oxygen Downstream from J.C. Boyle Dam (RM 224.7 to 228.3) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).
 Source: NCRWQCB 2010a.

Figure 3.2-17. Predicted Dissolved Oxygen at the Oregon-California State line (RM 208.5) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).
 Source: NCRWQCB 2010a.

Under the *Proposed Action*, long-term (2–50 years following dam removal) slight increases in summer and fall dissolved oxygen concentrations and daily fluctuations downstream from J.C. Boyle Dam would be beneficial. Slight decreases in daily fluctuations at the California-Oregon State line would be less than significant. Elimination of seasonal extremes in dissolved oxygen (i.e., supersaturation in surface waters and oxygen depletion in bottom waters) in the riverine reaches replacing Copco 1 and Iron Gate Reservoirs in the Hydroelectric Reach would be beneficial.

Lower Klamath Basin

Sediment release associated with the Proposed Action could cause short-term (<2 years following dam removal) increases in oxygen demand (IOD and BOD) and reductions in dissolved oxygen in the Lower Klamath River, the Klamath Estuary and the marine nearshore environment. Under the Proposed Action, high SSCs are expected in the middle and Lower Klamath River immediately following dam removal (see Alternative 2 – Full Facilities Removal of Four Dams – Suspended Sediments). The high fraction of organic carbon present in the reservoir sediments (see Section 3.2.3.1) allows for the possibility of oxygen demand generated by microbial oxidation of organic matter exposed to the water column from deep within the sediment profile and mobilized during dam removal.

Based on results from a dissolved oxygen spreadsheet model (see Section 3.2.4.1), IOD downstream from Iron Gate Dam would be 0–8.6 mg/L and BOD would be 0.3–43.8 mg/L for all water year types considered (i.e., wet, median, dry) and for all six months following drawdown (see Table 3.2-12). The highest predicted oxygen demand levels (i.e., IOD and BOD) would occur during the first four to eight weeks following drawdown of Copco 1 and Iron Gate Reservoirs (i.e., in February 2020) corresponding to the peak SSCs in the river (see above section on suspended sediments). Despite the relatively high predicted IOD and BOD values, dissolved oxygen concentrations downstream from Iron Gate Dam would generally remain greater than 5 mg/L (see Table 3.2-13). Exceptions include predicted concentrations in February 2020 for median (WY1976) and typical dry year (WY2001) hydrologic conditions, which exhibit minimum values of 3.5 mg/L and 1.3 mg/L, respectively.

For all water year types (wet, median, dry), the predicted dissolved oxygen minimum values would occur by approximately RM 188–190 (\approx 1–3 km downstream from Iron Gate Dam) and would return to at least 5 mg/L by approximately RM 175–177 (within 20–25 km of the dam), or near the confluence with the Shasta River (RM 176.7) (see Table 3.2-13). The North Coast Basin Plan water quality objective for dissolved oxygen is expressed as percent saturation; at 90 percent saturation, the water quality objective for November through April, assuming average February (2009) water temperatures, would be 9.6–10.6 mg/l (see Table 3.2-5). Based on the spreadsheet model results, recovery to the North Coast Basin Plan water quality objective of 90 percent saturation would occur generally within the reach from Seiad Valley (RM 129.4) to the mainstem confluence with Clear Creek (see Figure 3.2-1 for location of Clear Creek), or within a distance of 100–150 km (62–93 mi) downstream from the Hydroelectric Reach, for all water year

¹ Initial dissolved oxygen downstream from Iron Gate Dam calculated for 80% saturation using average monthly water temperature, salinity = 0 ppt, and elevation = 707 m (2,320 ft). An initial dissolved oxygen at 70% saturation was used for the November model runs. See average monthly dissolved oxygen (% saturation) for 2009 in Appendix C, Table C-7. Raw daily water temperature data from <http://www.pacificcorp.com/es/hydro/hl/kr.html#> (PacifiCorp 2009).

² Minimum acceptable dissolved oxygen concentration for salmonids. Although the minimum acceptable water quality objective for dissolved oxygen in the Klamath River for warm freshwater, saline, and marine habitats was previously 5 mg/L (NCRWQCB 2006), recent Basin Plan amendments require 85-90% saturation (generally ranging from 6–11 mg/L) depending on location and month (NCRWQCB 2010). Section 3.3 (Aquatics) of this EIS/EIR references a threshold of 6 mg/L for migrating adult anadromous salmonids (USEPA 1986), which is also a useful benchmark for dissolved oxygen concentrations. Based on BOD/IOD model results, a return to 6 mg/L dissolved oxygen would occur further downstream than the results presented in Table 3.2-13, on the order of 5–15 miles (10–25 km) depending on hydrologic conditions.

³ NA = not applicable because dissolved oxygen consistently remains greater than 5 mg/L.

Under the *Proposed Action*, long-term (2–50 years following dam removal) slight increases in summer and fall dissolved oxygen concentrations and daily fluctuations downstream from J.C. Boyle Dam would be beneficial. Slight decreases in daily fluctuations at the California-Oregon State line would be less than significant. Elimination of seasonal extremes in dissolved oxygen (i.e., supersaturation in surface waters and oxygen depletion in bottom waters) in the riverine reaches replacing Copco 1 and Iron Gate Reservoirs in the Hydroelectric Reach would be beneficial.

Lower Klamath Basin

Sediment release associated with the Proposed Action could cause short-term (<2 years following dam removal) increases in oxygen demand (IOD and BOD) and reductions in dissolved oxygen in the Lower Klamath River, the Klamath Estuary and the marine nearshore environment. Under the Proposed Action, high SSCs are expected in the middle and Lower Klamath River immediately following dam removal (see Alternative 2 – Full Facilities Removal of Four Dams – Suspended Sediments). The high fraction of organic carbon present in the reservoir sediments (see Section 3.2.3.1) allows for the possibility of oxygen demand generated by microbial oxidation of organic matter exposed to the water column from deep within the sediment profile and mobilized during dam removal.

Under the *Proposed Action*, the short-term (<2 years following dam removal) decrease in dissolved oxygen concentrations would be a significant impact on the Lower Klamath River from Iron Gate dam possibly to Clear Creek, but would not affect dissolved oxygen in the Klamath Estuary or the marine nearshore environment.

Removal of the Four Facilities under the Proposed Action could cause long-term (2-50 years following dam removal) overall increases in dissolved oxygen, as well as increased daily variability in dissolved oxygen, in the Lower Klamath River, particularly for the reach immediately downstream from Iron Gate Dam. KRWQM (see Section 3.2.1.1 for model background) results using 2001–2004 data indicate that substantial improvements in long-term dissolved oxygen may occur immediately downstream from Iron Gate Dam if the Four Facilities are removed, with increases of 3 to 4 mg/L possible during summer and late fall (PacifiCorp 2005). KRWQM output also predicts greater daily variations in dissolved oxygen concentrations downstream from Iron Gate Dam to the Trinity River confluence (RM 42.5) in the absence of the KHP dams, based upon the assumption that periphyton growth would occur in this reach if the dams were removed and would increase daily dissolved oxygen fluctuations due to photosynthetic oxygen production and respiratory consumption. However, the KRWQM does not include nutrient retention in the mainstem river downstream from Iron Gate Dam and assumes relatively high nutrient contributions from tributaries (Asarian and Kann 2006b), which could amplify model predicted daily variations in dissolved oxygen due to periphyton growth.

The Klamath TMDL model (see Appendix D) also indicates that under the Proposed Action (similar to the TMDL TCD2RN scenario), dissolved oxygen concentrations immediately downstream from Iron Gate Dam during July through November would be greater than those under the No Action/No Project (similar to the TMDL T4BSRN scenario), due to the lack of stratification and oxygen depletion in bottom waters in the upstream reservoirs as compared with a free-flowing river condition (see Figure 3.2-18). The model also predicts that daily fluctuations in dissolved oxygen at this location during this same period would be greater under the Proposed Action (TCD2RN) than the No Action/No Project Alternative (T4BSRN) (Figure 3.2-18), a condition potentially linked to periphyton establishment in the free-flowing reaches of the river that are currently occupied by reservoirs and associated daily swings in photosynthetic oxygen production and respiratory consumption. Differences in long-term dissolved oxygen concentrations between the Proposed Action and the No Action/No Project Alternative diminish with distance downstream from Iron Gate Dam, with similar or the same predicted dissolved oxygen concentrations and similar magnitude and duration of daily fluctuations by Seiad Valley (RM 129.4) and no differences by the confluence with the Trinity River (RM 42.5) (see Figure 3.2-18 to Figure 3.2-21).

At all modeled locations, the Klamath TMDL model indicates consistent compliance with the California North Coast Basin Plan water quality objective of 85 percent saturation (see Figure 3.2-18 to Figure 3.2-21). Further downstream, near the confluence with the Trinity River (see Figure 3.2-21), results also indicate that while minimum values may occasionally dip below the current Hoopa Valley Tribe minimum water quality objective (8 mg/L) (applicable from \approx RM 45–46), they would not fall below the 80 percent saturation objective modeled for the TMDL and would likely also not fall below the 90 percent saturation Hoopa Valley Tribe objective awaiting approval by USEPA (see Table 3.2-6) (90 percent saturation objective not shown in Figure 3.2-21, but the general trend is apparent). Winter time (January–March) dissolved oxygen concentrations would be slightly lower under the Proposed Action, but would not fall below Basin Plan minimum criteria for the winter season (90 percent saturation; see Table 3.2-4).

The magnitude of the increased daily fluctuations in dissolved oxygen immediately downstream from Iron Gate Dam predicted by the PacifiCorp and Klamath TMDL modeling efforts are not entirely certain; the role of photosynthesis and community respiration from periphyton growth in the free-flowing reaches of the river replacing the reservoirs at the Four Facilities is unknown because nutrient cycling and resulting rates of primary productivity under the No Action/No Project Alternative are uncertain (see Section 3.4, Algae). Therefore, overall, the removal of the Four Facilities under the Proposed Action would cause long-term increases in summer and fall dissolved oxygen in the Lower Klamath River immediately downstream from Iron Gate Dam, along with increases in daily variability, although the magnitude of the increased variability is somewhat uncertain. Effects would diminish with distance downstream from Iron Gate Dam, such that there would be no measurable effects on dissolved oxygen by the confluence with the Trinity River. **Under the Proposed Action, the long-term (2–50 years following dam removal) increases in summer and fall dissolved oxygen concentrations immediately downstream from Iron Gate Dam would be beneficial.**

pH

Upper Klamath Basin

Removal of the Four Facilities under the Proposed Action and conversion of the reservoir areas to a free-flowing river could result in short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) decreases in summertime pH in the Hydroelectric Reach. While both reservoir and riverine reaches upstream of the Hydroelectric Reach (i.e., from RM 231 to RM 251, Upper Klamath Lake, Agency Lake, and the Sprague River) are included on Oregon’s 303(d) list for pH, the Hydroelectric Reach itself is not currently identified as being impaired (see Table 3.2-8). While the California Klamath River TMDLs do not include specific allocations or targets for pH, it is included under load allocations and targets for nutrients as biostimulatory substances (NCRWQCB, 2010a), which are assigned to the KHP and are designed to limit algal photosynthesis. Consistent with this, pH values in Copco 1 and Iron Gate Reservoirs can exceed 9, with large (0.5–1.5 pH units) daily fluctuations occurring in reservoir surface waters during periods of intense algal blooms (see Section 3.2.6).

Modeling of pH conducted for development of the Oregon and California Klamath River TMDLs (Kirk et al. 2010, NCRWQCB 2010a) provides information applicable to the assessment of long-term effects of the Proposed Action on pH in riverine reaches in the Upper Klamath Basin. Klamath TMDL model results indicate that under the Proposed Action (similar to the TMDL TOD2RN scenario), pH in the Hydroelectric Reach immediately downstream from J.C. Boyle Dam would be the same as pH levels modeled under the No Action/No Project (similar to the TMDL T4BSRN scenario), with the potential for some small decreases in minimum daily values (see Figure 3.2-22). At the Oregon-California State line, pH levels under the Proposed Action would exhibit less daily variability during spring (March–May) and fall (October–November) (see Figure 3.2-23), while daily variability in the river during the period June–September would be similar or somewhat greater under the Proposed Action, likely due to enhanced periphyton growth in the free-flowing river reaches previously occupied by the upstream J.C. Boyle Reservoir. The modeled increases at the Oregon-California State line would consistently meet the Oregon water quality objective of 9.0 units for support of beneficial uses and would therefore be less than significant. While there are no TMDL model results for riverine locations upstream of Copco 1 or Iron Gate Reservoirs, these locations would be expected to exhibit similar patterns as those predicted for the Klamath River at the Oregon-California State line.

The Proposed Action would also eliminate the occurrence of high pH (> 9 pH units) and large (0.5–1.5 pH units) daily fluctuations occurring in the surface waters of Copco 1 and Iron Gate Reservoirs during periods of intense algal blooms. pH in the free-flowing reaches of the river replacing these reservoirs would not exhibit such extremes, instead possessing the riverine signal described above.

Figure 3.2-22. Predicted pH Downstream from J.C. Boyle Reservoir (RM 224.7) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario). Source: NCRWQCB 2010a.

Figure 3.2-23. Predicted pH at the Oregon-California State line (RM 208.5) for the Klamath TMDL Scenarios Similar to the Proposed Action (TOD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario). Source: NCRWQCB 2010a.

Similar to dissolved oxygen (see above section), the changes in daily fluctuations for pH indicated by the Klamath TMDL modeling efforts are not entirely certain; the role of photosynthesis and community respiration from periphyton growth in the free-flowing reaches of the river replacing the reservoirs at the Four Facilities (including Keno Impoundment/Lake Ewauna as an assumption of the TOD2RN model [Appendix D]) is not well known because nutrient cycling and resulting rates of primary productivity under the No Action/No Project Alternative are not well known (see Section 3.2.1.1).

The timing of reservoir drawdown under the Proposed Action was optimally developed to minimize environmental effects. Because drawdown of the reservoirs would begin in winter and would be largely complete by March/April of 2020, pH effects of the Proposed Action in the Hydroelectric Reach would occur, either partially or fully, within the first 1 to 2 years following dam removal and be a short-term effect as well as a long-term effect. The exception to this is the potential for increased daily variability in pH due to increases in periphyton growth in the Hydroelectric Reach. However, increased daily variability due to periphyton growth likely would not occur in the short term because high SSCs and scour in the river 1-2 years following dam removal would limit the establishment of periphyton in the free-flowing river reaches.

Under the *Proposed Action*, the short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) slight summertime increases in pH and daily pH fluctuations at the Oregon-California State line and upstream and downstream reaches that are currently riverine would be less than significant. The decrease in high summertime daily pH fluctuations in the free-flowing reaches of the river that replace Copco 1 and Iron Gate Reservoirs in the Hydroelectric Reach would be beneficial.

Lower Klamath Basin

Removal of the Four Facilities under the Proposed Action and conversion of the reservoir areas to a free-flowing river could result in long-term (2–50 years following dam removal) summertime increases in pH in the Lower Klamath River immediately downstream from Iron Gate Dam. Modeling of pH conducted for the development of the California Klamath River TMDLs provides information applicable to the assessment of long-term effects of the Proposed Action on pH in the Lower Klamath Basin. In general, results from the Klamath TMDL model (see Appendix D for a summary of model attributes) indicate that spikes in photosynthetic activity in the relatively low alkalinity (typically <100 mg/L; PacifiCorp 2005, Karuk Tribe of California 2010) water of the Klamath River, coupled with high air temperatures and high levels of biostimulatory nutrients during the late-summer and early-fall months, would result in large daily variation in pH and generally high pH levels in the Klamath River downstream from Iron Gate Dam (see Figure 3.2-24). This condition is not unlike current conditions, where pH during late-summer and early-fall months (August–September) in the Klamath River downstream from Iron Gate Dam (particularly upstream of the Shasta River confluence [RM 176.7]) ranges from just above neutral to greater than 9, with large (0.5–1.5 pH units) daily fluctuations occurring in the lower river during periods of high photosynthesis (see Section 3.2.3.6).

Predicted differences in pH between the Proposed Action and No Action/No Project Alternative decrease in magnitude with distance downstream from Iron Gate Dam, and are considerably dampened by the Scott River confluence (RM 143.0) (see Figure 3.2-25). The Hoopa Valley Tribe water quality objective for pH (7.0-8.5) (see Table 3.2-6) is met at all times under the Proposed Action (similar to the TMDL TCD2RN scenario) for the Klamath River at the reach of Hoopa jurisdiction (\approx 45–46).

Similar to the pH analysis for the Upper Klamath Basin (see prior section), the changes in daily fluctuations for pH indicated by the Klamath TMDL modeling efforts immediately downstream from Iron Gate Dam are not entirely certain because the magnitude of photosynthesis and community respiration from periphyton growth in the free-flowing reaches of the river replacing the reservoirs at the Four Facilities is not well known. The final Klamath TMDL targets and allocations are based on several lines of evidence and results from a number of different analytical tools; this is a particularly important consideration for the reach immediately downstream from Iron Gate Dam because the modeled pH changes are relatively larger than those predicted further upstream in the Hydroelectric Reach (see above discussion). The Klamath River mainstem periphyton target (150 $\mu\text{g}/\text{m}^2$ chlorophyll-*a*) was developed using the California NNE framework and calculation tools (Creager et al. 2006, Tetra Tech 2008). Building on the NNE analysis, Butcher (2008) determined that the periphyton target is met for the TMDL dams-out model scenario nutrient concentration targets (TP and TN targets are presented in Section 3.2.4.2.2.2, page 3.2-44). Because it uses a slightly different periphyton biomass estimate than the NNE framework tool, the TMDL model may overestimate summertime pH levels and variability immediately downstream from Iron Gate Dam. Additionally, based on the NNE analysis, pH is not expected to exceed the NCRWQCB Basin Plan objective of pH 8.5 on a regular basis for the dams out condition. Mitigating factors that could potentially limit periphyton densities to levels below the TMDL model estimate include increased scour and alterations in nutrient dynamics in the free flowing river due to retention from periphyton growth further upstream – see Section 3.4, Algae). As discussed under the No Action/No Project Alternative (see page 3.2-61), adaptive management strategies will be employed to refine efforts toward achieving water quality objectives and targets as part of the TMDL process. Given that there are multiple lines of evidence suggesting potentially different responses to pH from dam removal, adaptive management monitoring under the Proposed Action should include provisions for monitoring periphyton density in the reaches downstream from where Iron Gate Dam is currently located. Overall, the weight of evidence suggests that the potential for long-term pH increases during the summer months immediately downstream from Iron Gate Dam is less than significant.

Figure 3.2.25. Predicted Klamath River pH upstream of the Scott River (RM 143.0) for the Klamath TMDL Scenarios Similar to the Proposed Action (TCD2RN Scenario) and the No Action/No Project Alternative (T4BSRN Scenario).
Source: NCRWQCB 2010a.

The timing of reservoir drawdown under the Proposed Action was optimally developed to minimize environmental effects. Because drawdown of the reservoirs would begin in winter and would be largely complete by March/April of 2020, pH effects of the Proposed Action in the Lower Klamath River would occur, either partially or fully, within the first 1 to 2 years following dam removal and be a short-term effect as well as a long-term effect. The exception to this is the potential for increases in pH due to increases in periphyton growth in the Lower Klamath River. The latter likely would not occur in the short term because high SSCs and scour in the river 1-2 years following dam removal would limit the establishment of periphyton in the free-flowing river reaches.

Long-term summertime increases in pH under the *Proposed Action* would be less than significant for the reach from Iron Gate Dam to the Scott River (RM 143). There would be no change from existing conditions on pH in the short term (<2 years following dam removal) and long-term (2–50 years following dam removal) for the Klamath River downstream from the Scott River, the Klamath Estuary, and the marine nearshore environment.

Chlorophyll-a and Algal Toxins

Upper Klamath Basin

*Removal of the Four Facilities under the Proposed Action and conversion of the reservoir areas to a free-flowing river could substantially reduce or eliminate short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) levels of chlorophyll-a and algal toxins in the Hydroelectric Reach. Despite the slightly increased total nutrient concentrations anticipated under the Proposed Action in the Hydroelectric Reach (see Alternative 2 – Full Facilities Removal of Four Dams – Nutrients), elimination of the lacustrine (reservoir) environment that currently supports growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa* would result in decreases in high seasonal concentrations of chlorophyll-a (>10 µg/L) and periodically high levels of algal toxins (> 8 µg/L microcystin) generated by suspended blue-green algae.*

The timing of reservoir drawdown under the Proposed Action was optimally developed to minimize environmental effects. Because drawdown of the reservoirs would begin in winter and would be largely complete by March/April of 2020 (i.e., the beginning of the growth season), elimination of the lacustrine (reservoir) environment under the Proposed Action would occur, either partially or fully, within the first 1 to 2 years following dam removal. Therefore, this would be a short-term effect on chlorophyll-a and algal toxins in the Hydroelectric Reach as well as a long-term effect.

Under the *Proposed Action*, the short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) decrease in chlorophyll-a and substantial decrease or elimination of algal toxins and in the Hydroelectric Reach would be beneficial.

Lower Klamath Basin

*Removal of the Four Facilities under the Proposed Action and conversion of the reservoir areas to a free-flowing river could substantially reduce or eliminate short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) levels of chlorophyll-*a* and algal toxins transported into the Lower Klamath River and potentially the Klamath Estuary.* In addition to the decreases in high seasonal concentrations of chlorophyll-*a* (>10 µg/L) and periodically high levels of algal toxins (>8 µg/L microcystin) generated by nuisance algal species that are described for the Hydroelectric Reach (see Section 3.2.4.3.2.6, Upper Klamath Basin), growth of *M. aeruginosa* in reaches of the Klamath River downstream from Iron Gate Dam would be reduced in the absence of significant reservoir blooms. While algal toxins and chlorophyll-*a* produced in Upper Klamath Lake (see Section 3.2.3.1) may still be transported into the Lower Klamath Basin, existing data indicate that concentrations of microcystin leaving Upper Klamath Lake have rarely, if ever, been measured at levels that exceed water quality objectives for Oregon and California. In contrast, algal production in Iron Gate and Copco Reservoirs is responsible for the observed public health exceedances occurring in the Klamath River downstream from Iron Gate Dam (see Section 3.2.3.7 and Appendix C, Section C.6). Under the Proposed Action, the *in situ* production of toxins and chlorophyll-*a* associated with suspended algae in the reservoirs would be eliminated.

The timing of reservoir drawdown under the Proposed Action was optimally developed to minimize environmental effects. Because drawdown of the reservoirs would begin in winter and would be largely complete by March/April of 2020 (i.e., the beginning of the growth season), effects of the Proposed Action on chlorophyll-*a* and algal toxins in the Lower Klamath River would occur, either partially or fully, within the first 1 to 2 years following dam removal and be a short-term effect as well as a long-term effect.

Under the Proposed Action, the short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) decreases in the production of algal toxins and chlorophyll-*a* in upstream reservoirs and subsequent transport into the Lower Klamath River and the potentially the Klamath Estuary would be beneficial.

Inorganic and Organic Contaminants

Upper Klamath Basin

Sediment release associated with the Proposed Action could cause short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) increases in concentrations of inorganic and organic contaminants and result in low-level exposure for freshwater aquatic species in the Hydroelectric Reach. Due to the relatively small volume of the sediment deposits behind J.C. Boyle Dam (i.e., 15 percent of total volume for the Four Facilities, see also Figure 3.3-8), concentrations of suspended sediments downstream from J.C. Boyle Reservoir would be considerably less than those anticipated to occur downstream from Iron Gate Reservoir. Because the transport of contaminants would be associated with the elevated SSCs, as a conservative estimate, effects of sediment release on inorganic and organic contaminants in the Hydroelectric Reach downstream from J.C. Boyle Dam would be the same as those for the Lower Klamath

River. Under the *Proposed Action*, the short-term (< 2 years following dam removal) and long-term (2–50 years following dam removal) effects of sediment release on freshwater aquatic species due to low-level exposure to sediment-associated inorganic and organic contaminants in the Hydroelectric Reach would be a less-than-significant impact.

The Proposed Action could result in short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) human exposure to contaminants from contact with deposited sediments on exposed reservoir terraces and river banks following reservoir drawdown. Potential human health risks associated with exposure to sediments deposited on exposed reservoir terraces and river banks within the Hydroelectric Reach were evaluated using comparisons of the 2009–2010 Secretarial Determination reservoir sediment core data to USEPA residential soil screening levels, and calculation of human/mammal TEQs and comparison to ODEQ Bioaccumulation screening level values (SLVs) (“Exposure Pathway 3” in CDM [2011]). No samples exceeded the total non-carcinogenic screening levels.

Forty-five samples exceeded the USEPA total carcinogenic screening level for residential soils for arsenic or nickel, including samples from J.C. Boyle, Copco 1 and Iron Gate Reservoirs. For arsenic, sampled concentrations in the reservoirs ranged from 4.3 to 15 mg/kg (see Appendix C, Table C-6), while the USEPA total carcinogenic screening level is 0.39 mg/kg. However, these screening levels were developed assuming residential exposure patterns (a 30-year exposure duration with soil ingestion rate of 200 mg/day for children over 6 years and 100 mg/day for adults over 24 years) (USEPA 1991), which is quite conservative and the measured values are well within the range of available soil concentrations for the Klamath Basin (arsenic may be naturally elevated in the Upper Klamath Basin [see Appendix C, Section C.7.1]). Additionally, ODEQ suggests a default background soil/sediment concentration for arsenic of 7 mg/kg (ODEQ 2007), a similar magnitude to the concentrations measured in reservoir sediments and a similar factor by which the reservoir sediments and background soils exceed the USEPA screening levels. Along these lines, ODEQ (2007) recommends the use of background concentrations as the screening levels when natural background is higher than a screening level. Lastly, under KHSA Section 7.6.4.A, the reservoir footprint areas would be designated as parcel B lands, which includes public interest purposes such as fish and wildlife habitat restoration and enhancement, public education, and public recreational access, and would not be used as residential lands. Therefore, potential exposure to arsenic measured in the reservoir sediments under the Proposed Action would be less than that assumed for the USEPA total carcinogenic screening levels, and it would be unlikely to have adverse effects under Exposure Pathway 2.

For nickel, sampled concentrations in the reservoirs ranged from 18 to 33 mg/kg (see Appendix C, Table C-6), while the USEPA total carcinogenic screening level is 0.38 mg/kg. As with arsenic, available Klamath Basin soil concentrations of nickel (median values 33 mg/kg and 65.7 mg/kg from two different studies) are in the same range as those measured in reservoir sediments (see Appendix C, Section C.7.1) and they exceed the USEPA total carcinogenic screening level for residential soils by a similar factor.

The highest concentrations of nickel were found in sediments from the Klamath River Estuary, which further suggests that release of reservoir sediments downstream would not negatively affect nickel concentrations in downstream reaches. Accordingly, the observed concentrations of nickel are unlikely to have adverse effects to humans under Exposure Pathway 2.

For 19 analytes measured during 2009–2010, laboratory analytical reporting limits were greater than the applicable human health screening levels, including PCBs, VOCs, and SVOCs (CDM 2011). It is not possible to directly confirm that these compounds are above or below applicable human health screening levels.

TEQs calculated for dioxin, furan, and dioxin-like PCBs were at concentrations above ODEQ Bioaccumulation SLVs for mammals in sediments from each of the reservoirs (CDM 2011). ODEQ Bioaccumulation SLVs are not applicable to water bodies in California; however, they provide a reference for comparison purposes. Although site-specific background data are lacking, TEQs are also only slightly above regional background concentrations and thus have limited potential for adverse effects for humans exposed to sediment deposits on reservoir terraces or river banks. The sources of the slightly elevated dioxin, furan, and dioxin-like PCB compounds are not known; however, sources may include atmospheric deposition, regional forest fires, and possibly burning of plastic items (CDM 2011).

Results from the 2009–2010 Secretarial Determination sediment chemistry analyses indicate that sediment deposits associated with the Proposed Action would cause no adverse effects on humans (terrestrial biota were also evaluated qualitatively, but are not discussed here) (see Figure 3.2-2). **Under the Proposed Action, the effects of sediment deposition on reservoir terraces and river banks on short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) human exposure to sediment-associated inorganic and organic contaminants in the Hydroelectric Reach would be a less-than-significant impact.**

Dam deconstruction and revegetation (i.e., hydroseeding) activities could cause short-term (<2 years following dam removal) increases in inorganic and organic contaminants from hazardous materials associated with construction and revegetation (i.e., hydroseeding) equipment in the Hydroelectric Reach. These effects would be reduced through implementation of BMPs for deconstruction and revegetation activities that would occur in or adjacent to the Klamath River. BMPs would minimize or eliminate the potential for toxic substances to enter the water. Under the Proposed Action, the short-term (<2 years following dam removal) effects on inorganic and organic contaminants in the Hydroelectric Reach from dam deconstruction and restoration (i.e., hydroseeding) activities would be a less-than-significant impact.

Under the Proposed Action, herbicide application associated with management of the reservoir footprint area could result in short-term (<2 years following dam removal) levels of organic contaminants in runoff that are toxic to aquatic biota in the Hydroelectric Reach. Based on the reservoir area management planning currently

underway, establishment of herbaceous vegetation in drained reservoir areas will be undertaken to stabilize the surface of the sediment and minimize erosion from exposed terrace surfaces following drawdown (O’Meara et al. 2010). Herbicides would be necessary during this period to control the growth of invasive plant species, with application occurring during the first year following dam removal and potentially during the second, if further treatments are necessary. Herbicide application would be required for 25 percent, 50 percent, and 75 percent of the total reservoir area for the low, most probable, and high cost restoration estimates, respectively (O’Meara et al. 2010).

The reservoir area management plan recognizes the potential water quality effects of herbicide application and calls for the use of herbicides with low soil mobility, and thus low potential to leach into groundwater or surface waters. It also calls for low use rates of herbicides and application of chemicals that pose a low toxicity risk to fish and aquatic organisms. Glyphosate is suggested in the management plan as one potential herbicide with such characteristics (O’Meara et al. 2010). To minimize use rates, spot treatments of a post-emergent herbicide such as glyphosate would be used rather than aerial application.

If glyphosate is chosen as a suitable herbicide for reservoir invasive plan management, it is recommended that glyphosate formulations containing POEA or R-11 are avoided to reduce risks to amphibians and other aquatic organisms (BLM 2010). Aquatic formulations of glyphosate (i.e., Glyfos Aquatic) are developed for use in sensitive protected environments such as habitat restoration sites and wetlands. Additionally, best management practices such as the “no rain” rule should be followed, such that glyphosate would never be applied when weather reports predict precipitation within 24 hours of application, before or after (BLM 2010). If another herbicide is chosen, it should meet the characteristics of low soil mobility and low toxicity to fish and aquatic organisms, and should be applied using BMPs such as low use rates (i.e., spot treatments), avoidance of application in the rain, avoidance of treatments during periods when fish are in life stages most sensitive to the herbicide(s) used, and adherence to appropriate buffer zones around stream channels (BLM 2010). **Under the *Proposed Action*, given implementation of applicable BMPs, the effect of herbicide application on toxicity and/or bioaccumulation in the Hydroelectric Reach during the revegetation period would be a less-than-significant impact.**

Lower Klamath Basin

Freshwater Aquatic Life Toxicity and/or Bioaccumulation

Sediment release associated with the Proposed Action could cause short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) increases in concentrations of inorganic and organic contaminants and result in low-level exposure for freshwater aquatic species in the Lower Klamath River. Organic and inorganic contaminants have been identified in the sediment deposits currently trapped behind the dams (see Section 3.2.3.1). Under the Proposed Action, short-term (<2 years following dam removal) pathways of contaminant exposure for freshwater aquatic species include exposure during sediment transit through the Lower Klamath Basin river reaches (“Exposure Pathway 2” in CDM [2011]), while long-term (2-50 years following dam

removal) pathways include exposure following deposition of sediments along river beds and the estuary bottom (exposure “Scenario 4” in CDM [2011]).

As described for the No Action/No Project Alternative, existing sediment chemistry data (2004–2005) collected from 26 cores in J.C. Boyle, Copco 1, and Iron Gate Reservoirs indicate generally low levels of metals, pesticides, chlorinated acid herbicides, PCBs, VOCs, SVOCs, cyanide, and dioxins (Shannon & Wilson, Inc. 2006; see Section 3.2.3.8). Collection of additional sediment cores in 2009–2010 for the Secretarial Determination process indicates no positive exceedances of applicable screening levels indicating a low risk of toxicity to freshwater sediment-dwelling organisms in the Lower Klamath River under the Proposed Action. Results from acute (10-day) sediment bioassays for two national benchmark toxicity species (see above discussion under No Action/No Project Alternative) indicate generally equal or greater survival in reservoir sediments as compared with laboratory control samples. The exception is J.C. Boyle Reservoir, which exhibited considerably lower survival for *Chironomus dilutus* in the on-thalweg sample as compared with the laboratory control (64 percent versus 95 percent) and somewhat lower survival for the off-thalweg sample (83 percent versus 95 percent) (CDM 2011).

Although this result suggests potential for toxicity to freshwater benthic organisms downstream from the dams, under the Proposed Action, sediments from all three reservoirs will mix as they move downstream, exposing downstream aquatic biota to an “average” sediment composition rather than a reservoir-specific composition. Further, under current conditions, the total volume of erodible sediments in Copco 1 and Iron Gate Reservoirs (7.4 million yd³ and 4.7 million yd³, respectively; see Section 2.5.1) is considerably greater than that of J.C. Boyle Reservoir (1 million yd³; see Section 2.5.1), diminishing the potential influence of J.C. Boyle Reservoir sediments downstream biota exposure (also see Section 2.2, text box on sediment weight and volume). Finally, fine sediments released during drawdown and dam removal will be transported by large water volumes, and are unlikely to settle along the riverbed (Reclamation 2012, Stillwater Sciences 2008); therefore, downstream freshwater benthic organisms are unlikely to experience the same intensity of exposure to sediment elutriate concentrations or reservoir sediments as during the bioassays themselves. Overall, the freshwater sediment bioassays indicate a low likelihood of acute toxicity to downstream benthic organisms due to sediment release under the Proposed Action.

Elutriate chemistry results indicate that before consideration of dilution, aluminum, chromium, copper, lead, and mercury are present at concentrations above fresh water quality criteria for samples from J.C. Boyle, Copco 1, and Iron Gate Reservoirs (CDM 2011). However, as described above, dilution of mobilized sediments with reservoir and river water is anticipated during drawdown and dam removal activities, with further dilution occurring downstream from Iron Gate Dam due to tributary inflows. Thus, water column toxicity due to the concentrations under the Proposed Action is unlikely (CDM 2011).

Elutriate bioassay results indicate no statistically significant reduction of mean 96-hour rainbow trout survival for exposure to samples from Copco 1 and Iron Gate Reservoirs tested at 1 percent and 10 percent elutriate treatments, but a significant reduction from Copco 1 at 100 percent elutriate treatment and from Iron Gate at 50 percent and 100 percent elutriate treatments. Of these, the 1 percent and 10 percent treatments are considered to be most representative of field conditions upon reservoir drawdown due to the expectation of substantial mixing and dilution with river water and tributary inputs (CDM 2011). For J.C. Boyle Reservoir, elutriate bioassay results indicate that no further dilution would be required to prevent water column toxicity to freshwater fish, even without considering the dilution that will take place during drawdown and dam removal (CDM 2011).

Combined, results from the 2004–2005 Shannon & Wilson, Inc. (2006) study and the 2009–2010 Secretarial Determination study (CDM 2011) indicate that in the short term (<2 years following dam removal), one or more chemicals are present at levels with potential to cause minor or limited adverse effects on freshwater aquatic species (see Figure 3.2-2). In the long-term, one or more chemicals present, but at levels unlikely to cause adverse effects based on the lines of evidence.

Under the *Proposed Action*, the short-term (< 2 years following dam removal) and long-term (2–50 years following dam removal) effects of sediment release, transit, and potential downstream river-bank deposition on freshwater aquatic species due to low-level exposure to sediment-associated inorganic and organic contaminants in the Lower Klamath River would be a less-than-significant impact.

Marine Aquatic Life Toxicity and/or Bioaccumulation

Sediment release associated with the Proposed Action could cause short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) increases in concentrations of inorganic and organic contaminants and result in low-level exposure for aquatic species in the Klamath Estuary and marine nearshore environment. Organic and inorganic contaminants have been identified in the sediment deposits currently trapped behind the dams (see Section 3.2.3.8). Under the Proposed Action, short-term pathways of contaminant exposure for marine aquatic species include short-term exposure during sediment transit through the Klamath Estuary and marine nearshore environment as well as exposure following deposition in the marine nearshore environment (“Exposure Pathway 5” in CDM [2011]).

For the 2009–2010 Secretarial Determination study, there were no positive exceedances of the applicable and available maximum marine screening levels (CDM 2011), with the exception of a small number of sediment samples from J.C. Boyle Reservoir, which exceeded the applicable marine screening level for dieldrin and 2,3,4,7,8,-PECDF (CDM 2011). As the marine screening levels are designed to be protective of direct toxicity to benthic and epibenthic organisms, corresponding to a “no adverse effects level,” the vast majority of 2009–2010 samples indicate a low risk of toxicity to sediment-dwelling organisms. Additionally, the Proposed Action would result in mixing and dilution during sediment release and transit through the Klamath River estuarine

and/or marine nearshore environment, exposing downstream aquatic biota to an “average” water column concentration rather than a reservoir- or site-specific concentration. For 33 analytes, laboratory analytical reporting limits were greater than the marine screening level itself (CDM 2011). For these analytes, it is not possible to determine whether these compounds are present in reservoir sediments either above or below levels of concern.

Sediment bioassays from a single upper Klamath Estuary sample indicate greater survival (89–99 percent survival) of national benchmark toxicity species in the estuary sediment sample as compared with the laboratory control samples (81–94 percent survival) (see CDM 2011). A simple comparison between the estuary area composite acute toxicity results and the reservoir super-composite results indicates similar survival for *Chironomus dilutus* (89 percent vs. 64–94 percent, respectively) and greater survival for *Hyalella azteca* (99 percent vs. 80–94 percent, respectively). The similarity in results is suggestive that under the Proposed Action, no further acute toxicity would be anticipated in the estuarine and/or marine environment as compared with that of the reservoir sediments; however, additional toxicity testing using estuarine and marine test organisms is needed to confirm this assumption. Elutriate chemistry results (prior to consideration for mixing and dilution) do not indicate likely toxicity in the marine nearshore environment under the Proposed Action (CDM 2011).

With respect to bioaccumulation potential, there are no exceedances of applicable marine bioaccumulation screening levels (CDM 2011). Further, with the exception of four samples in J.C. Boyle Reservoir (CDM 2011), levels of other known bioaccumulative compounds did not exceed ODEQ bioaccumulation SLVs for marine fish. Note that ODEQ bioaccumulatory screening levels are not strictly applicable in the California marine offshore environment; however, they are indicative of potentially bioaccumulative compounds.

Elutriate chemistry results indicate that several chemical concentrations in elutriate exceed one or more water quality criteria for evaluation of surface water exposures for marine biota. Chemicals that exceed marine surface water criteria include those generally considered to be nontoxic (e.g., phosphorus) as well as those with substantial potential for contributing to adverse effects (e.g., copper). Exposures to suspended sediment with elevated concentrations of potentially toxic chemicals are of lower concern for marine receptors than exposures to elevated concentrations of dissolved chemicals. The chemicals with the greatest potential to cause adverse effects in elutriate (e.g., copper) are, under field conditions associated with this exposure pathway, expected to bind to particulate matter and therefore are unlikely to contribute substantially to elevated concentrations of dissolved forms in the water column. Further, substantial dilution of river water and associated suspended sediments in the marine environment would reduce the amount of sediment suspended in the water column compared to conditions directly below Iron Gate Dam (CDM 2011).

Although not conducted specifically for estuarine or marine organisms, additional lines of evidence from the 2009–2010 Secretarial Determination study including the evaluation of

elutriate toxicity bioassay results for rainbow trout, sediment toxicity bioassay results for benthic invertebrate national benchmark species, comparisons of tissue-based TRVs to chemical concentrations in laboratory-reared freshwater clams and worms exposed to field collected sediments (see prior discussion of Proposed Action potential effects on freshwater aquatic species), and comparisons of tissue-based TRVs and TEQs to chemical concentrations in field collected fish tissue (see discussion under No Action/No Project, Section 3.2.4.3.1.7), exposure to inorganic and organic compounds in sediments released from the reservoirs under the Proposed Action is unlikely to cause adverse long-term impacts on estuary and marine near shore aquatic species (see Figure 3.2-2).

Under the *Proposed Action*, the short-term (< 2 years following dam removal) and long-term (2–50 years following dam removal) effects of sediment release, transit, and deposition on aquatic species due to low-level exposure to sediment-associated inorganic and organic contaminants in the Klamath Estuary and marine nearshore environment would be a less-than-significant impact.

Human Health

Sediment release associated with the Proposed Action could result in short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) human exposure to contaminants from contact with deposited sediments on downstream river banks following reservoir drawdown. Under the Proposed Action, potential human exposure to inorganic and organic chemicals during periods of drawdown and near-term flushing of elevated SSCs in the Lower Klamath River (i.e., through ingestion of contaminants from drinking water withdrawals or dermal contact with water) is likely to be of limited occurrence and shorter duration and is not further addressed.

Short-term human exposure through fish consumption (i.e., a food web pathway) cannot be assessed with the available data. Resident fish species in the reservoirs are considered unlikely to survive and populate the riverine environment following the Proposed Action (see Section 3.3, Aquatic Resources). Exposure and bioaccumulation by resident riverine species in the Lower Klamath River and estuary from water and suspended sediments transported under the Proposed Action is understood to be short term (<2 years following dam removal). Human exposure to contaminants from contact with residual sediments deposited on downstream river banks is possible and the mechanism for exposure is the same as that for potential contaminants deposited on exposed reservoir terraces and river banks in the Hydroelectric Reach (see Section 3.2.4.3.2.7, Upper Klamath Basin and Figure 3.2-2).

Under the *Proposed Action*, the effects of sediment release on human health due to short-term (<2 years following dam removal) and long-term (2–50 years following dam removal) exposure to sediment-associated inorganic and organic contaminants in the Lower Klamath River would be a less-than-significant impact.

Dam deconstruction and restoration (i.e., hydroseeding) activities could cause short-term (<2 years following dam removal) increases in inorganic and organic contaminants from hazardous materials associated with construction and restoration (i.e., hydroseeding)

equipment in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment. These short-term effects would be a significant impact. However, the impacts may be reduced through implementation of BMPs for deconstruction and restoration activities that would occur in or adjacent to the Klamath River. BMPs would minimize or eliminate the potential for toxic substances to enter the water during the deconstruction and revegetation period. **Under the *Proposed Action*, the short-term (<2 years following dam removal) effects on inorganic and organic contaminants in the Lower Klamath River and the Klamath Estuary from dam deconstruction and restoration (i.e., hydroseeding) activities would be a less-than-significant impact. There would be no change from existing conditions on the marine nearshore environment.**

Keno Transfer

Implementation of the Keno Transfer could cause adverse water quality effects. The Keno Transfer is a transfer of title for the Keno Facility from PacifiCorp to the DOI. This transfer would not result in the generation of new impacts on water quality compared with existing facility operations. Following transfer of title, Reclamation would operate Keno in compliance with applicable law and would provide water levels upstream of Keno Dam for diversion and canal maintenance consistent with agreements and historic practice (see KHSa Section 7.5.4). **Therefore, implementation of the Keno Transfer would result in no change from existing conditions.**

East and Westside Facilities – Programmatic Measure

Decommissioning the East and Westside Facilities could result in slight decreases in ammonia levels in the Keno Impoundment/Lake Ewauna). Decommissioning of the East and Westside canals and hydropower facilities of the Link River Dam by PacifiCorp as a part of the KHSa will redirect water flows currently diverted at Link River Dam into the two canals, back into Link River. Redirection of water flows under the Proposed Action could potentially result in additional nitrification of Upper Klamath Lake outflows that would otherwise not have occurred in the East and Westside canals and hydropower facilities. The additional water flowing through the 0.6-mile long reach between the Link River Dam and the upstream end of the Keno Impoundment/Lake Ewauna could experience slightly increased dissolved oxygen in the river due to turbulent mixing. While this process occurs under existing conditions, it would affect a greater volume of water under the Proposed Action than under existing conditions (i.e., existing conditions flows plus the redirected flows). While the reaeration potential of this reach has not been quantified, it is possible that increased dissolved oxygen in the river would increase nitrification, the microbially mediated process that, in the presence of oxygen, converts ammonia into nitrate and nitrite. Deas (2008) reported that nitrification of Klamath River water occurs in the five-mile reach between Keno Dam and the upper end of J.C. Boyle Reservoir. The Link River reach is substantially shorter than the reach from Keno Dam to J.C. Boyle Reservoir, thus there would be relatively less increased nitrification potential due to the redirection of flows at Link River Dam. Nevertheless, there is potential for a slight long-term benefit in reduced ammonia toxicity in the Keno Impoundment/Lake Ewauna due to decommissioning of the East and Westside canals and hydropower facilities.

While increased dissolved oxygen could occur in the Link River due to the decommissioning, it may not translate into increased dissolved oxygen concentrations in the Keno Impoundment/Lake Ewauna itself since river turbulence would also break up algal cells and cause increased biological oxygen demand in the slow moving waters of the impoundment. Some of this algal cell destruction may also have occurred in the powerhouse turbines, therefore it is not clear whether there would be a net difference in the breakup of algal cells from Upper Klamath Lake outflows and how this would affect dissolved oxygen in the Keno Impoundment/Lake Ewauna. Further, there may be a slight decrease in daytime dissolved oxygen production in the Keno Impoundment/Lake Ewauna during large algal blooms due to the lost photosynthesis potential of algal cells that were destroyed in transit in the Link River. The increase in nitrification could also offset a portion of the oxygenation that occurs in the river, by chemically depleting the oxygen. Overall, given the competing dissolved oxygen effects and the relatively short extent of the Link River, it is likely that the East and Westside Facility Decommissioning action would result in no long-term change from existing conditions with respect to dissolved oxygen concentrations in the Keno Impoundment/Lake Ewauna. **Therefore, implementation of the East and Westside Facility Decommissioning action would be potentially beneficial due to slight decreases in ammonia levels.**

City of Yreka Water Supply Pipeline Relocation – Programmatic Measure

Construction of the City of Yreka Water Supply Pipeline under the Proposed Action could cause short-term increases in suspended material in the Hydroelectric Reach during the construction period. For construction of the City of Yreka Water Supply Pipeline, Dam Removal Entity (DRE) would construct a new, elevated pipeline and steel pipeline bridge to support the pipe above the river at the upstream end of Iron Gate Reservoir (see Section 2.4.3). The pipeline bridge would require in-water work in 2019 to build three concrete piers to support the bridge. Additional construction would occur along the Iron Gate Reservoir banks at each end of the new bridge where the new pipeline would be connected to the existing buried pipeline. The potential for sediments to enter the water during in-water pier construction and from construction site runoff can be minimized or eliminated in Iron Gate Reservoir through the implementation of BMPs for construction activities (Appendix B). Since the construction work will be undertaken in 2019, prior to dam removal, any disturbed sediments would be trapped by Iron Gate Reservoir and not transferred downstream to the Klamath River, particularly given implementation of BMPs. **Under the Proposed Action, the effect of City of Yreka Water Supply Pipeline construction activities on SSC in the Hydroelectric Reach at the upstream end of Iron Gate Reservoir would be a less-than-significant impact.**

KBRA – Programmatic Measures

The KBRA, which is a connected action to the Proposed Action, encompasses several programs that could affect water quality, including:

- Phases I and II Fisheries Restoration Plans
- Fisheries Reintroduction and Management Plan
- Wood River Wetland Restoration

- Water Diversion Limitations
- Water Use Retirement Program
- Interim Flow and Lake Level Program
- Upper Klamath Lake and Keno Nutrient Reduction

Implementation of restoration actions, programs, and/or plans presented in the KBRA would accelerate restoration actions currently underway throughout the Klamath Basin (with the exception of the Trinity Basin) including KHSA implementation (i.e., dam removal) and could affect short-term (i.e., during construction activities) and long-term water quality. Within the KBRA, the Fisheries Program and the Water Resources Program encompass the majority of the restoration actions envisioned under the agreement (see Section 2.4.3.8). Many of the KBRA implementation actions are for fisheries restoration, reintroduction, and actions that enhance the amount and timing of water available for fish. Restoration actions include, but are not limited to, prevention of fish entrainment, rehabilitation of uplands, flood plains, riparian habitats, and stream channels, provision of fish passage, and re-introduction of fish to the Upper Klamath Basin, and instream riparian, and upslope actions that protect water quality, improve water quality and/or increase habitat complexity. KBRA elements under both the Fisheries Program and Water Resources Program are also likely to affect water quality in the basin. Some actions will affect water quality through flow augmentation, while others, including the restoration and permanent protection of riparian vegetation, are anticipated to have non-flow-related water quality effects. The following sections present a programmatic analysis of potential KBRA effects on water quality.

Phase I Fisheries Restoration Plan

Implementation of the Phase I Fisheries Restoration Plan could result in long-term reductions in fine sediment inputs, reduced summer water temperatures, improved nutrient interception, and increased dissolved oxygen levels. Several ongoing resource management actions related to water quality may be amplified under the Phase I Plan (see Section 2.4.3.8). The following sections describe the ongoing actions and types of new programs that could be implemented, and their anticipated short-term and long-term effects at a programmatic level.

Floodplain Rehabilitation

Floodplain rehabilitation work would include activities to improve or restore connections between channels and floodplains to create and maintain off-channel habitat accessible to overwintering juvenile salmonids. Floodplain rehabilitation may also include activities such as riparian planting and understory thinning to facilitate the development of mature riparian stands that would provide streamside shade and large and small wood to stream channels and floodplains. Additionally, wetland restoration and levee setback or dike removal may be used to reconnect floodplain hydrology.

In the short term (i.e., during construction activities), these activities may involve the use of backhoe equipment to dig channels, remove/reposition levees and dikes, and conduct mechanical planting. These activities could increase suspended sediments and increase the potential for inorganic and organic contaminants from hazardous materials associated

with construction activities. In the long term, increased seasonal off-channel habitat, wetland restoration, and levee setbacks, may reduce fine sediment deposition in the main channel by allowing sediments and associated nutrients to deposit on floodplains and in wetlands during high flows. Increased stream shading would decrease summer temperatures and increase dissolved oxygen concentrations.

Wetland and Aquatic Habitat Restoration

Upstream of Upper Klamath Lake, activities would include the purchase of restoration easements and the creation of grass banks to facilitate habitat improvement and landowner economic stability. In the short term (i.e., during construction activities), these activities may involve the use of hydroseeding to conduct grass planting. In the long term, restoration easements may reduce fine sediment deposition in the main channel by allowing sediments and associated nutrients to deposit along streambanks and wetlands protected by easements and grass banks during high flows.

Woody Debris Placement

In-stream and streambank large woody debris placement may include both mobile wood (i.e., unanchored) and complex stationary (i.e., anchored) structures and may be used to create off-channel fish habitat or provide cover in deeper pools. In the short term, these activities may involve the use of construction equipment to place large wood in the stream channel or along banks.

Fish Passage Correction

Correction of fish passage issues throughout the Klamath Basin may include culvert upgrades or replacement to meet current fish passage standards and correction of other fish blockages to restore access to new or historical habitats. In the short term, these activities may include in-channel construction of culverts through existing roadways.

Cattle Exclusion Fencing

Cattle exclusion would include the construction of fencing as allowed by Federal and State regulations and local land management plans to prevent cattle from trampling stream banks and would allow the regeneration of riparian vegetation and improving channel structure. Cattle exclusion may be conducted in conjunction with riparian planting as part of the aforementioned floodplain rehabilitation activities. In the long-term, these activities would decrease fine sediment inputs and associated nutrients (primarily phosphorus) to water bodies in the Klamath Basin and promote increased stream shading and reduced summer water temperatures.

Mechanical Thinning and Prescribed Burning

Mechanical thinning and prescribed burning of upland forest areas may be used to mimic some of the functions and characteristics historically provided by a natural fire regime. In the long term, thinning and prescribed burning may reduce the potential for catastrophic fires and the associated high rates of erosion and nutrient release (primarily phosphorus) to tributaries and the main-stem Klamath River.

Purchase of Conservation Easements and/or Land

Purchase of conservation easements and land from willing sellers may allow for more direct land management for habitat enhancement purposes, where the majority of the land involved would be agricultural land. In the long term, these activities would remove acreage from fertilizer and pesticide/herbicide applications, and would decrease nutrients (primarily nitrogen) and organic contaminants runoff to the Klamath River.

Road Decommissioning

Road decommissioning would reduce road densities in areas with a high potential for slope failure and would stabilize hillsides. These activities would decrease the incidence of road failure and would minimize a source of chronic fine sediment and nutrient (primarily phosphorus) input into water bodies in the Klamath Basin.

Treatment of Fine Sediment Sources

Treatment of fine sediment sources would include management of stormwater runoff from roads and improved agricultural and forestry management practices. In the long term, these activities would help decrease the input of fine sediment and associated nutrients (primarily phosphorus) into water bodies in the Klamath Basin.

Gravel Augmentation

Gravel augmentation involves the direct placement of spawning size gravel into the stream channel. Gravel augmentation can increase spawning habitat in systems by increasing the amount of area with suitable substrate. Gravel augmentation activities may involve transportation of gravel from an off-site source using dump trucks and placement in the stream using backhoes. In the short term, these activities would increase suspended sediments in waters proximal to the gravel deposition site and would increase the potential for inorganic and organic contaminants from hazardous materials associated with construction activities.

Individual resource management actions under the Phase I Fisheries Restoration Plan would require separate project-level evaluations under NEPA and ESA; at the programmatic level considered for this EIS/EIR, there is insufficient information to evaluate project-specific short-term (i.e., during construction activities) effects on water quality from these actions. The timing of and specific locations where these resource management actions could be undertaken is not certain, but it is assumed that some of these actions could occur at the same time and in the vicinity of the hydroelectric facility removal actions analyzed above. Although negative short-term effects of increased suspended sediments and increased potential for inorganic and organic contaminants from hazardous materials associated with construction equipment could occur, implementation of construction-related BMPs would occur as part of the Phase I Fisheries Plan resource management actions. **Given these BMPs (including the BMP requiring biodegradable oils in construction equipment used in streams or rivers, see Appendix B.1.1 Water Quality, the short-term effects on suspended sediment concentrations and inorganic and organic contaminants would be less-than-significant.**

In the long term, most of the above resource management actions would reduce fine sediment inputs into streams in the Klamath Basin. Treatment of fine sediment sources may also include other management actions, including managing stormwater runoff from roads and other developed areas, improved agricultural and forestry management practices, and other specific actions depending on the sources of fine sediments. The Phase I Fisheries Restoration Plan activities would also improve shading and thus cool summer water temperatures, increase riparian and wetland nutrient interception and transformation, and increase dissolved oxygen levels (through decreased water temperatures and decreased nutrient loading). As noted above the timing of and specific locations where these resource management actions could be undertaken is not certain, but it is assumed that some of these actions could occur at the same time and in the vicinity of the hydroelectric facility removal actions analyzed above. **Resource management actions implemented under the KBRA Phase I Fisheries Restoration Plan would accelerate long-term improvements in fine sediment, water temperature, nutrients, and dissolved oxygen in the Klamath Basin and would be beneficial.**

Phase II Fisheries Restoration Plan

Implementation of the Phase II Fisheries Restoration Plan under the KBRA (see KBRA Section 10.2) would include a continuation of the same types of resource management actions as under Phase I along with provisions for adaptive management of these actions and would therefore have the same short-term (i.e., during construction activities) and long-term impacts as Phase I. Individual resource management actions under the Phase II Fisheries Restoration Plan would require separate project-level evaluations under NEPA and ESA; at the programmatic level considered for this EIS/EIR, there is insufficient information to evaluate project-specific short-term (i.e., during construction activities) effects on water quality from these actions. The timing of and specific locations where these resource management actions could be undertaken is not certain but it is assumed that some of these actions could occur at the same time and in the vicinity of the hydroelectric facility removal actions analyzed above. Although short-term adverse effects of increased suspended sediments and increased potential for inorganic and organic contaminants from hazardous materials associated with construction equipment could occur, implementation of construction-related BMPs would occur as part of the Phase II Fisheries Plan resource management actions. **Given these BMPs (see Appendix B.1.1 Water Quality), the short-term effects on suspended sediment concentrations and inorganic and organic contaminants would be less-than-significant. Resource management actions implemented under the KBRA Phase II Fisheries Restoration Plan would accelerate long-term improvements in fine sediment, water temperature, nutrients, and dissolved oxygen in the Klamath Basin and would be beneficial.**

Fisheries Reintroduction and Management Plan

Implementation of the trap and haul element of the Fisheries Reintroduction and Management Plan could affect water quality during construction. In the short term (i.e., during construction activities), constructing fish handling facilities downstream from Keno Dam and at Link River Dam would involve the use of construction equipment

for site work and building construction. These activities could increase suspended sediments and increase the potential for inorganic and organic contaminants from hazardous materials associated with construction activities. Although negative short-term effects could occur, implementation of construction-related BMPs would reduce these effects. **Given these BMPs (see Appendix B.1.1 Water Quality), the short-term effects on water quality would be less-than-significant.**

Wood River Wetland Restoration

Implementation of Wood River Wetland Restoration could result in warmer long-term spring water temperatures and reduced fine sediment and nutrient inputs to Upper Klamath Lake. Under the KBRA, the Wood River Wetland Restoration Project (see KBRA Section 18.2.3) would be a new project designed to provide additional water storage for a total of 16,000 acre-feet (AF) of storage in or adjacent to Agency Lake (see Section 2.4.3.8). Wood River Wetland is approximately 3,200 acres in size and is adjacent to Agency Lake and to the north of Agency Lake Ranch. Over 3,000 acres of wetland and two miles of Wood River channel have or are undergoing restoration actions. Options for water management may include using diked areas for pumped storage or breaching levees to reconnect former wetland areas to Agency Lake. Long-term water quality effects associated with the Wood River Restoration Project include the creation of warmer spring temperatures that would be beneficial for rearing juvenile fish in the wetlands (as compared to the cooler temperatures in the Wood River or Upper Klamath Lake) and improved interception and treatment of fine sediment from the Wood River, prior to entering Agency Lake. This may decrease overall nutrient inputs to Upper Klamath Lake by inundating wetland (peat) soils and creating anaerobic conditions that support nutrient retention, particularly in the case of phosphorus (Snyder and Morace 1997). Specific options still need to be developed and studied as part of a separate project-level NEPA evaluation and ESA consultation. There is insufficient information to evaluate project-specific construction-related effects on water quality from the Wood River Wetland Restoration project. The geographic location and timing of this project reduce the potential for any negative water quality effects generated by this action from contributing to the effects of the hydroelectric facility removal actions analyzed above. Although negative short-term effects could occur, implementation of construction-related BMPs would occur. **Given these BMPs (see Appendix B.1.1 Water Quality), the short-term effects would be less-than-significant. Under the KBRA, the Wood River Wetland Restoration Project would accelerate ongoing long-term improvements in water temperature, fine sediment, and nutrients in Agency Lake and would be beneficial.**

Water Diversion Limitations

Implementation of Water Diversion Limitations could result in long-term decreased summer water temperatures in the Klamath River upstream of the Hydroelectric Reach. Under the KBRA, the Water Diversions Limitations (see KBRA Section 15.1) would be a new project that provides specific allocations of water for refuges and limitations on specific diversions for Reclamation's Klamath Project (see Section 2.4.3.8). Actions reducing availability of irrigation water would increase stream flow and decrease summer

water temperatures in the Klamath River upstream of the Hydroelectric Reach, as needed for fisheries. The water quality improvements generated by these water diversion limitations would contribute to the long-term improvements anticipated from hydroelectric facility removal. Diversion limitations under KBRA would also provide a more reliable water supply to the National Wildlife Refuges (NWRs) and would be beneficial (see Section 3.14.4.3). **In the short term, there would be no change from existing conditions on water quality. In the long term, the KBRA Water Diversion Limitations would decrease summer water temperatures in the Klamath River upstream of the Hydroelectric Reach and would be beneficial.**

Water Use Retirement Program

Implementation of the Water Use Retirement Program could result in long-term decreases in summer water temperature and nutrient inputs to Upper Klamath Lake. Under the KBRA, the Water Use Retirement Program (WURP) (see KBRA Section 16.2.2) would be a new project that seeks to increase the inflow to Upper Klamath Lake by 30,000 acre-feet on an average annual basis (see Section 2.4.3.8). Actions reducing surface water use, such as the sale and retirement of irrigation surface water rights, split season irrigation, shift to dryland crops, and fallowing of crop land, would overall increase stream flows and lake levels in Upper Klamath Lake through decreased surface water withdrawals and increased groundwater recharge (see also Reclamation 2012). Overall increased stream flows and lake levels in Upper Klamath Lake would improve water quality by decreasing summer water temperatures and decreased irrigation. Fallowing of crop land would decrease fertilizer (nutrient) and pesticide/herbicide (inorganic and organic contaminants) inputs.

Water elevations in Upper Klamath Lake affect water elevations in the emergent wetlands of Upper Klamath NWR, with the wetlands approximately 90% dry at lake elevations below 4,139.50 feet (Mauser and Mayer 2011). In an analysis of the potential effects of KBRA on Upper Klamath NWR, Mauser and Mayer (2011) found that the frequency in which Upper Klamath Lake levels fall below 4,139.50 feet would be greater under the KBRA (82% of years) compared to the No Action/No Project Alternative (68% of years). This means that the frequency of wetland drying at Upper Klamath NWR would increase under KBRA. However, according to the analysis presented by Mauser and Mayer (2011), the duration of the drying episodes would be less than currently occur. Therefore, drying of soils could be more extensive or complete under the No Action/No Project Alternative than the Proposed Action, which could affect phosphorus cycling and release to Upper Klamath Lake. Note that the potential impacts of the KBRA on waterfowl and migrating birds in Upper Klamath NWR are discussed in Section 3.14.4.3 of this Klamath Facilities EIS/EIR.

Mauser and Mayer's (2011) projections for future lake levels did not account for the 2008 Biological Opinion (USFWS 2008), which dictates lake levels under the current conditions including the No Action/No Project Alternative. According to the Biological Opinion, lake levels currently are allowed to go below 4,139.50 feet during July through January, or about 7 out of 12 months during a year. Therefore, the difference in number of months that the Upper Klamath NWR could go dry as described by Mauser and Mayer

(2011) would be partially dictated by Biological Opinion minimum values. Under the 2008 Biological Opinion, this represents only a one month difference in lake level management between KBRA (6 of 12 months) and the No Action/No Project Alternative (7 of 12 months). Thus the hydrologic effect on the Upper Klamath Lake NWR under KBRA could be less than described by Mauser and Mayer (2011).

According to research conducted on wetlands around Upper Klamath Lake, drying of wetland soils and associated aerobic decomposition of peat can contribute to release of phosphorus (Snyder and Morace 1997, Aldous et al. 2005). However, the degree to which this occurs is not universal, and in fact appears to be substantially less in “undisturbed” wetlands, including Upper Klamath NWR, than “restored” wetlands that had been previously diked and drained (Aldous et al. 2005).

If Upper Klamath NWR dries more frequently in the summer and fall, but for shorter periods that allow wetlands soil to remain wet in the root zone below the water level, the breakdown of peat soils may be minimized if not completely negated. Aldous et al. (2005) tested different hydrologic treatments for cores from undisturbed and restored wetlands around Upper Klamath Lake. If wetlands were allowed to remain moist, rather than dry completely, the release of phosphorus was minimized, and the undisturbed wetlands, which included Upper Klamath NWR, effectively had no phosphorus release. Because KBRA-flows and their effects on Upper Klamath Lake water elevation cannot be conclusively predicted at this time, it is not possible to determine whether the NWR wetlands or their soils would remain moist even if they are drained more frequently, which would minimize phosphorus release, or if they would dry out significantly more, which could foster some phosphorus release.

An additional consideration is the magnitude of potential phosphorus release from NWR wetlands compared to the magnitude of other external and internal nutrient loading sources to the lake. As a conservative calculation, the phosphorus loads from the Upper Klamath NWR and from Upper Klamath Lake internal loading can be estimated for the period of potential drying as shown in Mauser and Mayer (2011) (i.e., July–October). Phosphorus flux from the refuge was initially taken as the median phosphorus release rate from diked and drained wetlands (3.7 pounds per acre per day; Table 13 from Snyder and Morace [1997]), which should be significantly greater than the actual phosphorus release rate from the NWR because it represents “disturbed” wetlands. This rate is about a factor of 10 greater than what was found when the Williamson River Delta was breached and reflooded (Wong et al. 2011), reinforcing the conservative nature of this analysis. Assuming a wetland area of 13,000 acres in the refuge (Snyder and Morace 1997), and accounting for unit changes (i.e., from English units to SI units), Upper Klamath NWR could contribute as much as about 7200 kg of phosphorus to Upper Klamath Lake during this 120 day period. These estimates were compared with estimated loads in Upper Klamath Lake from data collected by the Klamath Tribes (Kann and Walker 1999), averaged over the same 120 day period from 1991 to 1998. Median total external loading to Upper Klamath Lake during the same 120 day periods from 1991 to 1998 was approximately 39,200 kg. Thus, Upper Klamath NWR could provide a significant additional load of phosphorus to Upper Klamath Lake compared to existing

July-October external loading (i.e. about 18%) if the soils are allowed to dry significantly. However, the summertime nutrient and bloom dynamics of Upper Klamath Lake are dominated by internal loading; median July to October internal loading is about 163,000 kg, with total external and internal loading being about 201,000 kg. Therefore, loading from Upper Klamath NWR would be about 4.5% of the internal load, and 3.5% of the total load, as conservative estimates. Finally, whether this would actually represent a significant increase from current loading is unlikely, as the refuge can dry out for considerable periods under existing lake level management, as dictated by the NOAA Fisheries Service 2008 Biological Opinion, and therefore likely contributes nutrients in a similar fashion. Therefore, even if KBRA-related drying of Upper Klamath NWR wetland soils did increase the release phosphorus as hypothesized, the effect on water quality or algal blooms in the lake would be negligible compared to other sources and ongoing loading from the wetlands, and the increase from current conditions would also be negligible.

There are timing issues associated with the hypothesized loading as well, depending on management of Upper Klamath Lake under the WURP. If the wetlands dry from July to October, the release of nutrients would most likely occur in the fall when the soils are rewetted. This is after the most sensitive period in the lake, when algal blooms typically drive dissolved phosphorus concentrations to limiting levels and additional phosphorus could spur additional algal growth. Instead, added nutrients would have little effect on algal growth and might be largely exported from the lake during the winter.

In summary, conservative calculations based on available research for Upper Klamath Lake and surrounding wetland areas suggests that, if additional nutrients are released as a result of an increased frequency of drying events under KBRA, concentrations will be small compared to other loading sources, notably the large internal load that occurs in most summers, and would have minimal effect on the water quality or algal blooms in the lake. As noted previously, the hydrologic effect on the Upper Klamath Lake NWR under KBRA could be less than described by Mauser and Mayer (2011), hence any associated nutrient effect could also be less. Further, KBRA is analyzed in this EIS/EIR at the programmatic level and future environmental compliance would be necessary to implement the various projects. As part of these future analyses, measures to limit potential adverse effects would be developed and some of those measures could include keeping the refuge soils moist during the summer periods to minimize unintended release of phosphorus, or keeping the drying periods relatively short to reduce the amount of phosphorus released, possibly even compared to current conditions (i.e., provide a net benefit).

Since decreased irrigation and fallowing of crop land under WURP would decrease nutrient inputs via fertilizer use, while increased drying of wetland soils in Upper Klamath NWR would only slightly increase nutrient (phosphorus) input to the lake (or could have no effect), overall, the water quality improvements generated by the WURP in Upper Klamath Lake would translate downstream to the Klamath River and would contribute to the long-term improvements anticipated from hydroelectric facility removal.

In the short term, there would be no change from existing conditions on water quality. The KBRA Water Use Retirement Program would decrease long-term water temperatures, nutrients, and pesticides and herbicides in Upper Klamath Lake and would be beneficial.

Interim Flow and Lake Level Program

Implementation of the Interim Flow and Lake Level Program could result in long-term decreases in summer water temperature and nutrient inputs to Upper Klamath Lake.

Under the KBRA, the Interim Flow and Lake Level Program (see KBRA Section 20.4) would be an interim program of water purchase and lease to further the goals of the fisheries programs during the interim period prior to full implementation of the On-Project Plan and WURP. Because it is focused on reducing surface water use, it would have the same effects on water quality as the WURP. The water quality improvements generated by the Interim Flow and Lake Level Program would contribute to the long-term improvements anticipated from hydroelectric facility removal. **In the short term, there would be no change from existing conditions on water quality. The KBRA Interim Flow and Lake Level Program would decrease long-term water temperatures and decrease nutrients in Upper Klamath Lake and would be beneficial.**

Upper Klamath Lake and Keno Nutrient Reduction

Implementation of the Upper Klamath Lake and Keno Nutrient Reduction Program could result in long-term decreases in nutrient inputs, increases in seasonal dissolved oxygen, and decreases in concentrations of nuisance algal species in these waterbodies. KBRA (Appendix C-2, line 11) includes a program to study and reduce nutrient concentrations in the Keno Impoundment/Lake Ewauna and Upper Klamath Lake in order to reduce dissolved oxygen and nuisance algal problems in both water bodies. Restoration actions to control nutrients have not been developed, and there are many possible actions that could require construction of treatment wetlands, construction of facilities, or chemical treatments of bottom sediment, among other possibilities. A nutrient reduction program in the Keno Impoundment/Lake Ewauna and Upper Klamath Lake would be designed to improve water quality (increasing seasonally low dissolved oxygen and reducing seasonal algal blooms) and fish passage through the Keno Impoundment/Lake Ewauna in summer and fall months, however implementation of this nutrient reduction program will require future environmental compliance investigations and a determination on significance cannot be made at this time.

3.2.4.3.3 Alternative 3: Partial Facilities Removal of Four Dams

The Partial Facilities Removal of Four Dams Alternative would remove enough of the material from each dam to allow the river to retain a free-flowing condition and volitional fish passage under all river stages and flow conditions. Some portion of each dam and much of the appurtenant infrastructure would remain, such as the dam foundations, power houses, buildings, tunnels, and pipes. All tunnel openings would be sealed with concrete, remaining buildings would be fenced, and all hazardous materials would be removed from the site. This alternative would include the transfer of the Keno Facility to the Reclamation and implementation of the KBRA. The Partial Facilities Removal of Four

Dams Alternative would result in the release of sediments trapped behind the dams and would have the same short-term (<2 years following dam removal) effects on suspended sediments, dissolved oxygen, nutrients, and inorganic and organic contaminant concentrations in both the Upper and Lower Klamath Basin as the Proposed Action, as follows:

- **The short-term increases in SSC in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment would be a significant impact.**
- **The short-term decrease in dissolved oxygen concentrations would be a significant impact on the Lower Klamath River from Iron Gate Dam to approximately Clear Creek (≈RM 100). There would be no change from existing conditions on the Klamath Estuary or the marine nearshore environment.**
- **The short-term increase in nutrients in the Hydroelectric Reach, the Lower Klamath River, and the Klamath Estuary would be a less-than-significant impact.**
- **The short-term effects on organic and inorganic contaminants in the Hydroelectric Reach, the Lower Klamath River, and the Klamath Estuary would be a less-than-significant impact.**

Dam deconstruction activities under the *Partial Facilities Removal of Four Dams Alternative* would have the same short-term effects on suspended sediments in the Hydroelectric Reach, the Lower Klamath River, and the Klamath Estuary as the Proposed Action and would be a less-than-significant impact. There would be no change from existing conditions on the marine nearshore environment.

Construction activities associated with implementation of IMs 7 (J.C. Boyle Gravel Placement and/or Habitat Enhancement) and 16 (Water Diversions) would have the same short-term effects on suspended sediments in the Hydroelectric Reach as the Proposed Action and would be a less-than-significant impact. There would be no change from existing conditions on the Lower Klamath River, Klamath Estuary, or the marine nearshore environment.

Revegetation activities (i.e., hydroseeding) under the *Partial Facilities Removal of Four Dams Alternative* would have the same short-term effects on erosion of fine sediments from exposed reservoir terraces in the Hydroelectric Reach and transport into the Lower Klamath River and Klamath Estuary as the Proposed Action and would be beneficial. There would be no change from existing conditions on the marine nearshore environment.

Under the Partial Facilities Removal Alternative, interception and retention of sediments and nutrients behind the dams at the Four Facilities would no longer occur and would have the same long-term (2–50 years following dam removal) effects in both the Upper and Lower Klamath Basin as the Proposed Action. **Long-term increases in suspended sediments and nutrients in the Hydroelectric Reach, the Lower**

Klamath River, the Klamath Estuary, and the marine nearshore environment as the Proposed Action and would be a less-than-significant impact.

Additionally, elimination of the lacustrine environment of the reservoirs would have the same long-term (2–50 years following dam removal) effects on water temperature, dissolved oxygen, pH, algal toxins and chlorophyll-*a*, and inorganic and organic concentrations in both the Upper and Lower Klamath Basin as the Proposed Action, as follows:

- **The long-term increases in summer/fall water temperatures and diel temperature variation in the J.C. Boyle Bypass Reach due to the elimination of hydropower peaking operations would be a less than significant impact. Slight decreases in long-term summer/fall water temperatures and less diel temperature variation in the J.C. Boyle Peaking Reach would be beneficial. Downstream from Copco 1 and Iron Gate Dams, the long-term increase in spring water temperatures would be less than significant, and the decrease in late summer/fall water temperatures would be beneficial for the Hydroelectric Reach and the Lower Klamath River from Iron Gate Dam to the confluence with the Salmon River. There would be no direct effect on water temperature for Klamath River downstream from the Salmon River, the Klamath Estuary, or the marine nearshore environment.**
- **Long-term increases in summer and fall dissolved oxygen concentrations in the Hydroelectric Reach and immediately downstream from Iron Gate Dam would be beneficial. There would be no change from existing conditions on dissolved oxygen by the confluence with the Trinity River.**
- **Long-term slight summertime increases in pH and daily pH fluctuations at the Oregon-California State line and upstream and downstream reaches that are currently riverine would be less than significant. The decrease in high summertime daily pH fluctuations in the free-flowing reaches of the river that replace Copco 1 and Iron Gate Reservoirs in the Hydroelectric Reach would be beneficial. The summertime increases in pH in the Lower Klamath River from Iron Gate Dam to the Scott River would be less than significant. There would be no change from existing conditions on pH for Klamath River just downstream from Seiad Valley, the Klamath Estuary, and the marine nearshore environment. The long-term decrease in chlorophyll-*a* and substantial decrease or elimination of algal toxins and in the Hydroelectric Reach and subsequent transport into the Lower Klamath River and the Klamath Estuary would be beneficial.**
- **Long-term effects on inorganic and organic contaminants in the Hydroelectric Reach, the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment would be a less-than-significant impact.**

Keno Transfer

Implementation of the Keno Transfer could cause adverse water quality effects. The Keno Transfer is a transfer of title for the Keno Facility from PacifiCorp to the Reclamation. This transfer would not result in the generation of new impacts on water

quality compared with existing facility operations. Following transfer of title, Reclamation would operate Keno in compliance with applicable law and would provide water levels upstream of Keno Dam for diversion and canal maintenance consistent with agreements and historic practice (see KHSA Section 7.5.4). **Therefore, implementation of the Keno Transfer would result in no change from existing conditions.**

East and Westside Facilities – Programmatic Measure

Decommissioning the East and Westside Facilities could result in slight decreases in ammonia levels in the Keno Impoundment/Lake Ewauna. Decommissioning of the East and Westside canals and hydropower facilities of the Link River Dam by PacifiCorp as a part of the KHSA would have the same effect as described under the Proposed Action. **Therefore, implementation of the East and Westside Facility Decommissioning action would be potentially beneficial due to slight decreases in ammonia levels.**

City of Yreka Water Supply Pipeline Relocation – Programmatic Measure

Construction activities for the City of Yreka Water Supply Pipeline under the *Partial Facilities Removal of Four Dams Alternative* would have the same short-term effects on suspended sediments in the Hydroelectric Reach as the Proposed Action and would be a less-than-significant impact. There would be no change from existing conditions on the Lower Klamath River, Klamath Estuary, or the marine nearshore environment.

KBRA – Programmatic Measures

KBRA Actions under the Partial Facilities Removal of Four Dams Alternative would be the same as those under the Proposed Action. **Therefore, under the *Partial Facilities Removal of Four Dams Alternative*, KBRA actions would accelerate long-term improvements in water quality (i.e., suspended sediment, water temperature, nutrients, and dissolved oxygen) anticipated under KHSA implementation (i.e., dam removal) and would be beneficial.**

3.2.4.3.4 Alternative 4: Fish Passage at Four Dams

The Fish Passage at Four Dams Alternative would provide upstream and downstream fish passage at the Four Facilities, but would not include implementation of the KBRA. The ongoing restoration actions, described in the No Action alternative, would continue. The alternative would incorporate the mandatory prescriptions from the Departments of the Interior and Commerce imposed during the FERC relicensing process, including fishway installation for both upstream and downstream migrations at all facilities and barriers to prevent juvenile salmonid entrainment into turbines. In addition to the fishways, there is a series of flow-related measures, including a condition that requires at least 40 percent of the inflow to the J.C. Boyle Reservoir to be released downstream. This alternative would limit generation of peaking power at J.C. Boyle Powerhouse to one day per week as water supplies allow, and would include recreation flows one day a week. The flow requirements would reduce the overall power generation.

Short-term effects on water quality from construction activities associated with new fish passage facilities would occur, including increased suspended sediments and increased

potential for inorganic and organic contaminants from hazardous materials associated with construction equipment. These short-term effects would be a significant impact. However, the impacts would be reduced through implementation of BMPs for construction activities that occur in or adjacent to the reservoirs and the Klamath River. BMPs would minimize in-water work and would minimize or eliminate the potential for sediment or toxic substances entering the water. The short-term effects would likely follow the schedule prescribed in the FERC relicensing process (see Table 2-26), which would allow downstream facilities to be installed prior to upstream passage facilities and would take place over a 4 to 8 year period. Accordingly, short-term construction related effects on water quality would occur in association with construction activities for each of the fish passage improvements (i.e., upstream fish passage, spillway modifications, tailrace barriers, screens and bypass structures).

Under the *Fish Passage at Four Dams Alternative*, short-term increases in SSCs and potential inorganic and organic contaminants in the Hydroelectric Reach, the Lower Klamath River, the Klamath Estuary and the marine nearshore environment due to construction activities would be a less-than-significant impact.

Under the Fish Passage at Four Dams Alternative, the overall higher flow releases would result in more reservoir water entering the Bypass Reach and correspondingly warmer water temperatures during summer and early fall, and cooler temperatures in late fall and winter. These effects would be similar to those under the Proposed Action; however, as with the Proposed Action, areas adjacent to the coldwater springs in the Bypass Reach would continue to serve as thermal refugia for aquatic species because the springs themselves would not be affected by the Fish Passage at Four Dam Alternative. Since J.C. Boyle Reservoir, with its large thermal mass, would remain in place, effects on diel temperature variation in the Bypass Reach under the Fish Passage at Four Dams Alternative would be similar to those described for the No Action/No Project Alternative (i.e., reduced diel temperature variation). Similar to the Proposed Action, maximum water temperatures in the Peaking Reach would be slightly cooler and temperatures would be less artificially variable, also due to higher overall flows and the lower frequency of peaking operations at the J.C. Boyle Powerhouse.

Under the *Fish Passage at Four Dams Alternative*, long-term (2–50 years following construction of fish passage facilities) increases in summer/early fall water temperatures in the J.C. Boyle Bypass Reach, due to the higher overall flow releases would be a less than significant impact. Continued reduced diel temperature variability in the Bypass Reach would be similar to those under the No Action/No Project Alternative (i.e., no change from existing conditions). Slight decreases in long-term maximum summer/fall water temperatures and less artificial diel temperature variation in the J.C. Boyle Peaking Reach would be beneficial. Long-term water temperature effects in the remainder of the Hydroelectric Reach (i.e., Copco 1 and Iron Gate Reservoirs) would be similar to those under the No Action/No Project Alternative (i.e., no change from existing conditions).

The altered (more stable) flow regime in the J.C. Boyle Peaking Reach may also affect dissolved oxygen, pH, and nutrients due to increased periphyton growth at this location. However, changes in these parameters are not certain; the role of photosynthesis and community respiration from periphyton growth in the Peaking Reach is unknown because nutrient cycling and resulting rates of primary productivity under the No Action/No Project Alternative are uncertain (see Section 3.2.1.1). Other than this potential and unknown effect related to the flow regime downstream from J.C. Boyle Dam, the presence of fish passage facilities at each of the Four Facilities would not affect other long-term water quality parameters in the Hydroelectric Reach. **Under the *Fish Passage at Four Dams Alternative*, long-term (2–50 years following construction of passage facilities) effects on water quality in the Upper or Lower Klamath Basin would be the same as effects under the No Action/No Project Alternative (i.e., no change from existing conditions).**

Trap and Haul – Programmatic Measure

Implementation of the trap and haul measure could affect water quality during construction. In the short term (i.e., during construction activities), constructing fish handling facilities downstream from Keno Dam and at Link River Dam would involve the use of construction equipment for site work and building construction. These activities could increase suspended sediments and increase the potential for inorganic and organic contaminants from hazardous materials associated with construction activities. Although negative short-term effects could occur, implementation of construction-related BMPs would reduce these effects. **Given these BMPs (see Appendix B.1.1 Water Quality), the short-term effects on water quality would be less-than-significant.**

3.2.4.3.5 Alternative 5: Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative proposes to remove the two largest dams in the Hydroelectric Reach and install fishways for volitional fish passage on the remaining installations. Most of the mandatory prescriptions associated with fish passage would still apply to the remaining dams, including flow requirements and standards for fish passage facilities. Alternative 5 would include no peaking power generation or release of flow for recreation at J.C. Boyle Powerhouse because Copco 1 and Iron Gate Dams would not be present to reregulate flows downstream. For the purposes of this analysis, alternatives that would not result in full implementation of the KHSAs do not include the KBRA as a connected action to the alternative. In the Hydroelectric Reach of the Upper Klamath Basin, this alternative would result in the release of sediments trapped behind Copco 1 and Iron Gate Dams. This release would have short-term (<2 years following dam removal/construction of fish passage facilities) effects on sediment and turbidity, dissolved oxygen, nutrients, and inorganic and organic contaminant concentrations in the Klamath River.

Interception and retention of sediments would still occur behind J.C. Boyle and Copco 2 Dams; this would have long-term (2–50 years following dam removal/construction of fish passage facilities) effects on sediment and turbidity. Additionally, elimination of the lacustrine environment of Copco 1 and Iron Gate Reservoirs under this alternative would

have long-term effects on water temperature, dissolved oxygen, nutrients, pH, algal toxins and chlorophyll-*a* in the downstream river. The following sections provide detail regarding the anticipated effects of this alternative on water quality.

Water Temperature

Upper Klamath Basin

Since the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would include no peaking power generation or release of flow for recreation at J.C. Boyle Dam, water temperature effects in the J.C. Boyle Bypass Reach would be similar to those under the Fish Passage at Four Dams Alternative (see Section 3.2.4.3.4) because the Fish Passage at Four Dams Alternative also keeps J.C. Boyle Reservoir in place and includes significantly increased flow releases over the No Action/No Project Alternative, approaching the flow conditions for this alternative (i.e., no peaking power generation or release of recreation flows). Thus, the effects would be continued low diel temperature variation and overall warmer water temperatures in the Bypass Reach during summer and early fall, and cooler temperatures in late fall and winter. In the Peaking Reach, water temperature effects would be the same as under the Proposed Action (i.e., slightly lower maximum water temperatures and less artificial diel temperature variation during summer and early fall) since no peaking flows would occur and the effect of J.C. Boyle thermal mass on water temperatures does not extend this far downstream. The effects of removing Iron Gate and Copco 1 Reservoirs and converting the reservoir areas to a free-flowing river under this alternative would be similar to effects for the Lower Klamath River immediately downstream from Iron Gate Dam under the Proposed Action.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, long-term (2–50 years following dam removal/construction of fish passage facilities) increases in summer/fall water temperatures in the J.C. Boyle Bypass Reach due to the elimination of bypass flows and increased dilution of cold spring water with warmer reservoir water would be a less than significant impact. Slight decreases in long-term maximum summer/fall water temperatures and less artificial diel temperature variation in the J.C. Boyle Peaking Reach would be beneficial. From Copco 1 Reservoir to Iron Gate Reservoir, long-term increases in spring water temperatures would be less than significant and decreases in late summer/fall water temperatures in the Hydroelectric Reach would be similar to the Proposed Action and would be beneficial.

Lower Klamath Basin

While model results analyzed for the Proposed Action do not explicitly isolate the effects of the four individual reservoirs on water temperatures, the KRWQM includes a scenario in which only Iron Gate, Copco 1, and Copco 2 Dams are removed but J.C. Boyle remains in place (“WIGC” PacifiCorp 2004b, Dunsmoor and Huntington 2006, see also Appendix D). This scenario is analogous to the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative because Copco 2 Reservoir has no active storage and thus has a negligible effect on hydraulic residence time and water temperature. KRWQM WIGC results indicate that compared with removal of all four

reservoirs (“WIGCJCB”), the long-term effects of removing Iron Gate and Copco 1 Reservoirs and converting the reservoir areas to a free-flowing river under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be similar to effects on water temperature for the Lower Klamath Basin under the Proposed Action (see Figure 3.2-26).

3.2.4.3.6 Suspended Sediments

Upper Klamath Basin

Upstream of Copco 1 Dam, short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) SSCs under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be the same as SSCs under the No Action/No Project Alternative. However, because Copco 1 and Iron Gate Reservoirs contain 85 percent of the total erodible sediment contained with the reservoirs at the Four Facilities (CDM 2011), the short-term effects of sediment release on SSCs downstream from Copco 1 Dam under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be similar to effects for the Hydroelectric Reach under the Proposed Action. Compared to the Proposed Action, there would be approximately 15 percent less sediment mobilized from the reservoirs at the Four Facilities (sediments in J.C. Boyle would remain in place) and short-term SSCs within the Hydroelectric Reach may exhibit somewhat lower peaks. However, the overall pattern and duration of high SSCs would be the same, as would the general magnitude of the effect.

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, short-term (<2 years following dam removal/construction of fish passage facilities) increases in SSC in the Hydroelectric Reach due to mobilization of sediment deposits from Copco 1 Reservoir and Iron Gate Reservoir would be a significant impact.

Stormwater runoff from deconstruction activities under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 2 and Iron Gate Alternative may cause increases in suspended material in the Hydroelectric Reach during the deconstruction period. Dam deconstruction effects on suspended sediments would be limited to Copco 1 and Iron Gate Reservoirs and downstream river reaches, while fish passage construction effects would be limited to J.C. Boyle and Copco 2 Reservoirs and downstream river reaches. However, both dam deconstruction and fish passage construction activities would be complex and overlapping in terms of resulting river concentrations of suspended sediments and would require implementation of BMPs at each reservoir site. Therefore, dam deconstruction and fish passage construction activities in the Hydroelectric Reach under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be essentially the same as those for the Hydroelectric Reach under the Proposed Action.

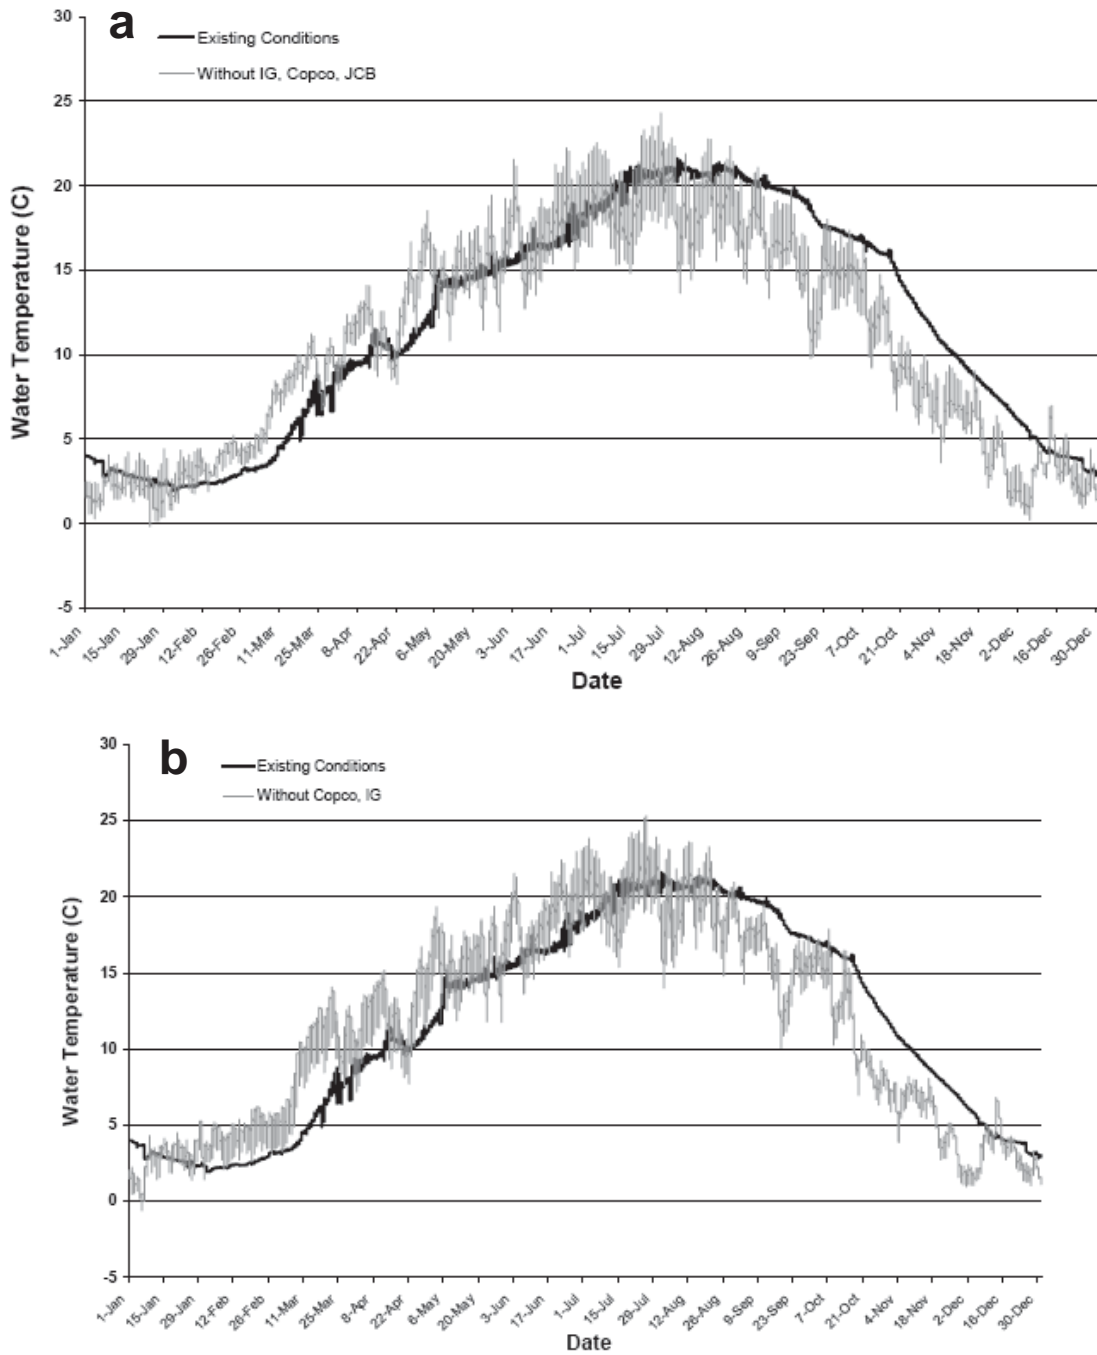

Figure 3.2-26. Simulated Hourly Water Temperature Downstream from Iron Gate Dam (RM 190.1) Based on Year 2004 for Current Conditions Compared to Hypothetical Conditions: (a) without Iron Gate (IG), Copco 1 and 2, and J.C. Boyle (JCB) Dams and (b) without Iron Gate (IG) and Copco 1 and 2 Dams. Source: PacifiCorp 2005.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, short-term (<2 years following dam removal/construction of fish passage facilities) deconstruction-related increases in SSC in the Hydroelectric Reach would be a less-than-significant impact.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, revegetation activities (i.e., hydroseeding) would have the same short-term (< 2 years following dam removal) effects on erosion of fine sediments from exposed reservoir terraces in the Hydroelectric Reach as the Proposed Action and would be beneficial.

Due to the lack of continued interception and retention of mineral (inorganic) and algal-derived (organic) suspended materials behind Copco 1 and Iron Gate Dams under the Fish Passage at Two Dams, Remove Copco 1 and Iron Gate Alternative, long-term (2-50 years following dam removal/construction of fish passage facilities) effects on SSCs for the Hydroelectric Reach would be similar to those for the Hydroelectric Reach under the Proposed Action. **Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, long-term (2–50 years following dam removal/construction of fish passage facilities) increases in mineral (inorganic) and algal-derived (organic) suspended material in the Hydroelectric Reach would be a less-than-significant impact.**

Lower Klamath Basin

Because Copco 1 and Iron Gate Reservoirs contain 85 percent of the total erodible sediment contained with the reservoirs at the Four Facilities (CDM 2011), the short-term (<2 years following dam removal/construction of fish passage facilities) effects of sediment release on concentrations of suspended sediments in the Lower Klamath Basin under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be similar to those for the Lower Klamath Basin under the Proposed Action. Because there would be approximately 15 percent less sediment mobilized (sediments in J.C. Boyle would remain in place), short-term (<2 years following dam removal/construction of fish passage facilities) SSCs in the Lower Klamath Basin may exhibit somewhat lower peaks. However, the overall pattern and duration of high SSCs would be the same, as would the general magnitude of the effect.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, short-term (<2 years following dam removal/construction of fish passage facilities) increases in SSC in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment would be a less-than-significant impact.

Stormwater runoff from deconstruction activities under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate alternative may cause increases in suspended material in the Klamath River downstream from Iron Gate Dam during the deconstruction period. Dam deconstruction effects on suspended sediments would be limited to Copco 1 and Iron Gate Reservoirs and downstream river reaches, while fish

passage construction effects would be limited to J.C. Boyle and Copco 2 Reservoirs and downstream river reaches. However, both dam deconstruction and fish passage construction activities would be complex and overlapping in terms of river SSCs and would require implementation of BMPs at each reservoir site. Therefore, dam deconstruction and fish passage construction activities would have the same effects on SSCs in the Lower Klamath Basin as the Proposed Action and the Fish Passage at Four Dams Alternative.

Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, deconstruction-related increases in SSC in the Lower Klamath River and the Klamath Estuary would be a less-than-significant impact. There would be no change from existing conditions on the marine nearshore environment.

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, revegetation activities (i.e., hydroseeding) would have the same short-term (< 2 years following dam removal) effects on erosion of fine sediments from exposed reservoir terraces in the Hydroelectric Reach and transport into the Lower Klamath River and Klamath Estuary as the Proposed Action and would be beneficial. There would be no change from existing conditions on the marine nearshore environment.

Under this alternative, long-term (2–50 years following dam removal/construction of fish passage facilities) effects on mineral (inorganic) and algal-derived (organic) suspended materials in the Lower Klamath Basin due to the lack of continued interception and retention of sediment behind Copco 1 and Iron Gate Dams would be similar to those for the Lower Klamath Basin under the Proposed Action.

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, the long-term (2–50 years following dam removal/construction of fish passage facilities) increases on mineral (inorganic) and algal-derived (organic) suspended materials in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment would be a less-than-significant impact.

Nutrients

Upper Klamath Basin

Upstream of Copco 1 Reservoir, effects on nutrients under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be the same as effects under the No Action/No Project Alternative because J.C. Boyle Dam would remain in place. However, Copco 1 and Iron Gate Reservoirs are the largest and deepest reservoirs in the Hydroelectric Reach with the longest residence times (FERC 2007), and the short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) the effects of removing them and converting the reservoir areas to a free-flowing river under this alternative would be similar to removing all four dams for the reach from Copco 1 Reservoir to Iron Gate Reservoir. Therefore, under this alternative, effects on nutrients

for the reach from Copco 1 Reservoir to Iron Gate Reservoir would be the same as effects for the Lower Klamath River immediately downstream from Iron Gate Dam under the Proposed Action.

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) increases in nutrients in the Hydroelectric Reach would be a less-than-significant impact.

Lower Klamath Basin

Copco 1 and Iron Gate Reservoirs are the largest and deepest reservoirs in the Hydroelectric Reach with the longest residence times, so the short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) effects of removing them and converting the reservoir areas to a free-flowing river under this alternative would be similar to removing all four dams. Therefore, under this alternative, effects on nutrients would be the same as effects for the Lower Klamath River under the Proposed Action.

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) increases in nutrients in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment would be a less-than-significant impact.

Dissolved Oxygen

Upper Klamath Basin

Upstream of Copco 1 Dam, short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) dissolved oxygen under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be the same as dissolved oxygen under the No Action/No Project Alternative. However, because Copco 1 and Iron Gate Reservoirs contain 85 percent of the total erodible sediment contained within the reservoirs at the Four Facilities (CDM 2011), the short-term effects of sediment release on dissolved oxygen concentrations downstream from Copco 1 Dam under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be similar to effects for the Hydroelectric Reach under the Proposed Action. Compared to the Proposed Action, there would be approximately 15 percent less sediment mobilized (sediments in J.C. Boyle would remain in place) and short-term SSCs in the Lower Klamath Basin may exhibit somewhat lower peaks. However, the overall pattern and duration of high SSCs would be the same, as would the general magnitude of the effect on dissolved oxygen. The short-term effects of sediment release on oxygen demand and dissolved oxygen concentrations in the Hydroelectric Reach under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be essentially the same as those for the Lower Klamath Basin under the Proposed Action.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, short-term (<2 years following dam removal/construction of fish passage facilities) decreases in dissolved oxygen in the Hydroelectric Reach from Copco 1 Reservoir to Iron Gate Reservoir would be a significant impact. The long-term (2-50 years following dam removal) increase in summer and fall dissolved oxygen concentrations in the Hydroelectric Reach would be beneficial.

Lower Klamath Basin

Because Copco 1 and Iron Gate Reservoirs contain 85 percent of the total erodible sediment contained within the reservoirs at the Four Facilities (CDM 2011), the short-term (<2 years following dam removal/construction of fish passage facilities) effects of sediment release on concentrations of dissolved oxygen in the Lower Klamath Basin under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be similar to those for the Lower Klamath Basin under the Proposed Action. Because there would be approximately 15 percent less sediment mobilized (sediments in J.C. Boyle would remain in place), short-term SSCs in the Lower Klamath Basin may exhibit somewhat lower peaks and dissolved oxygen demand may also decrease. However, the overall pattern and duration of high SSCs would be the same, as would the general magnitude of the effect on dissolved oxygen.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the short-term (<2 years following dam removal/construction of fish passage facilities) decrease in dissolved oxygen concentrations would be a significant impact on the lower basin from Iron Gate Dam to approximately Clear Creek (≈RM 100), but would not affect dissolved oxygen in the Klamath Estuary or the marine nearshore environment. The long-term (2–50 years following dam removal) increases in summer and fall dissolved oxygen concentrations immediately downstream from Iron Gate Dam would be beneficial.

pH

Upper Klamath Basin

Upstream of Copco 1 Reservoir, effects on pH under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be the same as effects under the No Action/No Project Alternative because J.C. Boyle Dam would remain in place. The effects of removing Iron Gate and Copco 1 Reservoirs and converting the reservoir areas to a free-flowing river under this alternative would be similar to effects on pH for the Lower Klamath River immediately downstream from Iron Gate Dam under the Proposed Action.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the long-term (2–50 years following dam removal/construction of fish passage facilities) decrease in high summertime daily pH fluctuations in the Hydroelectric Reach from Copco 1 Reservoir to Iron Gate Reservoir would be beneficial.

Lower Klamath Basin

Because J.C. Boyle Reservoir does not currently appear to substantially alter pH in the river downstream from the dam (see Figure 3.2-22.) having this dam in place would not affect pH downstream from the Hydroelectric Reach in the Lower Klamath Basin. However, apparent seasonal and daily pH fluctuations in Copco 1 and Iron Gate Reservoirs would be altered once these reservoir areas were converted to a free-flowing river. Therefore, effects on pH under this alternative would be similar to effects on pH for the Lower Klamath River immediately downstream from Iron Gate Dam under the Proposed Action.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, long-term (2–50 years following dam removal/construction of fish passage facilities) summertime increases in pH would be less than significant for the Lower Klamath River from Iron Gate Dam to the confluence with the Scott River. There would be no change from existing conditions on pH for the Klamath River just downstream from Seiad Valley, the Klamath Estuary, and the marine nearshore environment.

Chlorophyll-a and Algal Toxins

Upper Klamath Basin

Upstream of Copco 1 Reservoir, effects on algal toxins and chlorophyll-*a* under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be the same as effects under the No Action/No Project Alternative because J.C. Boyle Dam would remain in place. Copco 1 and Iron Gate Reservoirs are the largest reservoirs in the Hydroelectric Reach with the longest hydraulic residence times (FERC 2007) and potential for *in situ* algal growth, so the effects of removing them and converting the reservoir areas to a free-flowing river under this alternative would be similar to removing all four dams. Therefore, under this alternative, effects on algal toxins and chlorophyll-*a* would be the same as effects for the Upper Klamath Basin under the Proposed Action.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the long-term (2–50 years following dam removal/construction of fish passage facilities) decrease in chlorophyll-*a* and substantial decrease or elimination of algal toxins and in the Hydroelectric Reach from Copco 1 Reservoir to Iron Gate Reservoir would be beneficial.

Lower Klamath Basin

Copco 1 and Iron Gate Reservoirs are the largest reservoirs in the Hydroelectric Reach with the longest residence times (FERC 2007) and hence potential for *in situ* algal growth, so the effects of removing them and converting the reservoir areas to a free-flowing river under this alternative would be similar to removing all four dams. Therefore, under this alternative, effects on algal toxins and chlorophyll-*a* would be the same as effects for the Lower Klamath Basin under the Proposed Action.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the long-term (2–50 years following dam removal/construction of fish

passage facilities) decrease in production of algal toxins and chlorophyll-*a* in upstream reservoirs and subsequent transport into the Lower Klamath River and the Klamath Estuary would be beneficial.

Inorganic and Organic Contaminants

Upper Klamath Basin

Under this alternative, continued retention of sediments behind J.C. Boyle Dam and release of sediments trapped behind Copco 1 and Iron Gate Dams would occur. In J.C. Boyle Reservoir, short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) effects of sediment retention on concentrations of inorganic and organic contaminants, and the potential for bioaccumulation and/or toxicity to freshwater aquatic biota and humans, would be the same as those for the Hydroelectric Reach under the No Action/No Project Alternative. However, for the two largest reservoirs in the Hydroelectric Reach, Copco 1 and Iron Gate Reservoirs, short-term and long-term effects of sediment release on concentrations of inorganic and organic contaminants under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be the same as those for the Hydroelectric Reach under the Proposed Action.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) increases in potential inorganic and organic contaminants in the Hydroelectric Reach due to sediment release would be a less-than-significant impact.

Dam deconstruction and fish passage construction activities could cause increases in inorganic and organic contaminants from hazardous materials associated with construction equipment that could exceed applicable ODEQ and North Coast Basin Plan water quality objectives and adversely affect beneficial uses in the Hydroelectric Reach. These effects would be a significant impact. However, the impacts would be reduced through implementation of BMPs for deconstruction and construction activities that would occur in or adjacent to the Klamath. BMPs would minimize or eliminate the potential for toxic substances to enter the water.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the effects on inorganic and organic contaminants in the Hydroelectric Reach due to construction/deconstruction activities would be a less-than-significant impact.

Lower Klamath Basin

Under this alternative, release of the sediments trapped behind Copco 1 and Iron Gate Dams) would occur. Because Copco 1 and Iron Gate Reservoirs contain 85 percent of the total erodible sediment contained within the reservoirs at the Four Facilities (CDM 2011), the short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage

facilities) effects of sediment release on concentrations of inorganic and organic contaminants, and the potential for bioaccumulation and/or toxicity to freshwater aquatic biota, marine aquatic biota, and humans in the Lower Klamath Basin, would be similar to those for the Lower Klamath Basin under the Proposed Action.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the short-term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) increases in potential inorganic and organic contaminants due to sediment release would be a less-than-significant impact.

Dam deconstruction and fish passage construction activities could cause increases in inorganic and organic contaminants from hazardous materials associated with construction equipment that could exceed applicable North Coast Basin Plan water quality objectives and adversely affect beneficial uses in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment. These effects would be a significant impact. However, the impacts would be reduced through implementation of BMPs for deconstruction and construction activities that would occur in or adjacent to the Klamath River. BMPs would minimize or eliminate the potential for toxic substances to enter the water.

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the increases in potential inorganic and organic contaminants due to construction/deconstruction activities would be a less-than-significant impact.

Trap and Haul – Programmatic Measure

The impacts from the trap and haul measure under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be the same as those under the Fish Passage at Four Dams Alternative. **Therefore, under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, the short-term effects on water quality would be less-than-significant because of implementation of BMPs (see Appendix B.1.1 Water Quality).**

City of Yreka Water Supply Pipeline Relocation – Programmatic Measure

Under the *Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative*, construction activities for the City of Yreka Water Supply Pipeline would have the same short-term effects on suspended sediments in the Hydroelectric Reach as the Proposed Action and would be a less-than-significant impact.

3.2.5 Mitigation Measures

The timing of reservoir drawdown under the Proposed Action was optimally developed to minimize environmental effects (i.e., high SSCs, low DO) (see also Section 2, Proposed Action and Description of the Alternatives). While the Alternatives Formulation Report identified the option of mechanical sediment removal as mitigation for sediment erosion

impacts associated with removal of the Four Facilities, subsequent analysis found this measure to be infeasible (Lynch 2011).

3.2.5.1 Mitigation Measures Associated with Other Resource Areas

Several other mitigation measures require construction, including mitigation measures H-2 (flood-proof structures), GW-1 (deepen or replace affected wells), WRWS-1 (modify or screen affected water intakes), PHS-4 (repair damaged roads), PHS-5 (construct water storage tanks for fire fighting), REC-1 (develop new recreational facilities and access to river), TR-6 (assess and improve roads to carry construction loads), and TR-7 (assess and improve bridges to carry construction loads). Short-term effects on water quality from construction activities may include increased suspended sediments and inorganic and organic contaminants from hazardous materials associated with construction equipment to enter nearby or adjacent water bodies. Implementation of deconstruction and/or construction-related BMPs would also apply to these construction efforts.

Implementation of BMPs would reduce effects of these mitigation measures to less-than-significant levels.

3.2.6 Summary of Short-term and Long-term Impacts on Water Quality

Table 3.2-14 summarizes the short term (<2 years following dam removal/construction of fish passage facilities) and long-term (2–50 years following dam removal/construction of fish passage facilities) impacts of the Proposed Action and alternatives on water quality.

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
<i>Water Temperature</i>				
Upper Klamath Basin				
Continued impoundment of water in the reservoirs could cause short-term and long-term seasonal water temperatures that are shifted from the natural thermal regime of the river and do not meet applicable ODEQ and California Basin Plan water quality objectives and adversely affect beneficial uses in the Hydroelectric Reach.	1	NCFEC	None	NCFEC
Dam removal and/or reduction or elimination of hydropower peaking operations at J.C. Boyle Powerhouse could cause short-term and long-term alterations in overall water temperatures and diel temperature variation in the J.C. Boyle Bypass and Peaking Reaches.	2, 3, 4, 5	LTS for J.C. Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
construction/deconstruction areas.				
Removal of Iron Gate Dam would require relocation of the City of Yreka Water Supply Pipeline which could cause short-term increases in suspended material in the Hydroelectric Reach during the construction period.	2, 3, 5	LTS	None	LTS
Construction/deconstruction activities would include the demolition of various recreation facilities which could cause short-term increases in suspended material in the Hydroelectric Reach from stormwater runoff from the demolition areas.	2, 3, 5	LTS	None	LTS
Revegetation associated with management of the reservoir footprint area after dam removal could decrease the short-term erosion of fine sediments from exposed reservoir terraces in the Hydroelectric Reach.	2, 3, 5	B	None	B
Dam removal could eliminate the interception and retention of mineral (inorganic) suspended material behind the dams and result in long-term increases in suspended material in the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS
Dam removal could eliminate the interception and retention of algal-derived (organic) suspended material behind the dams and result in slight long-term increases in suspended material in the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS
Lower Klamath Basin				
Draining the reservoirs and release of sediment could cause short-term increases in suspended material in the Lower Klamath River and the Klamath Estuary.	2, 3, 5	S	None	S

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
Draining the reservoirs and release of sediment could cause short-term increases in sediment loads from the Klamath River to the Pacific Ocean and corresponding increases in concentrations of suspended material and rates of deposition in the marine nearshore environment.	2, 3, 5	LTS	None	LTS
Continued impoundment of water in the reservoirs could cause short-term and long-term interception and retention of mineral (inorganic) sediments by the dams and correspondingly low levels of suspended material immediately downstream from Iron Gate Dam.	1, 4	NCFEC	None	NCFEC
Continued impoundment of water in the reservoirs could result in short-term and long-term seasonal (April through October) increases in algal-derived (organic) suspended material in the KHP reservoirs and subsequent transport into the Klamath River downstream from Iron Gate Dam.	1, 4	NCFEC	None	NCFEC
Construction/deconstruction activities could cause short-term increases in suspended material in the Lower Klamath River, Klamath Estuary, and marine nearshore environment due to stormwater runoff from construction/deconstruction areas.	2, 3, 5	LTS NCFEC (Marine Nearshore Environment)	None	LTS
Revegetation associated with management of the reservoir footprint area after dam removal could decrease the short-term erosion of fine sediments from exposed reservoir terraces into the Lower Klamath River and Klamath Estuary.	2, 3, 5	B NCFEC (Marine Nearshore Environment)	None	B
Dam removal could eliminate the interception and retention of mineral (inorganic) suspended material behind the dams and result in long-term increases in suspended material in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment.	2, 3, 5	LTS	None	LTS

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
Dam removal could eliminate the interception and retention of algal-derived (organic) suspended material behind the dams and result in long-term increases in suspended material in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment.	2, 3, 5	LTS	None	LTS
Nutrients				
Upper Klamath Basin				
Continued impoundment of water in the reservoirs could result in long-term interception and retention of TN and TP in the Hydroelectric Reach on an annual basis but release of TP and, to a lesser degree TN from reservoir sediments on a seasonal basis.	1, 4	NCFEC	None	NCFEC
Draining the reservoirs and release of sediment could cause short-term increases in sediment-associated nutrients in the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS
Dam removal and conversion of the reservoir areas to a free-flowing river could cause long-term increases in nutrient levels in the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS
Lower Klamath Basin				
Continued impoundment of water in the reservoirs could cause long-term interception and retention of TP and TN on an annual basis and release (export) of TP on a seasonal basis	1, 4	NCFEC	None	NCFEC

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
Draining the reservoirs and release of sediment to the Lower Klamath River could cause short-term increases in sediment-associated nutrients in the river, the Klamath Estuary, and the marine nearshore environment.	2, 3, 5	LTS	None	LTS
Dam removal and conversion of the reservoir areas to a free-flowing river could cause long-term increases in nutrient levels in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment.	2, 3, 5	LTS	None	LTS
<i>Dissolved Oxygen</i>				
Upper Klamath Basin				
Continued impoundment of water in the reservoirs could cause long-term ¹ seasonal and daily variability in dissolved oxygen concentrations in the Hydroelectric Reach, such that levels do not meet ODEQ and California North Coast Basin Plan water quality objectives and adversely affect beneficial uses.	1, 4	NCFEC	None	NCFEC
Draining the reservoirs and release of sediment could cause short-term ² increases in oxygen demand (Immediate Oxygen Demand [IOD] and Biological Oxygen Demand [BOD]) and reductions in dissolved oxygen in the Hydroelectric Reach downstream from J.C. Boyle Reservoir.	2, 3, 5	S	None	S
Dam removal and conversion of reservoir areas to free-flowing river conditions could cause long-term slight increases in dissolved oxygen, as well as increased daily variability in dissolved oxygen, in the Hydroelectric Reach downstream from J.C. Boyle Dam, and would eliminate seasonal extremes in dissolved oxygen (i.e., supersaturation in surface waters and oxygen depletion in bottom waters) in the riverine reaches replacing Copco1 and Iron Gate Reservoirs.	2, 3	B	None	B

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
Dam removal and conversion of reservoir areas to free-flowing river conditions could cause long-term slight decreases in daily variability in dissolved oxygen in the Hydroelectric Reach at State line.	2, 3	LTS	None	LTS
Lower Klamath Basin				
Continued impoundment of water at the Four Facilities could result in continued release of water with seasonally low dissolved oxygen concentrations from Iron Gate Dam into the Klamath River such that levels immediately downstream from the dam do not meet California North Coast Basin Plan water quality objectives and adversely affect beneficial uses.	1, 4	NCFEC	None	NCFEC
Dam removal and sediment release could cause short-term increases in oxygen demand (IOD and BOD) and reductions in dissolved oxygen in the Lower Klamath River, the Klamath Estuary, and the marine nearshore environment.	2, 3, 5	S (Lower Klamath River from Iron Gate Dam to Clear Creek) NCFEC (Klamath Estuary or Marine Nearshore Environment)	None	S (Lower Klamath River from Iron Gate Dam to Clear Creek) NCFEC (Klamath Estuary or Marine Nearshore Environment)
Dam removal and conversion of reservoir areas to a free-flowing river could cause long-term overall increases in dissolved oxygen, as well as increased daily variability in dissolved oxygen, in the Lower Klamath River, particularly for the reach immediately downstream from Iron Gate Dam.	2, 3, 5	B	None	B
pH				
Upper Klamath Basin				
Continued impoundment of water in the reservoirs could cause long-term elevated seasonal pH and daily variability in pH due to large algal blooms in the reservoirs in the Hydroelectric Reach.	1, 4	NCFEC	None	NCFEC

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
Dam removal and conversion of the reservoir areas to a free-flowing river could cause short-term and long-term slight increases in pH and daily pH fluctuations in riverine reaches in the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS
Dam removal and conversion of the reservoir areas to a free-flowing river could cause short-term and long-term decreases in high summertime daily pH fluctuations in the free-flowing reaches of the river that replace Copco 1 and Iron Gate Reservoirs in the Hydroelectric Reach.	2, 3, 5	B	None	B
Lower Klamath Basin				
Continued impoundment of water in the reservoirs could cause long-term elevated seasonal pH and daily variability in pH in the Lower Klamath River immediately downstream from Iron Gate Dam due to large algal blooms in the reservoirs in the Hydroelectric Reach.	1, 4	NCFEC	None	NCFEC
Dam removal and conversion of the reservoir areas to a free-flowing river could cause long-term summertime increases in pH in the Lower Klamath River immediately downstream from Iron Gate Dam.	2, 3, 5	LTS for Lower Klamath River from Iron Gate Dam to confluence with the Scott River NCFEC for the Lower – Klamath River downstream from the Scott River, the Klamath Estuary, and the Marine Nearshore Environment	None	LTS for Lower Klamath River from Iron Gate Dam to confluence with the Scott River NCFEC for the Lower Klamath River downstream from the Scott River, the Klamath Estuary, and the Marine Nearshore Environment

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
<i>Chlorophyll-a and Algal Toxins</i>				
Upper Klamath Basin				
Continued impoundment of water in the reservoirs could support long-term growth conditions for toxin-producing nuisance algal species such as <i>M. aeruginosa</i> , resulting in high seasonal concentrations of chlorophyll-a and algal toxins (i.e., microcystin) in the Hydroelectric Reach.	1, 4	NCFEC	None	NCFEC
Dam removal and conversion of the reservoir areas to a free-flowing river would cause short-term and long-term decreases in levels of chlorophyll-a and substantially reduce or eliminate algal toxins (i.e., microcystin) in the Hydroelectric Reach.	2, 3, 5	B	None	B
Lower Klamath Basin				
Continued impoundment of water in the reservoirs could support long-term growth conditions for toxin-producing nuisance algal species such as <i>M. aeruginosa</i> , resulting in high seasonal concentrations of chlorophyll-a and algal toxins (i.e., microcystin) transported into the Klamath River from downstream from Iron Gate Dam to the Klamath Estuary, and likely to the marine nearshore environment.	1, 4	NCFEC	None	NCFEC
Dam removal and conversion of the reservoir areas to a free-flowing river would cause short-term and long-term decreases in levels of chlorophyll-a and substantially reduce or eliminate algal toxins (i.e., microcystin) in the Lower Klamath River and the Klamath Estuary.	2, 3, 5	B	None	B

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
<i>Inorganic and Organic Contaminants</i>				
Upper Klamath Basin				
Continued impoundment of water in the reservoirs and associated interception and retention of sediments behind the dams could cause long-term low-level exposure to inorganic and organic contaminants for freshwater aquatic species in the Hydroelectric Reach.	1, 4, 5	NCFEC	None	NCFEC
Continued impoundment of water in the reservoirs and associated interception and retention of sediments behind the dams could cause long-term low-level exposure to inorganic and organic contaminants in the Hydroelectric Reach for humans through the consumption of resident fish tissue.	1, 4, 5	NCFEC	None	NCFEC
Draining the reservoirs and sediment release could cause short-term increases in concentrations of inorganic and organic contaminants and result in low-level exposure for freshwater aquatic species in the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS
Draining the reservoirs and sediment release could cause short-term and long-term human exposure to contaminants from contact with deposited sediments on exposed reservoir terraces and river banks within the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS
Construction/deconstruction activities could cause short-term increases in inorganic and organic contaminants from hazardous materials associated with construction and revegetation equipment in the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
Reservoir area restoration activities could include herbicide application which could cause short-term levels of organic contaminants in runoff that are toxic to aquatic biota in the Hydroelectric Reach.	2, 3, 5	LTS	None	LTS
Lower Klamath Basin				
Dam removal and sediment release could cause short-term and long-term increases in concentrations of inorganic and organic contaminants and result in low-level exposure for freshwater aquatic species in the Lower Klamath River and aquatic species in the Klamath Estuary and marine nearshore environment.	2, 3, 5	LTS	None	LTS
Draining the reservoirs and sediment release could cause short-term and long-term human exposure to contaminants from contact with deposited sediments on exposed downstream river terraces and downstream river banks following reservoir drawdown.	2, 3, 5	LTS	None	LTS
Construction/deconstruction activities could cause short-term increases in suspended sediments and the potential for inorganic and organic contaminants from hazardous materials associated with construction equipment to be transported into the Lower Klamath River, Klamath Estuary, and the marine nearshore environment.	2, 3, 4, 5	LTS for Lower Klamath River and the Klamath Estuary NCFEC for Marine Nearshore Environment	None	LTS
Trip and Haul Operations				
Implementation of the trap and haul operations would affect water quality during construction.	4, 5	LTS	None	LTS

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
<i>Keno Transfer</i>				
Implementation of the Keno Transfer could cause adverse water quality effects.	2, 3	NCFEC	None	NCFEC
<i>East and West Side Facilities</i>				
Decommissioning the East and West Side Facilities could result in slight decreases in ammonia levels in the Keno Impoundment/Lake Ewauna.	2, 3	B	None	B
<i>KBRA</i>				
Implementation of the Phase I Fisheries Restoration Plan could result in short-term construction-related increases in suspended materials and long-term reductions in fine sediment inputs, reduced summer water temperatures, improved nutrient interception, and increased dissolved oxygen levels. .	2, 3	LTS (short term) B (long term)	None	LTS (short term) B (long term)
Implementation of the Phase II Fisheries Restoration Plan under the KBRA (KBRA Section 10.2) would include a continuation of the same types of resource management actions as under Phase I along with provisions for adaptive management of these actions and would therefore have the same short-term (i.e., during construction activities) and long-term impacts as Phase I.	2, 3	LTS (short term) B (long term)	None	LTS (short term) B (long term)
Implementation of the trap and haul element of the Fisheries Reintroduction and Management Plan could affect water quality during construction.	2, 3	LTS	None	LTS
Implementation of Wood River Wetland Restoration could result in short-term construction-related increases in suspended materials and long-term warmer spring water temperatures and reduced fine sediment and nutrient inputs to Upper Klamath Lake.	2, 3	LTS (short term) B (long term)	None	LTS (short term) B (long term)

Table 3.2-14. Summary of Short-term (<2 years) and Long-term (2–50 years) Water Quality Impacts

Potential Impact	Alternative(s)	Significance Pursuant to CEQA	Proposed Mitigation	Significance After Mitigation Pursuant to CEQA
Implementation of Water Diversion Limitations could result in decreased summer water temperatures in the Klamath River upstream of the Hydroelectric Reach.	2, 3	NCFEC (short term) B (long term)	None	NCFEC (short term) B (long term)
Implementation of the Water Use Retirement Program could result in decreases in summer water temperature and nutrient inputs to Upper Klamath Lake.	2, 3	NCFEC (short term) B (long term)	None	NCFEC (short term) B (long term)
Implementation of the Interim Flow and Lake Level Program could result in decreases in summer water temperature and nutrient inputs to Upper Klamath Lake.	2, 3	NCFEC (short term) B (long term)	None	NCFEC (short term) B (long term)
Implementation of the Upper Klamath Lake and Keno Nutrient Reduction Program could result in long-term decreases in nutrient inputs, increases in seasonal dissolved oxygen, and decreases in concentrations of nuisance algal species in these waterbodies.	2, 3	Not determined at this time	None	Not determined at this time

¹ Long term is defined as 2-50 years.

² Short term is defined as <2 years.

Key:

NCFEC = No change from existing conditions; B = Beneficial; LTS = Less than significant; S = Significant

CEQA = California Environmental Quality Act

3.3 Aquatic Resources

This section describes the effects that the Proposed Action and alternatives would have on aquatic resources, and specifically fish, freshwater mussels, and aquatic macroinvertebrates.

3.3.1 Areas of Analysis

This section of the Klamath Facilities Removal Environmental Impact Statement/ Environmental Impact Report (EIS/EIR) analyzes impacts on fish populations, fish species recovery, and changes to habitat in the Klamath River watershed, excluding the Lost River watershed, Tule Lake watershed, and most of the Trinity River. However, because the lower quarter-to-half mile of the Trinity River could be used as a refuge by Klamath River fish attempting to avoid exposure to sediment pulses that would result from dam removal, this use of the Trinity River was considered in the analysis.

The Lead Agencies assessed potential impacts within and across five study reaches of the Klamath Basin separated by changes in physiography (e.g., Upper and Lower Klamath Basins), the presence of Klamath Hydroelectric Project facilities, and degree of marine influence (Figure 3.3-1). The five study reaches within the area of analysis are as follows:

1. Upper Klamath River: upstream of the influence of J.C. Boyle Reservoir, including the following:
 - a. Upper Klamath Lake, Agency Lake, Keno Impoundment/Lake Ewauna, and Tule Lake
 - b. Tributaries to Upper Klamath Lake (Sprague, Wood, and Williamson rivers)
 - c. Bureau of Reclamation (Reclamation) Klamath Project facilities (e.g., Link River Dam)
2. Hydroelectric Reach: from the upstream end of J.C. Boyle Reservoir to Iron Gate Dam, including the following:
 - a. Tributaries to the Klamath River (examples include Jenny, Spencer, Shovel, and Fall Creeks)
 - b. J.C. Boyle, Copco 1, Copco 2, and Iron Gate Reservoirs
 - c. J.C. Boyle Bypass and Peaking Reaches
 - d. Copco 2 Bypass Channel
3. Lower Klamath River: downstream from Iron Gate Dam, including the following:
 - a. Major tributaries to the Klamath River (Shasta, Scott, and Salmon Rivers)
 - b. Minor tributaries to the Klamath River (examples include Bogus, Beaver, Humbug, and Cottonwood Creeks)
 - c. The lower portion of the Trinity River
4. Klamath River estuary
5. Pacific Ocean nearshore environment

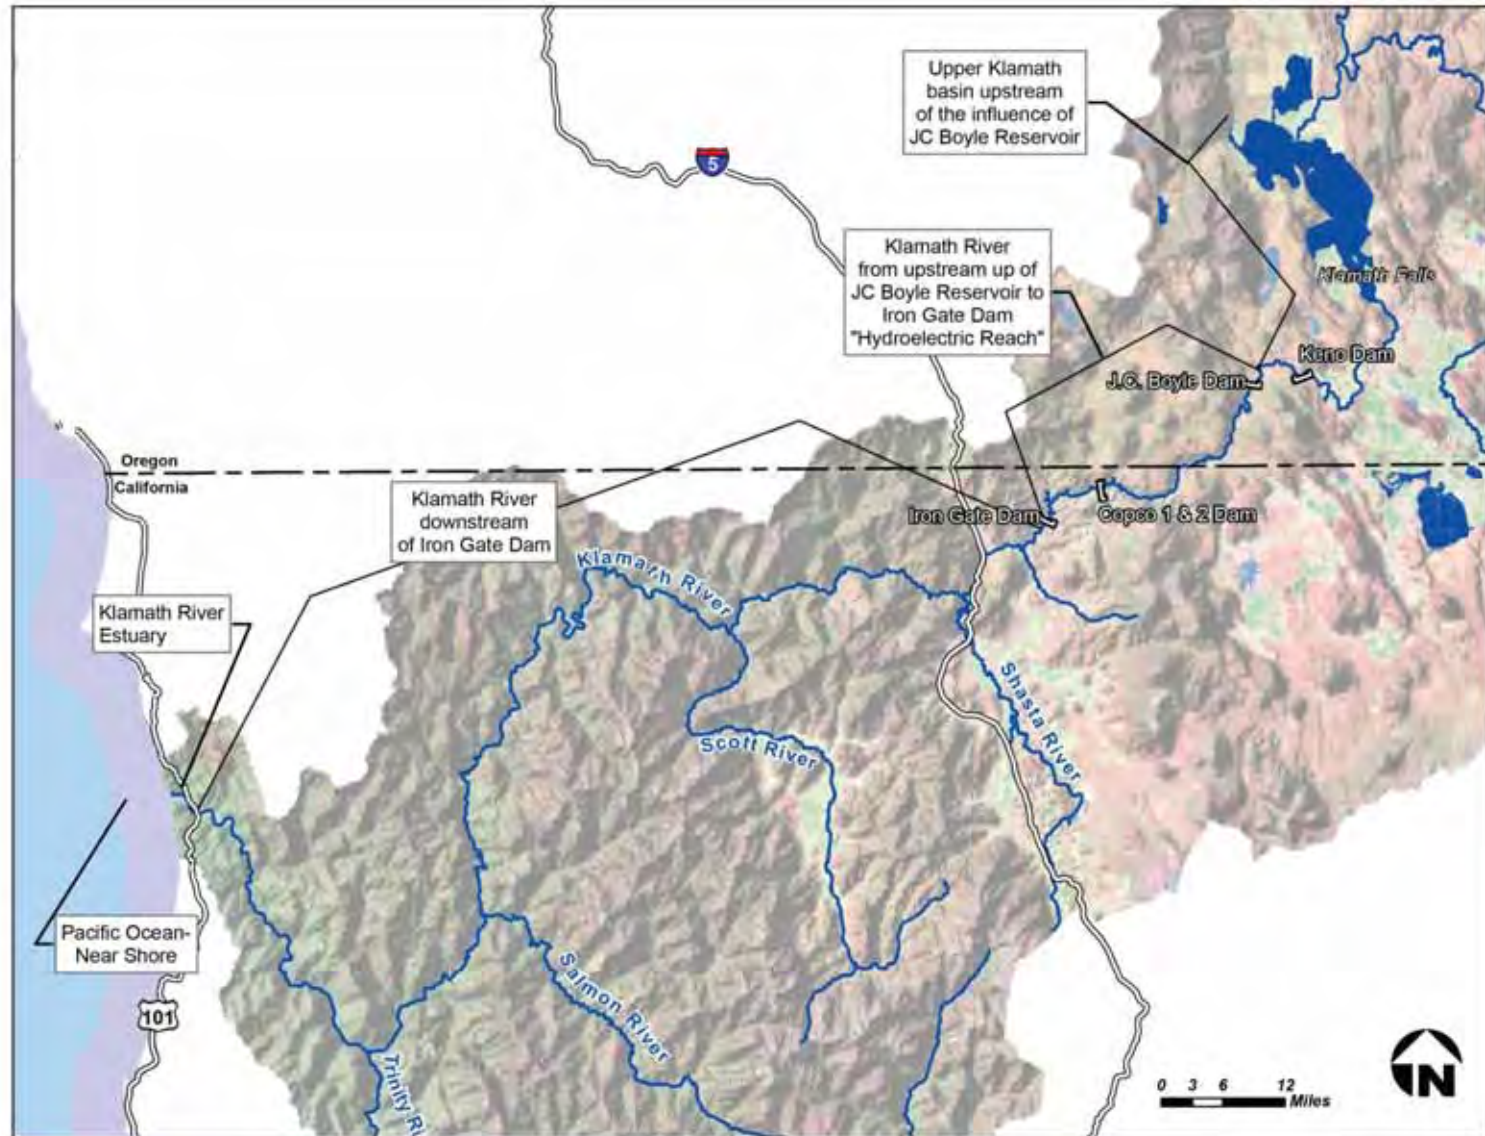

Figure 3.3-1. Five Study Reaches within the Area of Analysis for the Aquatic Resources Analysis.

The Klamath Basin has traditionally been divided into the Upper and Lower Klamath Basins at Iron Gate Dam (Natural Resources Council [NRC] 2004, 2008). For purposes of this evaluation, the Upper Basin was subdivided into two reaches at the upstream influence of J.C. Boyle Reservoir. The area upstream of the influence of J.C. Boyle Reservoir could experience some changes in flow in riverine reaches or water surface elevation in lakes and reservoirs due to changes in Reclamation's Klamath Project operations under some of the alternatives, but the physical structure of the habitat would remain similar to existing conditions (with the exception of habitat restoration efforts described for some alternatives). The Hydroelectric Reach encompasses the four dams proposed for removal. Under several of the alternatives, the physical structure of some or all reservoir habitat within the Hydroelectric Reach would be changed from lacustrine (lake) to riverine habitat. The Lower Klamath River: downstream from Iron Gate Dam corresponds to the traditional “Lower Basin” designation.

3.3.2 Regulatory Framework

Aquatic species within the area of analysis are regulated by several Federal and State laws and regulations, which are listed below.

3.3.2.1 Federal Authorities and Regulations

- Federal Endangered Species Act
- Fish and Wildlife Coordination Act
- Magnuson-Stevens Fishery Conservation and Management Act
- Marine Mammal Protection Act
- Wild and Scenic Rivers Act
- Federal Power Act
- Coastal Zone Management Act

3.3.2.2 State Authorities and Regulations

- California Endangered Species Act
- California Fish and Game Code
- Oregon Endangered Species Act
- Oregon Removal-Fill Law
- Oregon Statewide Planning Program
- Oregon Threatened and Endangered Species
- Oregon Wildlife and Commercial Fishing Codes
- Oregon Fish Passage Law
- Oregon Screening and By Pass Devices Law
- Oregon Klamath River Basin Fish Management Plan
- Oregon Native Fish Conservation Policy
- Oregon Fish and Wildlife Habitat Mitigation Policy
- Oregon Klamath River Basin Anadromous Re-Introduction Plan
- Oregon - Reauthorization of Hydroelectric Projects.
- Oregon Wildlife Policy

3.3.2.3 Local Authorities and Regulations

- Klamath Act

The regulation and protection of water quality including beneficial uses for aquatic species is discussed in Section 3.2, Water Quality.

3.3.3 Existing Conditions/Affected Environment

This section describes existing conditions in the area of analysis, including discussion of aquatic species (Section 3.3.3.1); physical habitat, water bodies within the different regions for the analysis (Section 3.3.3.2); and important factors affecting aquatic resources that the Lead Agencies anticipate would likely change if the Proposed Action or the alternatives are implemented (Section 3.3.3.3).

The species descriptions include a brief account of the current and historical distribution, life-history patterns, and habitat requirements of aquatic species. This section is subdivided into anadromous fish, native riverine fish, introduced species, estuarine species, and listed species. The last category includes species that would otherwise be included in the anadromous, riverine, or estuarine species.

The description of physical habitat provides information on the physical structure of the habitat. It contains a brief description of the water quality and other factors that may limit fish production in those water bodies, and describes the species that occur in these water bodies. This section also describes Federal Endangered Species Act (ESA) critical habitat and Magnuson-Stevens Fishery Conservation Management Act Essential Fish Habitat (EFH) occurring within the area of analysis.

Section 3.3.3.3, *Habitat Attributes Expected to be Affected by the Project*, provides a more detailed description of existing conditions for factors that are thought to have a major influence on aquatic resources. These factors form the basis for the effects evaluation in Section 3.3.4.

3.3.3.1 Aquatic Species

3.3.3.1.1 Fish

Numerous fish species use the Klamath Basin during all or some portion of their lives, including salmonids, lamprey, sturgeon, suckers, minnows, and sculpin. Many other species are present in the estuary. Species that have been introduced into the Basin include non-native yellow perch, largemouth bass, spotted bass, sunfish, and catfish. The species include introduced resident species, estuarine species, and species listed under the Federal or State ESAs. The number of species prohibits evaluation of each species. To address the impacts and benefits of the Proposed Action, target species have been selected for analysis based on their legal status or importance for tribal, commercial or recreational fisheries, and based on adequate data to conduct analysis. These target species are discussed below.

Anadromous Fish Species

The Klamath Basin provides habitat for many species of anadromous fish, many of which are salmonids, but which also include green sturgeon (*Acipenser medirostris* Ayres), Pacific lamprey, and American shad (non-native). Anadromous fish within the Klamath River watershed have nearly all declined compared to their historical abundance (Table 3.3-1). Although historical data are not available, green sturgeon appear to be in less decline than other fish species. Van Eenennaam et al. (2006) carefully suggests that based on reports of sturgeon captures during Yurok Tribal Chinook salmon gill-net fishery, the Klamath River green sturgeon population appears strong and stable, while cautioning against conclusions based on short time frames relative to their life history.

Table 3.3-1. Declines in Klamath River Anadromous Fish

Species	Historical run estimate	Reduction from historical numbers	Current run estimate	Source
Pacific lamprey	Unknown	98% (percent reduction in tribal catch per effort)	Unknown	Petersen Lewis 2009
Steelhead	400,000 ¹	67%	130,000	Leidy and Leidy 1984; Busby et al. 1994
Coho salmon	15,400–20,000	52% to 95%	760 to 9,550	Moyle et al. 1995; Ackerman et al. 2006
Fall-run Chinook salmon	500,000 ³	92% to 96%	20,000–40,000	Moyle 2002
Shasta River Chinook salmon ⁴	20,000–80,000	88% to 95%	A few hundred to a few thousand	Moyle 2002
Spring-run Chinook salmon	100,000	98%	2,000 ²	Moyle 2002

¹ Estimate from 1960. Anadromous fish numbers were already in decline in the early 1900s (Snyder 1931)

² Includes Klamath River and Trinity River Chinook salmon

³ Excludes hatchery-influenced escapement

⁴ Shasta River is a subset of the overall Klamath River Chinook salmon population

Anadromous salmonids in the Klamath River include fall- (including late-fall) and spring-run Chinook salmon; coho salmon; fall-, winter-, and summer-run steelhead; and coastal cutthroat trout. Anadromous salmonids share many similar life-history traits, but the timing of their upstream migrations, habitat preferences, and distributions differ. All anadromous salmonids spawn in gravel or cobble substrates that are relatively free of fine sediment with suitable surface and subsurface flow to carry oxygen to the eggs and carry metabolic waste away from the eggs. Once suitable spawning habitat is found, the adult female digs one or more nests and deposits up to 3,000 eggs. Her mate(s) will simultaneously fertilize the eggs and fend off other males and egg-eating predators. The female continues digging upstream of the nest, which forms a distinctive pit just upstream and a protective mound of gravel and cobble over the eggs. The female will continue the mound-building process and defend her nest location until her demise. Steelhead and coastal cutthroat trout have similar life histories, but may survive spawning, re-enter the

ocean, and return to spawn the following year(s). The eggs hatch several weeks or months after spawning, depending on species and water temperature. The resulting yolk-sac fry, also referred to as alevins, reside in the gravel for several more weeks until their yolk sac is depleted. The fry then emerge from the redd and seek slow shallow areas near shoreline or vegetative cover, gradually moving into deeper and faster water as they grow. Anadromous salmonids are generally considered "juveniles" when they have grown to a size of approximately 55 millimeters (mm). Juveniles feed and grow on their way downstream and may also rear for some time in the estuary prior to entering the ocean, but before entering brackish or salt water, they must undergo a physiological process called smoltification. After entering the ocean, smolts range up and down the coast as they grow to adulthood. Most adult salmonids return to spawn in the stream where they were born, although some straying does occur. Specific details of life history and distribution are described for each run of anadromous salmonid in the following section.

Chinook Salmon

Two Chinook salmon Evolutionarily Significant Units (ESUs) occur in the Klamath Basin—the Southern Oregon and Northern California Coastal ESU, which includes all naturally spawned Chinook salmon in the Lower Klamath River downstream from its confluence with the Trinity River, and the Upper Klamath and Trinity Rivers ESU, which includes all naturally spawned populations of Chinook salmon in the Klamath and Trinity rivers upstream of the confluence of the Klamath and Trinity Rivers. A status review in 1999 determined that neither ESU warranted listing (National Oceanic and Atmospheric Administration Fisheries Service (NOAA Fisheries Service 1999a).

Another petition to list Chinook salmon in the Upper Klamath and Trinity Rivers ESU under the Endangered Species Act was submitted to the NOAA Fisheries Service in January 2011 (Center for Biological Diversity (CBD) et al. 2011). In the petition NOAA Fisheries Service was asked to consider one of three alternatives for the listing of Chinook salmon in the Upper Klamath and Trinity River ESU: 1) list spring-run only as a separate ESU, 2) list spring-run as a distinct population segment within the Upper Klamath and Trinity River Chinook Salmon ESU, or 3) list the entire Chinook salmon Upper Klamath and Trinity River ESU including both spring-run and fall-run populations. In April 2011, NOAA Fisheries Service announced that the petition contained substantial scientific information warranting Federal review as to whether Chinook salmon within the Upper Klamath and Trinity River ESU should be listed as threatened or endangered (http://www.noaanews.noaa.gov/stories2011/20110411_chinook.html). As a result, the NOAA Fisheries Service formed a Biological Review Team (BRT) to assess the biological status of the species and determine if listing under the Endangered Species Act may be necessary. The BRT (Williams et al. 2011) found that recent spawner abundance estimates of both fall-run and spring-run Chinook salmon returning to spawn in natural areas are generally low compared to historical estimates of abundance; however, the majority of populations have not declined in spawner abundance over the past 30 years (i.e., from the late 1970s and early 1980s to 2010) except for the Scott and Shasta rivers where there have been modest declines (Williams et al. 2011). In addition, Williams et al. (2011) found that hatchery returns did not track escapement to natural spawning areas and they concluded

that there has been little change in the abundance levels, trends in abundance, or population growth rates since the review conducted by Myers *et al.* (1998). The BRT also noted that recent abundance levels of some populations are low, especially in the context of historical abundance estimates. This was most evident with respect to two of the three spring-run population units that were evaluated (Salmon River and South Fork Trinity River). Although current levels of abundance are low when compared to historical estimates of abundance, the current abundance levels do not constitute a major risk in terms of ESU extinction.

The BRT also concluded that spring-run Chinook salmon did not warrant designation as a separate ESU or distinct population segment within the Upper Klamath and Trinity River ESU. This finding was based in part on new genetic evidence that indicates that spring-run and fall-run life histories have evolved on multiple occasions across different coastal watersheds located north and south of the Klamath River. Kinziger *et al.* (2008) found that there are four genetically differentiated and geographically separated groups of Chinook salmon populations in the Upper Klamath and Trinity River basins and that spring-run and fall-run Chinook life histories have evolved independently and in parallel within both the Salmon and Trinity rivers. In addition, spring-run and fall-run populations in the Salmon River were nearly indistinguishable genetically and spring and fall-run populations in the South Fork Trinity were extremely similar to each other and to Trinity River hatchery stocks. Williams *et al.* (2011) concluded that spring-run and fall-run Chinook salmon within the Upper Klamath and Trinity River basins are genetically similar to each other and that the two runs are not substantially reproductively isolated from each other. In addition, ocean type and stream type life history strategies are exhibited by both run types, further suggesting that spring-run Chinook salmon in the Upper Klamath and Trinity River basins do not represent an important component in the evolutionary legacy of the species.

Regardless of the determination that spring-run and fall-run Chinook salmon comprises a single ESU, these two runs have different life history strategies and habitat requirements (NRC 2004) and a more detailed discussion of the two run types is described below.

Fall-Run Chinook Salmon. Fall-run Chinook salmon (*Oncorhynchus tshawytscha*) are distributed throughout the Klamath River downstream from Iron Gate Dam. Historical records reviewed by Hamilton *et al.* (2005) and genetic information obtained from archaeological sites analyzed by Butler *et al.* (2010) indicate that prior to the construction of Copco 1 Dam, Chinook salmon (both fall- and spring-run) spawned and were abundant in tributaries of the Upper Klamath Basin, including Jenny, Fall, and Shovel Creeks, as well as the Sprague, Williamson, and Wood rivers (Administrative Law Judge 2006).

Adult upstream migration through the estuary and Lower Klamath River peaks in early September and continues through late October (Moyle 2002; FERC 2007; Strange 2008). Spawning peaks in late October and early November, and fry begin emerging from early February through early April (Stillwater Sciences 2009a), although timing may vary somewhat depending on temperatures in different years and tributaries.

Fall-run Chinook salmon in the Klamath Basin exhibit three juvenile life-history types: Type I (ocean entry at age 0¹ in early spring within a few months of emergence), Type II (ocean entry at age 0 in fall or early winter), and Type III (ocean entry at age 1 in spring) (Sullivan 1989). Based on outmigrant trapping at Big Bar on the Klamath River from 1997 to 2000, 63 percent of natural Chinook salmon outmigrants are Type I, 37 percent are Type II, and less than 1 percent are Type III (Scheiff et al. 2001). Although, trapping efforts are not equal among seasons, the results are consistent with scale analysis of adult returns by Sullivan (1989).

Critical stressors on fall-run Chinook salmon in the basin include water quality and quantity in the mainstem and within spawning tributaries. Downstream from Iron Gate Dam, the mainstem Klamath River undergoes seasonal changes in flows, water temperature, dissolved oxygen, and nutrients, as well occasional blooms of *Microcystis aeruginosa*. During outmigration, juvenile Chinook salmon are vulnerable to contracting disease from pathogens, including the bacterium *Flavobacterium columnare*, and myxozoan parasites *Parvicapsula minibicornis* and *Ceratomyxa shasta*.

Spring-Run Chinook Salmon. Spring-run Chinook salmon in the Klamath Basin are distributed mostly in the Salmon and Trinity Rivers and on the mainstem downstream from these tributaries during migratory periods, although a few fish are occasionally observed in other areas (Stillwater Sciences 2009a). Based on data from 1992 to 2001 (California Department of Fish and Game [CDFG], unpublished data 2004), the Salmon River contributions to the overall escapement ranged from 1 to 20 percent of the total escapement, and from 2 to 35 percent of the natural escapement. No spawning has been observed in the mainstem Klamath River (Shaw et al. 1997). As described above, the BRT (Williams et al. 2011) concluded that while abundance is low compared with historical abundance (Table 3.3-1), the current Chinook salmon population (which includes hatchery fish) appear to have been fairly stable for the past 30 years. However, the BRT noted, as did Myers et al. (1998), that the recent spawner abundance levels of two of the three spring-run population components (Salmon River and South Fork Trinity River) are very low compared to historical abundance (less than 1,000 fish). The BRT was concerned about the relatively few populations of spring-run Chinook salmon and the low numbers of spawners within those populations (Williams et al. 2011).

The BRT (Williams et al. 2011) found the decline in spring-run fish especially troubling given that the spring-run population may have been equal to, if not larger than the fall-run (Barnhart 1994). Huntington (2006) reasoned that spring-run Chinook salmon likely accounted for the majority of the Upper Klamath Basin's actual salmon production under historical conditions. Spring Chinook salmon spawned in the tributaries of the Upper Klamath Basin (Moyle 2002; Hamilton et al. 2005 with large numbers of Chinook salmon spawning in the basin above Klamath Lake in the Williamson, Sprague, and Wood Rivers (Snyder 1931). Large runs of spring Chinook salmon also returned to the Shasta, Scott, and Salmon rivers (Moyle et al. 1995). The runs in the Upper Klamath Basin are thought to have been in substantial decline by the early 1900s, and then were

¹ A fish emerging in spring is designated as age 0 until January 1st of the following year, when it is designated as age 1 until January 1st of the next year, when it is designated age 2.

eliminated by the completion of Copco Dam in 1917 (Snyder 1931). The cause of the decline of the Klamath River spring-run Chinook salmon prior to Copco 1 Dam has been attributed to dams, overfishing, irrigation, and largely to commercial hydraulic mining operations (Coots 1962; Snyder 1931). These large scale mining operations occurred primarily in the late 1800's, and along with overfishing, left spring-run Chinook salmon little chance to recover prior to dam construction in early 1900's. Dam construction eliminated much of the historical spring-run spawning and rearing habitat and was partly responsible for the extirpation of at least seven spring-run populations from the Klamath-Trinity River system (Myers et al. 1998). The construction of Dwinnell Dam on the Shasta River in 1926 was soon followed by the disappearance of the spring Chinook salmon run in that tributary (Moyle et al. 1995).

Wild spring-run Chinook salmon from the Salmon River appear to primarily express a Type II life history, based on scale analyses of adults returning from 1990 to 1994 in the Salmon River (Olson 1996), as well as otolith analyses of Salmon River fry and adults (Sartori 2006). A small number of fish employ the Type III life history, although apparently not nearly as prevalent as the Type II.

Spring-run Chinook salmon upstream migration is observed during two time periods—spring (April through June) and summer (July through August) (Strange 2008). Snyder (1931) also describes a run of Chinook salmon occurring in Klamath River during July and August under historical water quality and temperature conditions. Adults spawn from mid-September to late-October in the Salmon River and from September through early November in the South Fork Trinity River (Stillwater Sciences 2009a). Emergence takes place from March and continues until early-June (West et al. 1990). Age-0+ juveniles rearing in the Salmon River emigrate at various times of the year, with one of the peaks of outmigration occurring in April through May (Olson 1996), which would be considered Type I life history. Based on outmigrant trapping from April to November in 1991 at three locations in the South Fork Salmon River, Olson (1996) reported that the greatest peak in outmigration of age-0+ juveniles (69 percent) was in mid-October, which would be considered Type II life history. Scale circuli patterns of adults with an identified Type II life history were consistent with those from juveniles outmigrating in mid-October. Sullivan (1989) reported that outmigration of Type II age-0+ juveniles can occur as late in the year as early-winter. On the South Fork Trinity River outmigration occurs in late-April and May with a peak in May (Dean 1994, 1995), although it is not possible to differentiate between spring and fall race juveniles and so the spring-run may have different run timing. Age-1 juveniles (Type III) have been found to outmigrate from the South Fork Trinity River during the following spring (Dean 1994, 1995).

It is unclear how much time outmigrating age-0+ juveniles spend in the Klamath River mainstem and estuary before entering the ocean. Sartori (2006) did identify a period of increased growth (estimated mean of 24 days) just prior to reaching an estuarine environment based on otolith analyses of returning adults to the Salmon River, but this period was never clearly linked to mainstem residence. From March to May, there were fair numbers of age-1 juvenile outmigrants captured in the Klamath River estuary

(Wallace 2004). Most were identified to be hatchery age-1 juvenile fall-run Chinook salmon, but nearly half were identified to be of natural origin, based on tag expansions.

Stressors on spring-run Chinook salmon related to water quality and quantity are similar to those for fall-run Chinook salmon in the mainstem Klamath River. Although water quality tends to improve in the mainstem downstream from the confluence with the Salmon River (the upstream-most spawning tributary), degradation of water quality (especially temperature and dissolved oxygen) can create critically stressful conditions for spring-run Chinook salmon for much of the summer (June through September). Production in the Salmon River is primarily controlled by high water temperatures that reduce adult holding and summer rearing habitat in the mainstem Salmon River, while increased fine sediment input within the watershed reduces spawning and rearing habitat quality in some locations (Elder et al. 2002).

Steelhead

Klamath Basin summer steelhead and winter steelhead (*O. mykiss irideus*) populations both belong to the Klamath Mountain Province ESU. NOAA Fisheries Service (2001) status review found that this ESU was not in danger of extinction or likely to become so in the foreseeable future, based on estimated populations for the ESU and lower estimates of genetic risk from naturally spawning hatchery fish than estimated in previous reviews, and consideration of existing conservation efforts that are benefiting steelhead in the ESU (NOAA Fisheries Service 2001).

Summer Steelhead. Summer steelhead are distributed throughout the Klamath River downstream from Iron Gate Dam and in its tributaries, and historically used habitat upstream of Upper Klamath Lake prior to the construction of Copco 1 Dam (Hamilton et al. 2011). Based on available escapement data, approximately 55 percent of summer steelhead spawn in the Trinity River and other lower-elevation tributaries. Most remaining summer steelhead are believed to spawn in tributaries between the Trinity River (River Mile [RM] 43) and Seiad Creek (RM 129), with high water temperatures limiting their use of tributaries farther upstream (NRC 2004). The mainstem Klamath River is used primarily as a migration corridor for adult summer steelhead to access holding and spawning habitat in tributaries to the Klamath River.

Summer steelhead adults enter and migrate up the Klamath River from March through June while sexually immature (Hopelain 1998), then hold in cooler tributary habitat until spawning begins in December (United States Fish and Wildlife Service [USFWS] 1998). Forty to 64 percent of summer steelhead in the Klamath River exhibit repeat spawning, with adults observed to migrate downstream to the ocean after spawning (also known as “runbacks”) (Hopelain 1998). Summer steelhead in the basin also have a “half-pounder” life-history pattern, in which an immature fish emigrates to the ocean in the spring, returns to the river in the fall, spends the winter in the river, then emigrates to the ocean again the following spring (Busby et al. 1994; Moyle 2002).

Juvenile summer steelhead in the Klamath Basin may rear in freshwater for up to 3 years before outmigrating. Although many juveniles migrate downstream at age 1+ (Scheiff

et al. 2001), those that outmigrate to the ocean at age 2+ appear to have the highest survival (Hopelain 1998). Juveniles outmigrating from tributaries at age 0+ and age 1+ may rear in the mainstem or in non-natal tributaries (particularly during periods of poor water quality) for 1 or more years before reaching an appropriate size for smolting. Age-0 juvenile steelhead have been observed migrating upstream into tributaries, off-channel ponds, and other winter refuge habitat in the Lower Klamath River (Stillwater Sciences 2010b). Juvenile outmigration can occur from the spring through fall. Smolts are captured in the mainstem and estuary throughout the fall and winter (Wallace 2004), but peak smolt outmigration normally occurs from April through June, based on estuary captures (Wallace 2004). Temperatures in the mainstem are generally suitable for juvenile steelhead, except during periods of the summer, especially upstream of Seiad Valley (for more species information see USFWS 1998; Moyle 2002; NRC 2004; and Stillwater Sciences 2009a). Critical limiting factors for summer steelhead are believed to include degraded habitats, fish passage, predation, and competition (Moyle et al. 2008).

Winter Steelhead. Moyle (2002) describes steelhead in the Klamath Basin as having a summer- and winter-run. Some divide the winter-run into fall and winter runs (Barnhart 1994; Hopelain 1998; USFWS 1998; Papa et al. 2007). In this section, “winter steelhead” refers to both fall and winter runs except in cases when the distinction is pertinent to the discussion. Effects on winter-and fall-run steelhead were differentiated wherever data was sufficient to analyze them separately.

Winter steelhead are widely distributed throughout the Klamath River and its tributaries downstream from Iron Gate Dam, and historically used habitat upstream of Upper Klamath Lake (Hamilton et al. 2011). The Trinity, Scott, Shasta, and Salmon Rivers are the most important spawning streams for winter steelhead. Winter steelhead adults generally enter the Klamath River from July through October (fall run) and from November through March (winter run) (USFWS 1998; Stillwater Sciences 2010b). Winter steelhead primarily spawn in tributaries from January through April (USFWS 1998), with peak spawn timing in February and March (ranging from January to April) (NRC 2004). Adults may repeat spawning in subsequent years after returning to the ocean. Half-pounders typically utilize the mainstem Klamath River until leaving the following March (NRC 2004), although they also utilize larger tributaries such as the Trinity River (Dean 1994, 1995).

Fry emerge in spring (NRC 2004), with fry observed in outmigrant traps in Bogus Creek and Shasta River from March through mid-June (Dean 1994). Age-0+ and 1+ juveniles have been captured in outmigrant traps in spring and summer in tributaries to the Klamath River above Seiad Creek (CDFG 1990a, b). These fish are likely rearing in the mainstem or non-natal tributaries before leaving as age-2+ outmigrants.

Juvenile outmigration appears to primarily occur between May and September with peaks between April and June, although smolts are captured in the estuary as early as March and as late as October (Wallace 2004). Most adult returns (86 percent) originate from fish that smolt at age 2+, representing 86 percent of adult returns; in comparison with only 10 percent for age-1 juveniles and 4 percent for age 3+ juveniles (Hopelain 1998).

Similar limiting factors listed for summer steelhead also affect winter steelhead populations, including degraded habitats, decreased habitat access, fish passage, predation, and competition (for more species information see USFWS 1998; NRC 2004; Wallace 2004; and Stillwater Sciences 2009a).

Coastal Cutthroat Trout

Klamath River coastal cutthroat trout (*Oncorhynchus clarki clarki*) belong to the Southern Oregon California Coasts ESU. In a 1999 status review, NOAA Fisheries Service determined that the Southern Oregon California Coasts ESU did not warrant ESA listing (Johnson et al. 1999). Coastal cutthroat trout are distributed primarily within smaller tributaries to the lower 22 miles of the Klamath River mainstem above the estuary (NRC 2004), but also within tributaries to the Trinity River (Moyle et al. 1995).

Cutthroat trout have not been extensively studied in the Klamath Basin, but it has been noted that their life history is similar to fall and winter steelhead in the Klamath River (NRC 2004). Both resident and anadromous life histories are observed in the Klamath Basin. Anadromous adults enter the river to spawn in the fall. Generally, spawning of anadromous and resident coastal cutthroat trout may occur from September to April (Moyle 2002). Sea-run adults may either return in summer to feed, or return in September or October to spawn and/or possibly overwinter (NRC 2004). Moyle (2002) noted that upstream migration in northern California spawning streams tends to occur from August to October after the first substantial rain.

Juveniles may spend anywhere from one to three years in freshwater to rear. Juveniles outmigrate during April through June, at the same time as Chinook salmon juvenile downstream migration (Moyle 2002; NRC 2004). Juveniles also appear to spend at least some time rearing in the estuary. Wallace (2004) found that estuary residence time ranged from 5 to 89 days, with mean of 27 days, based on a mark-recapture study.

Pacific Lamprey

Pacific lamprey are the only anadromous lamprey species in the Basin. Pacific lamprey, along with three other lamprey species, was petitioned for ESA listing in 2003 (Nawa 2003). Although the USFWS halted species status review in December 2004 due to inadequate information (USFWS 2004), efforts to list Pacific lamprey are anticipated to resume as more information is obtained. No current status assessments are available for any Klamath lampreys and little is known of their biology or sensitivity to environmental changes in the Klamath drainage (Hamilton et al. 2011).

Pacific lamprey are found in Pacific coast streams from Alaska to Baja California. They occur throughout the mainstem Klamath River downstream from Iron Gate Dam and its major tributaries: the Trinity, Salmon, Shasta, and Scott River Basins (Stillwater Sciences 2009a). Although the evidence is inconclusive as to whether Pacific lamprey were historically present above Iron Gate Dam, the record evidence shows that access to habitat would benefit that species of fish by providing it with additional spawning and rearing grounds (Administrative Law Judge 2006). Pacific lamprey are capable of

migrating long distances, and show similar distributions to anadromous salmon and steelhead (Hamilton et al. 2005).

Pacific lamprey are anadromous nest builders that die shortly after spawning. They enter the Klamath River during all months of the year, with peak upstream migration occurring from December through June (Stillwater Sciences 2009a). Spawning occurs at the upstream edge of riffles in sandy gravel from mid-March through mid-June (Stillwater Sciences 2009a). After lamprey eggs hatch, the larvae (ammocoetes) drift downstream to backwater areas and burrow into the substrate, feeding on algae and detritus (FERC 2007). Based on observations and available habitat, most ammocoete rearing likely occurs in the Salmon, Scott, and Trinity Rivers, as well as in the mainstem Klamath River. The Klamath River upstream of the Shasta River appears to have less available spawning and rearing habitat, and Pacific lamprey are not regularly observed there. Juveniles remain in freshwater for 5 to 7 years before they migrate to the ocean and transform into adults (Moyle 2002). They spend 1 to 3 years in the marine environment, where they parasitize a wide variety of ocean fishes, including Pacific salmon, flatfish, rockfish, and pollock. For more species information see Close et al. 2010; Stillwater Sciences 2009a; and PacifiCorp 2004a.

Major factors believed to be affecting their populations include barriers to upstream migration at dams, dewatering of larval habitat through flow regulation, stranding due to rapid downramping, reducing larval habitat by increasing water velocity and/or reducing sediment deposition areas, and mortality due to exposure to contaminants in the larval stage (Close et al. 2002, as cited in Hamilton et al. 2011).

Green Sturgeon

Green sturgeon (*Acipenser medirostris* Ayres) are an anadromous species that occurs in coastal marine waters from Mexico to the Bering Sea. NOAA Fisheries Service has identified two distinct population segments (DPSs): the Northern Green Sturgeon DPS, which includes populations spawning in coastal watersheds from the Eel River north, which is not listed as threatened or endangered but is on NOAA Fisheries Service's Species of Concern list, and the Southern Green Sturgeon DPS, encompassing coastal or Central Valley populations spawning in watersheds south of the Eel River, which is listed as threatened under the Federal ESA (NOAA Fisheries Service 2006a). Although the Southern DPS is considered a separate population from the Northern DPS based on genetic data and spawning locations, their ranges outside of the spawning season tend to overlap (CDFG 2002b; Israel et al. 2004; Moser and Lindley 2007). The Klamath Basin may support most of the spawning population of green sturgeon (Adams et al. 2002). Although Southern DPS green sturgeon may enter west coast estuaries to feed in the summer and fall, there has been no evidence of them entering the Klamath River estuary (Reclamation 2010).

Northern DPS green sturgeon in the Klamath River sampled during their spawning migration ranged in age from 16 to 40 years (Van Eenennaam et al. 2006). It is believed that in general green sturgeon have a life span of at least 50 years, and spawn every 4 years on average after around age-16, for a total of around eight spawning efforts in a

lifetime (Klimley et al 2007). Green sturgeon enter the Klamath River to spawn from March through July. Green sturgeon spawn primarily in the lower 67 miles of the mainstem Klamath River (downstream from Ishi Pishi Falls), in the Trinity River, and occasionally in the lower Salmon River (Klamath River Basin Fisheries Task Force [KRBFTF] 1991; Adams et al. 2002; Benson et al. 2007). Most green sturgeon spawning occurs from the middle of April to the middle of June (NRC 2004). After spawning, around 25 percent of green sturgeon migrate directly back to the ocean (Benson et al. 2007), and the remainder hold in mainstem pools in the Klamath River from RM 13 to 65 through November.

During the onset of fall rainstorms and increased river flow, adult sturgeon move downstream and leave the river system (Benson et al. 2007). Juvenile green sturgeon may rear for 1 to 3 years in the Klamath River system before they migrate to the estuary and ocean (NRC 2004; FERC 2007; CALFED 2007), usually during summer and fall (Emmett et al. 1991, as cited in CALFED 2007; CH2M Hill 1985; Hardy and Addley 2001).

The timing and magnitude of high flows downstream from Iron Gate Dam that are related to Project operations have the potential to reduce green sturgeon survival in the mainstem. Adult green sturgeon that have held over the summer in the river after spawning appear to migrate downstream in conjunction with increases in discharge in the fall. Attenuation of high flows downstream from Iron Gate Dam may affect a key environmental cue used to stimulate the fall outmigration of adult green sturgeon that have remained in holding pools over the summer (Benson et al. 2007). This lower portion of the river was quite responsive to discharge increases related to rainfall events; the timing of peak flows changed significantly following the construction of the Project (Balance Hydrologics, Inc. 1996). Under existing conditions, the Project results in higher flows in October compared with historical conditions and lower flows in late spring and summer (Balance Hydrologics, Inc. 1996). Because temperatures in the lower river are close to lethal for eggs and embryos in dry years, reductions in flows related to the Project may exacerbate the effects of temperature on reproductive survival in these years, as would any temperature increases occurring as a result of climate change in the future. Shifts in the timing of seasonal life-history cues could also affect survival rates by changing the timing of their entry into habitats, such as entry of juveniles into the estuary.

Resident Riverine Fish Species

Rainbow and Redband Trout

Rainbow trout (*Oncorhynchus mykiss*) exhibit a wide range of life-history strategies, including anadromous forms (steelhead, described above) and resident forms, described here. The Klamath Basin has two subspecies of rainbow trout. Behnke (1992) identifies the inland form as the Upper Klamath redband trout, *Oncorhynchus mykiss newberrii*, but considers steelhead and resident rainbow trout downstream from Upper Klamath Lake to be primarily coastal rainbow trout, *Oncorhynchus mykiss irideus*. Since construction of Copco 1 Dam and Iron Gate Dam, resident trout upstream of Iron Gate Dam are

considered redband trout, and resident trout downstream from Iron Gate Dam are considered coastal rainbow trout (FERC 2007). Behnke (2002) indicates that two distinct groups of redband trout may be in the Upper Klamath Basin: one that is adapted to lakes and another that is adapted to streams. The area upstream of Iron Gate Dam, and particularly Upper Klamath Lake, supports populations of redband trout. These fish support a substantial recreational fishery.

The Upper Klamath Basin supports the largest and most functional adfluvial redband trout population of Oregon's interior basins (Hamilton et al. 2011). Adfluvial adult redband trout migrate from lake habitats into tributaries to spawn. Peak spawning occurs in December and January, but redband trout in Spring Creek have been documented to spawn nearly year-round, in all months from October through August. Their progeny typically spend one year rearing in tributaries before migrating back to the lake. In the Hydroelectric Reach, most redband trout spawning is thought to occur in Spencer and Shovel Creeks. Redband trout need to migrate among habitats, mainstem, tributaries, and reservoirs to meet their life-history requirements. Redband trout are not susceptible to *C. shasta* or other diseases potentially brought upstream by anadromous fishes (Hamilton et al. 2011). For more species information, see USFWS (1998); USFWS (2000); Behnke (2002); Moyle (2002); NRC (2004); PacifiCorp (2004a); Starcevich et al. (2006); Messmer and Smith (2007); and Stillwater Sciences (2009a).

Resident Lampreys

In addition to the anadromous Pacific lamprey, described above, at least five or six resident species are present in the Klamath Basin (PacifiCorp 2006; Hamilton et al. 2011):

- Pit-Klamath brook lamprey (*Entosphenus lethophagus*)
- Modoc brook lamprey (*Entosphenus folletti*)
- Western brook lamprey (*Lampetra richardsoni*)
- Klamath River lamprey (*Entosphenus similis*)
- Miller Lake lamprey (*Entosphenus minima*)
- “Klamath Lake lamprey,” an undescribed, parasitic species

All lamprey species have a similar early life history where ammocoetes drift downstream to areas of low velocity with silt or sand substrate and proceed to burrow into the stream bottom and live as filter feeders (USFWS 2004). After they transform into adults, the non-parasitic species do not feed, while the parasitic species feed on a variety of fish species (FERC 2007).

Klamath River lamprey are found both upstream and downstream from Iron Gate Dam, from Spencer Creek downstream, and are common in the Lower Klamath River and the low-gradient tributaries there (NRC 2004). They are also found in the Trinity River, and in the Link River of the Upper Klamath Basin (Lorion et al. 2000, as cited in Close et al. 2010). “Klamath Lake lamprey,” an as yet undescribed species, reside in Upper Klamath Lake and migrate upstream in the Sprague River to spawn (Close et al. 2010). Klamath Lake lamprey ammocoetes are reported to metamorphose in the fall, spend 12 to

15 months in Upper Klamath Lake parasitizing fish, and then spawn in the spring in the Sprague River (FERC 2007).

Cyprinids

The blue chub (*Gila coerulea*) and tui chub (*Gila bicolor*) are both found in the Klamath Basin. These species prefer habitat with quiet water, well-developed beds of aquatic plants, and fine sediment or sand bottoms. Although chubs can withstand a variety of conditions including cold, clear lake water, and can also tolerate low dissolved oxygen levels, they are most often found in habitats with summer water temperatures higher than 20°C. These fish are omnivores and can play an important role in nutrient cycling. Chub spawning takes place from April through July, in shallow rocky areas in temperatures of 15 to 18°C (Moyle 2002).

Sculpin

Several sculpin (*Cottidae*) species are found in coastal streams and rivers from Alaska to southern California. At least 7 species of sculpin are known to occur in the Klamath River or its estuary, including Pacific staghorn, prickly, slender, sharpnose, coastrange, marbled, and Klamath Lake sculpin. Mainstem river habitat may be important to sculpin populations as it can provide an important migration corridor (White and Harvey 1999). Pacific staghorn sculpin are found predominantly in brackish waters of the estuary. Coastal populations of prickly and coastrange sculpin are generally assumed to be estuary-dependent for part of their early life history (White and Harvey 1999). The marbled sculpin (*Cottus klamathensis*) is a relatively wide-ranging species found in a variety of habitats in northern California and southern Oregon (Daniels and Moyle 1984). Marbled sculpin are found mainly in low gradient, spring-fed streams and rivers where the water temperature is less than 20°C in the summer and in habitat with fine substrate that can support beds of aquatic plants. They are typically found in 60 to 70 centimeters (cm) of water and are in velocities around 23 centimeters per second (cm/sec) (Moyle 2002).

Smallscale Sucker

The Klamath smallscale sucker (*Catostomus rimiculus*) is common and widely distributed in the Klamath River and its tributaries downstream from the city of Klamath Falls, Oregon, and in the Rogue River (Moyle 2002). They tend to inhabit deep, quiet pools in mainstem rivers and slower-moving reaches in tributaries; however, they can be found in faster-flowing habitats when feeding or breeding (Moyle 2002). McGinnis (1984) reported that this species spawns in small tributaries to the Klamath and Trinity Rivers. Spawning in tributaries to Copco Reservoir has been observed from mid-March to late April (Moyle 2002). Juveniles are most commonly found in the streams that are used for spawning. This species does not achieve a large size and is relatively long-lived. Fish measuring 45 cm have been aged through scale analysis as being 15 years old (Scoppetone 1988, as cited in Moyle (2002). Moyle (2002) speculated that dams and diversions have benefitted this species by increasing the availability of its preferred warmer, low-velocity habitat.

Electrofishing by PacifiCorp and Oregon Department of Fish and Wildlife (ODFW) in the J.C. Boyle Peaking Reach revealed the existence of a good population of smallscale suckers in moderate velocity habitat—smallscale sucker dominated the fish assemblage in most samples (W. Tinniswood, June 2011, pers. comm.). The dams have increased reservoir habitat that does not appear to be conducive to a riverine sucker species such as smallscale suckers. The J.C. Boyle Dam blocks the migration of suckers to spawning habitat in Spencer Creek. Spawning now occurs in the mainstem Klamath River where smallscale suckers are exposed to flow fluctuations that can displace their broadcast eggs or desiccated them during power peaking (Dunsmoor 2006). Electrofishing in Jenny Creek revealed adult smallscale suckers occupying deep, moderate-velocity habitat among boulders (W. Tinniswood, June 2011, pers. comm.).

Non-native Fish Species

Goldfish

Goldfish (*Carassius auratus*) are abundant in J.C. Boyle Reservoir and Keno Impoundment/Lake Ewauna; in September 2010, they were the most abundant species captured during ODFW electrofishing surveys.

Yellow Perch

Yellow perch (*Perca flavescens*) prefer weedy rivers and shallow lakes. They are found in reservoirs and ponds along the Klamath River. Optimal temperature for growth is 22–27°C but yellow perch can survive in temperatures up to 30–32°C. They can survive low levels of dissolved oxygen (less than 1 milligram per liter [mg/L]) but are most abundant in areas with high water quality, as they are visual feeders. Larval and juvenile yellow perch feed on zooplankton; adults are opportunistic predators that may feed on larger invertebrates and small fish (Knight et al. 1984). The preferred habitat of the yellow perch includes large beds of aquatic plants for spawning and foraging. Their spawning takes place in 7 to 19°C water in April and May and usually occurs in their second year (Moyle 2002).

Bass and Sunfish

Several species of bass (*Micropterus* spp.) and sunfish (*Lepomis* spp.) have been introduced into the Klamath Basin, including largemouth bass, white and black crappie, bluegill, pumpkinseed and green sunfish. Largemouth bass and sunfish (*Centrarchidae*) prefer lakes, ponds, or low-velocity habitat in rivers. They prefer habitats with aquatic vegetation and will spawn in a variety of substrates. They prefer water temperatures above 27 degrees Celsius (°C). Juvenile and adult largemouth bass tend to feed on larger invertebrates and fish (Moyle 2002). Smaller members of the family, such as sunfish, are opportunistic feeders and eat a variety of aquatic insects, fish eggs, and planktonic crustaceans (Moyle 2002).

Sacramento Perch

Sacramento Perch (*Archoplites interruptus*) occur in J.C. Boyle Reservoir and Keno Impoundment/Lake Ewauna. The species is native to the Sacramento-San Joaquin watershed of California's Central Valley, from which they were extirpated.

Catfish

Several species of catfish have been introduced into the Klamath Basin, including black, brown, and channel catfish, and yellow bullhead (NRC 2004). Catfish prefer slow moving, warm water habitat. Brown bullhead (*Ameiurus nebulosus*) can tolerate a wide range of salinities and live at temperatures of 0 to 37°C, but their optimum temperature range is 20 to 33°C. Brown bullhead are most active at night and form feeding aggregations. Catfish are opportunistic omnivores and scavenge off the bottom of their habitat (Moyle 2002).

Trout

Brook trout (*Salvelinus fontinalis*) is an introduced species in the Upper Klamath Basin (FERC 2007) found in clear, cold lake and stream habitats. They prefer temperatures between 14 and 19°C but can survive in temperatures ranging from 1 to 26°C. Brook trout feed predominantly on terrestrial insects and aquatic insect larvae, though they may also opportunistically feed on other types of prey such as crustaceans, mollusks, and other small fish. Brook trout spawn in the fall and prefer habitats with small-sized gravel and nearby cover (Moyle 2002).

Brown trout (*Salmo trutta*) has also been introduced to the Klamath River and are found in both the Upper and Lower Klamath Basin. Brown trout prefer clear, cold water and can utilize both lake and stream habitats. Like brook trout, they spawn in the fall in streams with areas of clean gravel. Brown trout become piscivorous (fish eaters) once they reach a size where their gape can accommodate small fish available as prey.

Kokanee

Kokanee are landlocked sockeye salmon (*Oncorhynchus nerka*) that have been found in Upper Klamath Lake and Fourmile Creek.

American Shad

American shad (*Alosa sapidissima*) are an introduced, anadromous fish species that enjoys some popularity as a sport fish.

Fathead Minnow

Fathead minnow (*Pimephales promelas*) are an introduced bait fish widely distributed in the Upper Klamath Basin; however, it is thought that their introduction into the upper Klamath lakes may be a result of their use for pollution bioassays (Simon and Markle 1997, Moyle 2002).

Estuarine Species

The estuary is the mixing zone for freshwater and ocean water. The balance of fresh and saltwater changes over the course of the day with tides and is also strongly influenced by river flows. Because of this, both marine and freshwater species can often be found in different portions of the estuary at different times. All anadromous fish pass through the estuary during their migrations from freshwater to the sea and back again, and juvenile salmonids may rear in the estuary for varying periods of time, prior to moving into the ocean. CDFG surveys in the freshwater portion of the estuary commonly find Klamath speckled dace, Klamath smallscale sucker, prickly sculpin, and Pacific staghorn sculpin.

Other fairly common species include northern anchovy, saddleback gunnel, and bay pipefish. Other species in the estuary include federally listed eulachon, State listed longfin smelt (described under listed species), silversides, surf smelt, stickleback, and several gobies. Impacts to the estuarine species were assessed based on effects on EFH for groundfish and pelagic fish, as described in subsequent sections.

3.3.3.1.2 Freshwater Mollusks

Four species of native freshwater mussels have been observed within the Klamath Basin (FERC 2007; Westover 2010). PacifiCorp surveys in 2002 and 2003 found Oregon floater (*Anodonta oregonensis*), California floater (*A. californiensis*) and western ridged mussel (*Gonidia angulata*) along Klamath River reaches from the Keno Impoundment/Lake Ewauna to the confluence of the Klamath and Shasta Rivers. Westover (2010) found western pearlshell mussel (*Margaritifera falcata*) in addition to these species along the Klamath River from Iron Gate Dam to the confluence of the Klamath and Trinity Rivers.

Anodonta spp. are habitat generalists, more tolerant of lentic conditions than other native species (Nedeau et al. 2005). *Anodonta* spp. are also more tolerant of siltier substrates, as their thin shells allow individuals to “float,” or rest on top of silt-dominated streambeds (these species are commonly referred to as “floaters”). *G. angulata* is the largest and most common type of freshwater mussel found within the Klamath Basin (Nedeau et al. 2005). Known fish hosts include hardhead (*Mylopharodon conocephalus*), Pit sculpin (*Cottus pitensis*), and tule perch (*Hysterocarpus traski*), but a full list of host fish species for *G. angulata* is unknown (Jepsen et al. 2010). *G. angulata* is known to prefer cold, clean water, but can tolerate seasonal turbidity, and can be found in aggrading, or depositional areas as it can partially bury itself within bed sediments without affecting filter feeding (Vannote and Minshall 1982; Westover 2010). A full understanding of *G. angulata*’s former and current distribution is particularly lacking, but it is believed to have been extirpated in central and southern California and has probably declined in many other watersheds, including the Columbia and Snake River basins (Jepsen et al. 2010). The Klamath River appears unusual in that *G. angulata* dominates its mussel community, unlike other rivers in the Pacific Northwest (Westover 2010). *M. falcata* has also been observed within the Klamath Basin downstream from Iron Gate Dam, though in lesser abundance than other species (Westover 2010). *M. falcata* occupies low shear stress habitats (e.g., pools and near banks) and interstices within bedrock and cobble (Howard and Cuffey 2003).

Adult freshwater mussels are generally found wedged into gravel, rock substrate or partially buried in finer substrates, using a muscular foot to maintain position. Freshwater mussels filter feed on plankton and other organic material suspended in the water column.

While life history traits of individual species of freshwater mussels have not been fully studied, the general life cycle is as follows. Eggs within female freshwater mussels are fertilized by sperm that is brought into the body cavity. From April through July thousands of tiny larvae, called glochidia, are released into the water where they must

encounter a host fish for attachment within hours, otherwise they perish (Haley et al. 2007). Most juvenile freshwater mussels from these species drop off the fish hosts to settle from June to early August. They may spend an undetermined amount of time buried in the sediment where they grow to the point where they can maintain themselves at or below the substrate surface in conditions that are optimal for filter feeding (Nedeau et al. 2009). Freshwater mussels are fed upon by muskrats, river otters, and sturgeon (Nedeau et al. 2009). They were also a food of cultural significance for the Karuk Tribe (Westover 2010) and The Klamath Tribes.

Seven to eight species of fingernail clams and peaclams (Family: Sphaeriidae) were also found in the Hydroelectric Reach and from Iron Gate Dam to Shasta River during re-licensing surveys. One of the clam species, the montane peaclam (*Pisidium ultramontanum*), has special status as a Federal species of concern and a United States Forest Service (USFS) sensitive species. The montane peaclam is generally found on sand-gravel substrates in spring-influenced streams and lakes, and occasionally in large spring pools. The original range included the Klamath and Pit Rivers in Oregon and California, as well as some of the larger lakes (Upper Klamath, Tule, Eagle, and possibly, lower Klamath lakes). On USFS lands they are currently present or suspected in streams and lakes of Lassen and Shasta-Trinity National Forests. Fingernail clams and peaclams are relatively short-lived (1 to 3 years) compared to freshwater mussels (10 to 15 years or 100 plus years for some species). These small clams live on the surface or buried in the substrate in lakes, ponds or streams. They bear small numbers of live young several times throughout the spring and summer (Thorp and Covich 2001).

There are also many species of freshwater snails, some of which are endemic to the Klamath Basin and have restricted ranges, often associated with cold-water springs. Several of these have recently been petitioned for listing. However, based on their restricted distribution outside of any areas that could be affected by the Proposed Action they were considered, but not included in any additional analysis.

3.3.3.1.3 Benthic Macroinvertebrates

Benthic macroinvertebrates (BMIs) include immature, aquatic stages of insects such as midges, mayflies, caddisflies, stoneflies, dragonflies, and damselflies. They also include immature and adult stages of aquatic beetles; crayfish, amphipods and isopods (crustaceans); clams and snails; aquatic worms and other major invertebrate groups. Many BMIs are the primary consumers in riverine food webs, feeding on primary producers—algae, aquatic plants, phytoplankton, bacteria, as well as leaves and other materials from terrestrial plants, and detritus. By converting organic material into biomass available to a wide variety of consumers, these organisms form an important component of the aquatic food web. Some BMIs are secondary consumers, feeding on the primary consumers. Together the BMIs are the primary food source for most fish species, and changes in abundance, distribution, or community structure can negatively affect fish populations. BMIs are also used as general indicators of water quality in indices of biological integrity based upon the richness or diversity of pollution tolerant and resistant species. BMIs are also particularly sensitive to changes in fine and coarse sediment load, which could occur under the Proposed Action and alternatives. Food

supply can limit growth of salmonids, and this is especially true at higher temperatures; i.e., as water warms, a fish needs more food to sustain growth (Brett 1971; McCullough 1999). Growth is critical to juvenile salmonids because a larger size often confers a survival advantage during the overwintering period, smolt outmigration, or ocean residence. If fish are chronically exposed to warmer temperatures and food availability is low, growth may cease, fish may experience physiological stress, and mortality from disease, parasites, and predation may increase. But in a productive system with high densities of macroinvertebrates or forage fish, a high rate of growth can be sustained at temperatures higher than would be considered optimal under conditions where food is limiting.

Relicensing studies evaluated BMIs from Link River Dam to the Shasta River and on Fall Creek in 2002 and 2003 (FERC 2007). These studies show that macroinvertebrates are abundant, with densities of 4,000 to 8,000 individuals per square meter.

Macroinvertebrate densities in fall of 2002 ranged from a low of 4,000 per square meter downstream from the powerhouse on the Klamath River to 21,000 per square meter below Keno Dam (PacifiCorp 2004b). Abundance of macroinvertebrates in the peaking reach of the Klamath River was as low as 500 per square meter in the spring of 2003. Dominant species in the riverine areas were caddisflies, blackflies, midges, beetles, and mayflies. The reservoirs had high abundance of invertebrates but low diversity, and were dominated by species tolerant of impaired water quality conditions.

3.3.3.1.4 Listed Species Coho Salmon

The Southern Oregon/Northern California Coast (SONCC) coho salmon (*O. kisutch*) ESU is listed as federally threatened (NOAA Fisheries Service 1997a). This ESU includes all naturally spawning populations between Punta Gorda, California and Cape Blanco, Oregon, which encompasses the Trinity and Klamath Basins (NOAA Fisheries Service 1997a). Three artificial propagation programs are considered to be part of the ESU: the Cole Rivers Hatchery, Trinity River Hatchery, and Iron Gate Hatchery coho salmon programs. NOAA Fisheries Service has determined that these artificially propagated stocks are no more than moderately diverged from the local natural populations. In addition, coho salmon in the Klamath Basin have been listed by the California Fish and Game Commission as threatened under the California Endangered Species Act (CESA) (CDFG 2002a).

Coho salmon are native to the Klamath Basin. Williams et al. (2006) described nine historical coho salmon populations within the Klamath Basin, including the Upper Klamath River, Shasta River, Scott River, Salmon River, Mid-Klamath River, Lower Klamath River, and three population units within the Trinity River watershed (upper Trinity River, lower Trinity River, and South Fork Trinity River). Although coho salmon are native to the Klamath River, documentation of coho salmon in the Klamath River is scarce prior to the early 1900's due, in part, to the apparent difficulty in recognizing there were different species of salmon inhabiting the rivers of the area (Snyder 1931). Snyder (1931) reported that coho salmon were said to migrate to the headwaters of the Klamath

River to spawn, but that most people did not distinguish between the species. During 2006 administrative hearings it was concluded that coho salmon migrated past the present site of Iron Gate Dam based on historical records and tribal accounts (Administrative Law Judge 2006).

Coho salmon are currently widely distributed in the Klamath River downstream from Iron Gate Dam (RM 190), which blocks the upstream migration of coho salmon to historically available habitat in the upper watershed. Before the construction of the dams, coho salmon were apparently common and widely distributed throughout the watershed, probably in both mainstem and tributary reaches up to and including Spencer Creek at RM 228 (NRC 2004, as cited in NOAA Fisheries Service 2007; Hamilton et al. 2005). Coho salmon utilize the mainstem Klamath River for some or all of their life history stages (spawning, rearing and migration). However, the majority of returning adult coho salmon spawn in the tributaries to the mainstem (Magneson and Gough 2006, NOAA Fisheries Service 2010a).

Coho salmon adults in the Klamath Basin migrate upstream from September through late December, peaking in October and November. Spawning occurs mainly in November and December, with fry emerging from the gravel in the spring, 3 to 4 months after spawning (Trihey and Associates 1996; NRC 2004).

Some fry and age-0+ juveniles enter the mainstem in the spring and summer following emergence (Chesney et al. 2009). Large numbers of age-0 juveniles from tributaries in the mid-Klamath River move into the mainstem in the fall (October through November) (Soto et al. 2008; Hillemeier et al. 2009). Juvenile coho salmon have been observed to move into non-natal rearing streams, off-channel ponds, the Lower Klamath River, and the estuary for overwintering (Soto et al. 2008; Hillemeier et al. 2009). Some proportion of juveniles generally remain in their natal tributaries to rear.

Age 1+ coho salmon migrate from tributaries into the mainstem Klamath River from February through mid-June with a peak in April and May, which often coincides with the descending limb of the spring hydrograph (NRC 2004; Chesney and Yokel 2003; Scheiff et al. 2001). Once in the mainstem, smolts appear to move downstream rather quickly; Wallace (2004) reported that numbers of coho salmon smolts in the Klamath River estuary peaked in May, the same month as peak outmigration from the tributaries.

The major activities identified as responsible for the decline of coho salmon in Oregon and California and/or degradation of their habitat included logging, road building, grazing, mining, urbanization, stream channelization, dams, wetland loss, beaver trapping, artificial propagation, overfishing, water withdrawals, and unscreened diversions for irrigation (NOAA Fisheries Service 1997a). In 2007, NOAA Fisheries Service published a Klamath River Coho Salmon Recovery Plan to comply with Magnuson-Stevens Fishery Conservation and Management Reauthorization Act of 2006 (not equivalent to recovery plans under ESA); the plan includes the following actions identified as high priority for recovery:

- Complete and implement the NOAA Fisheries Service recovery plan for the SONCC coho salmon under the ESA.
- Restore access for coho salmon to the Upper Klamath Basin by providing passage beyond existing mainstem dams.
- Fully implement the Trinity River Restoration Program.
- Provide incentives for private landowners and water users to cooperate in (1) restoring access to tributary streams that are important for coho spawning and rearing; and (2) enhancing mainstem and tributary flows to improve instream habitat conditions.
- Continue to improve the protective measures already in place to address forestry practices and road building/maintenance activities that compromise the quality of coho salmon habitat.
- Implement restorative measures identified through fish disease research results to improve the health of Klamath River coho salmon populations.

Eulachon

Eulachon (*Thaleichthys pacificus*) is an anadromous fish that occurs in the lower portions of certain rivers draining into the northeastern Pacific Ocean, ranging from northern California to the southeastern Bering Sea in Bristol Bay, Alaska (McAllister 1963; Scott and Crossman 1973; Willson et al. 2006, as cited in NOAA Fisheries Service 2010b). The southern population of Pacific eulachon consists of populations spawning in rivers south of the Nass River in British Columbia, Canada, to and including the Mad River in California (NOAA Fisheries Service 2009a). On March 18, 2010, NOAA Fisheries Service listed the southern DPS of eulachon as threatened under the ESA (NOAA Fisheries Service 2010b). Final critical habitat was designated in October of 2011 (NOAA Fisheries Service 2011).

Historically, the Klamath River was described as the southern limit of the range of eulachon (Gustafson et al. 2010). Other accounts have described large spawning aggregations of eulachon occurring regularly in the Klamath River (Fry 1979, Moyle et al. 1995, Larson and Belchik 1998, Moyle 2002, Hamilton et al. 2005), and occasionally in the Mad River (Moyle et al. 1995, Moyle 2002) and Redwood Creek (Moyle et al. 1995). In addition, small numbers of eulachon have been reported from the Smith River (Moyle 2002). The only reported commercial catch of eulachon in northern California occurred in 1963 when a combined total of 25 metric tons (56,000 lbs) was landed from the Klamath River, the Mad River, and Redwood Creek (Odemar 1964). Since 1963, the run size has declined to the point that only a few individual fish have been caught in recent years. Moyle (2002) indicates that eulachon have been scarce in the Klamath River since the 1970s, with the exception of three years: they were plentiful in 1988 and again in 1989 and 1998. After 1998, they were thought to be extinct in the Klamath Basin until a small run was observed in the estuary in 2004. According to accounts of Yurok Tribal elders, the last noticeable runs of eulachon were observed in the Klamath River in 1988 and 1989 by Tribal fishermen (Larson and Belchik 1998). Larson and Belchik (1998) reported that eulachon have not been of commercial importance in the Klamath in recent years and that their current run strength is unknown. However, in

January 2007, six eulachon were reportedly caught by tribal fishermen on the Klamath River. Another seven were captured between January and April of 2011 at the mouth of the Klamath River (NOAA Fisheries Service 2011).

Historically, eulachon runs in northern California were said to start as early as December and January and peak in abundance during March and April. Historically, large numbers of eulachon migrated upstream in March and April to spawn, but they rarely moved more than 8 miles inland (NRC 2004). Spawning occurs in gravel riffles, with hatching about a month later. The larvae generally move downstream to the estuary following hatching.

Southern Green Sturgeon DPS

The Southern Green Sturgeon DPS is listed as threatened under the Federal ESA (NOAA Fisheries Service 2006a). Juvenile and adult Southern Green Sturgeon enter many estuaries along the West Coast during the summer months to forage, but their use of the Klamath River estuary has not been documented. No sturgeon tagged by the Yurok Tribe within the Klamath River have ever been detected in the range of Southern Green Sturgeon DPS (primarily San Francisco Bay) despite the presence of numerous receivers that would have detected Klamath River tagged fish if they had ventured there (McCovey 2011). No Southern Green Sturgeon tagged in the Sacramento/San Joaquin and/or San Francisco Bay region have ever been detected in the Klamath River. Southern Green Sturgeon have been detected immediately offshore of the Klamath River, but have not been detected in the Klamath River estuary or mainstem despite the presence of functioning acoustic receivers in the Klamath River estuary (McCovey 2011). Overall, it appears unlikely that sturgeon from the Southern Green Sturgeon DPS currently occur within the Klamath River.

Lost River and Shortnose Suckers

Lost River (*Deltistes luxatus*) and shortnose (*Chasmistes brevirostris*) suckers are endemic to the Upper Klamath Basin of southern Oregon and northern California (Moyle 2002). These species are listed as endangered under the ESA (USFWS 1988), and are endangered under CESA, as well as fully protected species under California Fish and Game Code Section 5515(a)(3)(b)(4) and (6), respectively; thus any take of these species is prohibited. Threats to the population include: the damming of rivers, instream flow diversions, hybridization, competition and predation by exotic species, dredging and draining of marshes, water quality problems associated with timber harvest, the removal of riparian vegetation, livestock grazing, agricultural practices, and low lake elevations, particularly in drought years. Reduction and degradation of lake and stream habitats in the Upper Klamath Basin is considered by USFWS to be the most important factor in the decline of both species (USFWS 1993).

The Lost River sucker historically occurred in Upper Klamath Lake (Williams et al. 1985) and its tributaries and the Lost River watershed, Tule Lake, Lower Klamath Lake, and Sheepy Lake (Moyle 1976). Shortnose suckers historically occurred throughout Upper Klamath Lake and its tributaries (Williams et al. 1985; Miller and Smith 1981). The present distribution of both species includes Upper Klamath Lake and its tributaries (Buettner and Scopettone 1990), Clear Lake Reservoir and its tributaries (USFWS

1993), Tule Lake and the Lost River up to Anderson-Rose Dam (USFWS 1993), and the Klamath River downstream to Copco Reservoir and probably to Iron Gate Reservoir (USFWS 1993). Shortnose sucker occur in Gerber Reservoir and its tributaries, but Lost River sucker do not.

Lost River and shortnose suckers are lake-dwelling, but spawn in tributary streams or springs (USFWS 1988). They spawn from February through May, depending on water depth and stream temperature (Buettner and Scoppettone 1990; Andreassen 1975, USFWS 2008). When spawning occurs over cobble and armored substrate, eggs fall between crevices or are swept downstream (Buettner and Scoppettone 1990). Larval Lost River and shortnose suckers spend relatively little time in tributary streams, migrating back to the lake shortly after emergence, typically in May and early June (Buettner and Scoppettone 1990). Adults return to Upper Klamath Lake soon after spawning. Lake fringe emergent vegetation is the primary habitat used by larval suckers (Cooperman and Markle 2004). Juvenile suckers utilize a wide variety of near-shore habitat including emergent vegetation, non-vegetated areas and off-shore habitat (Hamilton et al. 2011). Refugial areas of relatively good water quality are important for fish in Upper Klamath Lake during the summer and early fall, when dissolved oxygen and pH levels can be stressful or lethal in much of the lake (Coleman and McGie 1988). A recovery plan for Lost River and shortnose suckers was completed in 1994 and revised in 2011 (USFWS 2011a). Critical habitat was proposed but not finalized in 1994 (USFWS 1994) and re-proposed for the two species on December 7, 2011 (USFWS 2011b). More detailed information for this species can be found in USFWS (2008).

Bull Trout

Bull trout (*Salvelinus confluentus*) are listed as threatened under the ESA in 1999 (USFWS 1999), and a recovery plan for the Klamath River Bull Trout DPS was published in 2002 (USFWS 2002). Historically, bull trout occurred throughout the Klamath Basin in Oregon. Currently bull trout are found in two streams in the Upper Klamath Lake watershed (Sun and Threemile creeks), six streams in the Sprague River watershed (Deming, Brownsworth, Leonard, Boulder, Dixon, North Fork Sprague), and one stream in the Sycan River watershed (Long Creek).

The distribution and numbers of bull trout are believed to have declined in the Klamath Basin due to habitat isolation, loss of migratory corridors, poor water quality, and the introduction of nonnative species. The geographic isolation of the Klamath populations places them at greater risk of genetic effects and extirpation (NRC 2004). Bull trout exhibit two basic life-history strategies: resident and migratory. Migratory bull trout live in larger river and lake systems and migrate to small stream headwaters to spawn. In general, migratory fish are larger than resident fish. Research indicates that various types of bull trout interbreed at times, which helped maintain viable populations throughout the fish's range (Rieman and McIntyre 1993).

Bull trout reach sexual maturity in 5 to 7 years and spawn from the end of August through November. Spawning may occur annually for some populations, and every other year for the rest. Bull trout require particularly clean gravel substrates for spawning.

High sediment levels suffocate eggs by reducing dissolved oxygen (Rieman and McIntyre 1996). Bull trout eggs incubate over the winter and hatch in the late winter or early spring. Emergence usually requires an incubation period of 120 to 200 days.

Juvenile bull trout migrate upstream of spawning areas to grow and take advantage of cool headwater temperatures. Bull trout less than 1 year old are generally found in areas along stream margins and inside channels. Most migratory juvenile bull trout remain in headwater tributaries for 1 to 3 years before emigrating downstream to larger stream reaches. Emigration usually takes place from June to August (Rieman and McIntyre 1996).

Southern Resident Killer Whale

The Southern Resident Killer Whale (*Orcinus orca*) DPS is designated as endangered under the ESA (NOAA Fisheries Service 2005). This DPS primarily occurs in the inland waters of Washington State and southern Vancouver Island, particularly during the spring, summer, and fall, although individuals from this population have been observed off coastal California in Monterey Bay, near the Farallon Islands, and off Point Reyes (Heimlich-Boran 1988; Felleman et al. 1991; Olson 1998; Osborne 1999; NOAA Fisheries Service 2005). Southern Resident Killer Whale survival and fecundity are correlated with Chinook salmon abundance (Ward et al. 2009; Ford et al. 2009). Southern Resident Killer Whales could potentially be affected by changes in salmon populations in the Klamath River caused by the Proposed Action (food abundance is one of the elements of their critical habitat, as described in the Critical Habitat Section). Hanson et al. (2010) found that Southern Resident Killer Whale stomach contents included several different ESUs of salmon, including Central Valley fall-run Chinook salmon.

Longfin Smelt

Longfin smelt (*Spirinchus thaleichthys*) are a State-listed threatened species throughout their range in California, but the USFWS denied the petition for Federal listing because the population in California (and specifically San Francisco Bay) was not believed to be sufficiently genetically isolated from other populations (USFWS 2009). This species generally has a 2 year lifespan, although 3-year-old fish have been observed (Moyle 2002). They typically live in bays, estuaries and have sometimes been observed in the nearshore ocean from San Francisco Bay to Prince William Sound, Alaska, including the Klamath River. They prefer salinities of 15 to 30 ppt, although they can tolerate salinities from freshwater to full seawater. They prefer temperatures of 16 to 18°C and generally avoid temperatures higher than 20°C. Longfin smelt may occur in the Klamath River throughout the year. They would only be expected to use the estuary and the lowest reaches of the river. Longfin smelt spawning occurs primarily from January to March, but may extend from November into June, in fresh or slightly brackish water over sandy or gravel substrates. Temperatures during spawning in the San Francisco estuary are 7 to 14.5 °C. Embryos hatch in 40 days in 7 °C water temperature (25 days in 10.6 °C water) and are quickly swept downstream by the current to more brackish areas. The importance of ocean rearing is unknown. Little is known about longfin smelt populations in the Klamath River, except that they are presumably small.

3.3.3.2 Physical Habitat Descriptions

3.3.3.2.1 Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Aquatic habitat in the Upper Klamath Basin includes both lacustrine and riverine habitats, and also includes large, thermally stable coldwater springs. The Upper Klamath River upstream of Iron Gate Dam once supported large populations of anadromous salmon and steelhead by providing spawning and rearing habitat (Hamilton et al. 2005). Further, Butler et al. (2010) documented fish remains from six archaeological sites located upstream of Upper Klamath Lake to provide an independent record of Chinook salmon the Upper Klamath Basin.

Upper Klamath Lake is the most prominent feature in this part of the Basin, although other lakes and reservoirs are also present. Lake Ewauna, another lake on the Klamath River mainstem, is connected to Upper Klamath Lake via the Link River. The Keno Impoundment/Lake Ewauna is formed by Keno Dam, which regulates water surface elevations in the impoundment to facilitate agricultural diversions. Implementation of the Klamath Hydroelectric Settlement Agreement (KHSA) and the Klamath Basin Restoration Agreement (KBRA) would result in the reintroduction of anadromous fish into these lakes and their tributary streams. The KBRA has substantial funding designated to improve water quality above Keno Dam.

Lower Klamath Lake, Tule Lake, Clear Lake and Gerber Reservoir in the Upper Klamath Basin could be affected by changes in water management associated with the Proposed Action and alternatives. The KBRA includes provisions for specific water allocations and delivery obligations for the Lower Klamath Lake and Tule Lake National Wildlife Refuges, which will increase availability and reliability of water supplies above historical refuge use in most years (Hetrick et al. 2009). These two refuges contain important habitat for Pacific Flyway waterfowl and waders (see Section 3.5). Tule Lake, Clear Lake, and Gerber Reservoir support populations of shortnose and Lost River suckers (FERC 2007; USFWS 2007a, b; NRC 2008).

Upper Klamath Lake and Lake Ewauna are affected by poor water quality conditions. During the summer months these water bodies exhibit episodic high pH, broad daily shifts in dissolved oxygen, and elevated ammonia concentrations (Hamilton et al. 2011). In Upper Klamath Lake several incidents of mass adult mortality of shortnose and Lost River sucker have been associated with low dissolved oxygen levels (Perkins et al. 2000, Banish et al. 2009). Instances of pH levels above 10 and extended periods of pH levels greater than 9 lasting for several weeks are associated with large algal blooms occurring in the lake (Kann 2010). On a diel basis, algal photosynthesis can elevate pH levels during the day, with changes exceeding 2 pH units over a 24-hour period. During November–April (non-growing season) pH levels in Upper Klamath Lake are near neutral (Aquatic Scientific Resources 2005). Additional detail is provided in Section 3.2, Water Quality.

Fish passage over Link Dam is provided by a ladder. This ladder is designed to modern standards to allow the passage of shortnose and Lost River suckers, salmonids and other

migratory fish, including anadromous salmonids and Pacific lamprey, if present. Keno Dam is equipped with a 24-pool weir and orifice type fish ladder, which rises 19 feet over a distance of 350 feet, designed to pass trout and other resident fish species (FERC 2007). The fishway at Keno Dam currently complies with passage criteria for salmonid fish, but plans are being developed to have the fishway rebuilt to criteria for lamprey and for greater anadromous salmonid runs if the Keno facility is transferred to the government as part of settlement (T. Hepler, Reclamation, pers. comm., as cited in Hamilton et al. 2011). Although suckers have been observed to use the Keno Dam fish ladder, the ladder was not designed for sucker passage and is considered generally inadequate for sucker passage (Reclamation 2002).

The Williamson and Wood Rivers are the largest tributaries to Upper Klamath Lake, with the Williamson River being the largest tributary. The Sprague River is tributary to the Williamson River, and the Sycan River is tributary to the Sprague River (Hamilton et al. 2011). These tributaries currently provide habitat for redband trout, bull trout, shortnose sucker and Lost River sucker, as well as other species. Historically these tributaries provided substantial habitat for Chinook salmon and steelhead (Hamilton et al. 2005, 2011). Important flow contributions from springs into these tributaries provide cool summer baseflows with water temperatures and dissolved oxygen levels generally adequate to support coldwater fish habitat requirements (Hamilton et al. 2011); though these tributaries suffer from some water quality impairments as described in Section 3.2, Water Quality.

In addition to redband trout, shortnose and Lost River sucker, the Upper Klamath Basin supports many other fish species. Resident fishes include several species of minnow, sucker, sculpin, and salmonids. At least 18 species have been introduced into the Upper Klamath Basin including several species of minnow, catfish, sunfish, largemouth bass, and spotted bass, as well as yellow perch.

3.3.3.2.2 Hydroelectric Reach: J.C. Boyle Reservoir Downstream to Iron Gate Dam

The hydroelectric reach, from the upstream extent of J.C. Boyle Reservoir to Iron Gate Dam, includes four reservoirs (J.C. Boyle, Copco 1, Copco 2, and Iron Gate) and two riverine reaches. Several coolwater tributaries enter the Klamath River and reservoirs in this reach. The reservoirs are productive and nutrient rich. They tend to be warm during the summer months, with mean daily temperatures sometimes reaching 23°C (FERC 2007). Water quality in the Copco 1 and Iron Gate Reservoirs during the summer is generally quite poor due to warm surface waters and annual blooms of the *Aphanizomenon flos-aquae*, *Anabaena flos-aquae*, and *M. aeruginosa* (see Section 3.4). *M. aeruginosa*, and to an unknown extent *Anabaena flos-aquae*, produce toxins that could be harmful to fish and other animals and humans. Routine sampling from areas frequented by recreational users of the reservoirs has documented cell counts up to 4,000 times greater than what the World Health Organization considers a moderate health risk (see Section 3.4). This has resulted in Copco and Iron Gate reservoirs being posted by local health officials during each summer since 2005.

The 22 miles long riverine reach between J.C. Boyle and Copco 1 Reservoirs, is divided into two reaches: a 4-mile long Bypass Reach, which receives bypass flows from J.C. Boyle Dam, and a 17-mile long “peaking reach,” which receives variable flow from hydroelectric operations. The downstream 6.2 miles is designated by CDFG as a Wild Trout Area with the whole reach managed for wild trout (FERC 2007) and the reach from the J.C. Boyle Powerhouse to the California-Oregon border is designated as a National Wild and Scenic River. Approximately 100 cubic feet per second (cfs) is released from J.C. Boyle Dam through a minimum flow outlet and the ladder. This is augmented by inflows from Big Springs of about 220 to 250 cfs (FERC 2007). In the peaking reach, this flow is added to flows from the powerhouse, which can range from 0 to over 3,000 cfs, depending on water availability (FERC 2007). Depending on water availability, power demands and whitewater boating needs, peaking operations can occur daily, or cycles may extend over several days. The 1.4 mile long Copco 2 Bypass Reach, has flows of about 5 cfs provided below Copco 2 Dam. Disregarding flow requirements, both of these riverine reaches provide complex physical habitat suitable for salmonid spawning and rearing.

A number of tributary streams come into this reach, including Spencer, Shovel, Fall, Spring, and Camp Creeks. These streams provide suitable coldwater spawning and rearing habitat for riverine fish.

The reservoirs currently provide a recreational fishery for non-native fishes including largemouth bass, trout, catfish, crappie, and sunfish (Hamilton et al. 2011). Fishing is popular in Copco 1 and Iron Gate Reservoirs, especially for yellow perch; this area is known locally as the best yellow perch fishery in California (Hamilton et al. 2011). These reservoirs also support small numbers of native shortnose and Lost River suckers that are believed to be individuals that have migrated down from the upstream reservoirs and that are not thought to be self-sustaining populations or to be contributing to populations in upstream areas (Hamilton et al. 2011). Fish collections by Oregon State University in Copco 1 Reservoir during 1998 and 1999 found about 13 percent of all adult fish caught were listed suckers, primarily shortnose sucker. One percent of the adult fish in Iron Gate Reservoir were listed sucker, and those were only shortnose sucker. Riverine sections between reservoirs support populations of speckled dace, marbled sculpin, tui chub, and rainbow and redband trout. This area historically supported anadromous fish populations, including Chinook and coho salmon, steelhead, and Pacific lamprey. These fish can no longer access this area because of the lack of adequate facilities for fish passage at the dams.

3.3.3.2.3 Klamath River from Iron Gate Dam Downstream to Estuary

The Lower Klamath River flows unobstructed for 190 miles downstream from Iron Gate Dam before entering the Pacific Ocean. Downstream from Iron Gate Dam, the Klamath River has a gradient of approximately 0.0025 and four major tributaries enter this reach: the Shasta, Scott, Salmon, and Trinity Rivers.

The Klamath Basin downstream from Iron Gate Dam supports anadromous fish, including fall-run and spring-run Chinook salmon, coho salmon, steelhead, green

sturgeon, American shad, and Pacific lamprey. Most of the anadromous salmonid species spawn primarily in the tributary streams, although fall-run Chinook salmon and coho salmon do spawn on the mainstem. The mainstem also serves as a migratory corridor and as rearing habitat for juveniles of many salmonid species (FERC 2007). The amount of time spent on the mainstem varies with species, run, temperature and hydrologic conditions in the mainstem and the tributaries. Pacific lamprey are also found throughout the mainstem Klamath River and its major tributaries downstream from Iron Gate Dam. Green sturgeon (belonging to the Northern Green Sturgeon DPS) spawn and rear in the Klamath River downstream from Ishi Pishi Falls, and in the Salmon and Trinity Rivers. Tributaries to the Klamath River provide hundreds of miles of suitable habitat for anadromous fish. Anadromous fish stocks have declined substantially from historical abundance (NRC 2004, FERC 2007). The ability of the mainstem Klamath River to support the rearing and migration of anadromous species is reduced by periodic high water temperatures during summer, poor water quality (low dissolved oxygen and high pH; see Sections 3.2.3.5 and 3.2.3.6), and disease outbreaks during spring. Habitat quality in the tributaries is also affected by high temperatures. The Shasta and Scott Rivers also are impaired by low flows, high water temperatures, stream diversions, non-native species, and degraded spawning habitat (Hardy and Addley 2001; FERC 2007; North Coast Regional Water Quality Control Board [NCRWQCB] 2010). In the Salmon River, past and present high severity fires and logging roads in the Watershed contribute to high sediment yields, and continued placer mining has disturbed spawning and holding habitat (NRC 2004).

The Trinity River (RM 42.8) is not expected to be directly affected by conditions in the mainstem Klamath River, but the lower one-quarter to one-half mile of the river may be used by fish as refuge from water quality impacts during implementation of the Proposed Action. Fish populations in the Trinity River are expected to be directly affected by the Proposed Action while migrating along the mainstem Klamath River, and indirectly affected by potential changes in salmonid escapement to the Basin.

3.3.3.2.4 Klamath River Estuary and Pacific Ocean Nearshore

Wallace (1998) surveyed the Klamath River Estuary, and noted formation of a sand berm at the river mouth each year in the late summer or early fall, raising the water level in the estuary, reducing tidal fluctuation, and restricting saltwater inflow. The surveys found a brackish water layer along the bottom of the estuary may be extremely important to rearing juvenile salmonids, as they appeared to be more abundant near the freshwater/saltwater interface. Juvenile Chinook salmon may also use the cooler brackish water layer as a thermal refuge

The Klamath River Estuary supports a wide array of fish species and may also serve as breeding and foraging habitat for marine and estuarine species. These species include, but are not limited to all of the anadromous fish listed previously, federally threatened Southern DPS green sturgeon, Pacific herring, surf smelt, longfin smelt, eulachon, top smelt, starry flounder and other flatfish, Klamath speckled dace, Klamath smallscale sucker, prickly sculpin, and Pacific staghorn sculpin, northern anchovy, saddleback gunnel, and bay pipefish.

3.3.3.3 *Habitat Attributes Expected to be Affected by the Project*

The action alternatives would affect the physical, chemical, and biological components of habitat throughout the Klamath River watershed, from the tributaries to Upper Klamath Lake downstream to the Pacific Ocean. These effects would result from changes in suspended sediment, bedload sediment, water quality, water temperature, disease and parasites, and flow related habitat. As described in the following sections, these changes would act in both beneficial and harmful ways on species, critical habitat, and EFH. Appendices E and F provide more detailed technical descriptions of suspended sediment and bedload sediment. Changes in water quality are discussed in greater detail in Section 3.2, Water Quality and its associated appendices, and a description of the effects of the action alternatives on algae is found in Section 3.4, Algae. A description of these parameters, water temperature, and disease and parasites under existing conditions is provided in the following sections.

3.3.3.3.1 Lower Klamath River: Downstream from Iron Gate Dam

The downstream transport of suspended sediment can affect species through elevated suspended sediment concentrations (SSCs) that may clog or abrade the gills of fish, or reduce foraging efficiency and as the material settles on the stream bed during declining flows, it can reduce the survival of incubating eggs and developing alevins in salmonid redds by impeding intergravel flow as well as the emergence of fry. Everest et al. (1987) concluded all salmonids can cope with the natural variability in sediments, but salmonid populations can be reduced by persistent fine sedimentation that exceeds the natural levels under which salmonids evolved. Suspended sediments under existing conditions in the Klamath River upstream and downstream from Iron Gate Dam are summarized in Section 3.2.3.3. In general, the data indicate that SSCs downstream from Iron Gate Dam range from less than 5 mg/L during summer low flows to greater than 5,000 mg/L during winter high flows. During large winter storms or following landslides in the Klamath Basin, extremely high SSCs have been observed in the Klamath River mainstem and tributaries. Appendix E provides a detailed analysis of the effects of suspended sediment on aquatic species downstream from Iron Gate Dam under existing conditions. To provide a reliable basis for a relative comparison of SSCs to the alternatives, SSCs under existing conditions were calculated using the SRH-1D model (Reclamation 2011) based on hydrology data from 1961 to present. SSCs were developed for two conditions meant to represent the existing range of variability under existing conditions, defined as follows:

- **Normal conditions:** SSCs and durations with a 50 percent exceedance probability for the mainstem Klamath River downstream from Iron Gate Dam (i.e., the probability of these concentrations and durations being equaled or exceeded in any one year is 50 percent). Exceedance probabilities were based on modeling SSC for all water years subsequent to 1961 with facilities in place. To assess “normal conditions” the median (50 percent) SSC and duration from these results was estimated (Figure 3.3-2).

- **Extreme conditions:** SSCs and durations with a 10 percent exceedance probability (i.e., the probability of these concentrations and durations being equaled or exceeded in any 1 year is 10 percent). This represents an extreme condition with high SSCs, such as a flood (Figure 3.3-3).

Under both normal and extreme conditions, SSCs of the magnitude and duration modeled are expected to cause major stress to migrating adult and juvenile salmonids primarily during winter (Newcombe and Jenson 1996, Appendix E). SSC generally increases in a downstream direction from the contribution of tributaries, and since Iron Gate Dam currently effectively traps most suspended sediment.

Figure 3.3-2. Normal conditions (50 Percent Exceedance Probability) SSCs for Three Locations Downstream from Iron Gate Dam under Existing Conditions, as Predicted Using the SRH-1D Model.

Figure 3.3-3. Extreme conditions (10 Percent Exceedance Probability) SSCs for Three Locations Downstream from Iron Gate Dam under Existing Conditions, as Predicted Using the SRH-1D Model.

Klamath River Estuary

Under existing conditions SSCs within the Klamath River Estuary are relatively high compared to SSC observed further upstream (Figures 3.3-2 and Figure 3.3-3). As described in Section 3.2.4.3.1.2, the Lower Klamath River downstream from the Trinity River confluence to the estuary mouth is currently listed as sediment impaired under Section 303(d) of the Clean Water Act, as related to protection of the cold freshwater habitat beneficial use associated with salmonids (NCRWQCB 2010). Modeling in the Klamath River (from Seiad Valley at approximately RM 128 downstream to the Klamath Station at RM 5) indicates that under normal conditions SSCs are relatively high during winter (typically 50 to 100 mg/L), and lower (< 10 mg/L) during summer. Under extreme conditions the SSC is generally 10 to 100 mg/L in summer and fall, with peaks between 100 and 1,000 mg/L during winter and spring (Figure 3.3-3).

Pacific Ocean Nearshore Environment

Under existing conditions a “plume” exists within the nearshore environment in the Klamath River vicinity that is subject to strong land runoff effects following winter rainfall events. The plume can create areas of low-salinity, high levels of suspended particles, high sedimentation, and low light (and potential exposure to land-derived contaminants). The extent and shape of the plume is variable, and influenced by wind patterns, upwelling effects, shoreline topography (especially Point Saint George), and longshore currents. High SSCs events contribute to the plume, especially during floods.

As described in detail in Section 3.2.4.3.2, in northern California, plume zones are primarily north of river mouths because alongshore currents and prevailing winds are northward during periods of strong runoff (Geyer et al. 2000, Pullen and Allen 2000, Farnsworth and Warrick 2007). River plumes and the associated habitat conditions they create are considered to be areas of high productivity for marine organisms (Grimes and Finucane 1991, Morgan et al. 2005), and create abrupt changes in marine water quality conditions (e.g., water temperature, salinity, sediment) that support salmonids (Schabetsberger et al. 2003, DeRobertis et al. 2005).

3.3.3.3.2 Bedload

Appendix F describes current habitat conditions and assesses the changes to bedload sediment within the analysis area for existing conditions, and under each Klamath River EIS/EIR alternative. The sections below provide a brief summary of the analysis provided in Appendix F. Bedload sediment movement and transport are vital to create and maintain functional aquatic habitat. Bedload sediment, in the form of sand, gravels, cobbles and boulders is naturally delivered to and transported in streams and rivers. Natural sediment pulses that result from heavy rainfall and snowmelt events are incorporated by stream and river processes into spawning beds, gravel bars, side channels, pools, riffles and floodplains that provide habitat and support food chains of aquatic species. These periodic inputs of bedload sediments are necessary for the long-term maintenance of aquatic habitats. Salmonids evolved with bedload sediment transport and depend on continued sediment delivery to provide substrate suitable for spawning and early rearing in streams and rivers. As described in detail below, these processes have been disrupted in the Klamath River by the construction of dams.

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

For all practical purposes, the amount of inorganic, fluvial sediment supplied to the Klamath River from the Klamath Basin upstream of Keno Dam is negligible (Reclamation 2012). Upper Klamath Lake, with its large surface area, traps nearly all inorganic sediment delivered from upstream tributaries, although some finer material may be transported through the lake during high runoff events.

Hydroelectric Reach: Klamath River from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

The Project reservoirs are the dominant feature in this 38-mile reach, with a 22-mile riverine section between J.C. Boyle Dam and Copco 1 Reservoir and a 1.4-mile riverine reach between Copco 2 Dam and Iron Gate Reservoir. Fluvial sediment (>0.063 mm) supply from the reach between Keno Dam and Iron Gate Dam is around 24,160 tons/year, which is 1.3 percent of the cumulative average annual basin wide sediment delivery to the Pacific Ocean (Stillwater Sciences 2010a). The four Project reservoirs currently store 13.1 million cubic yards (yd³) of sediment (Reclamation 2012), with Copco 1 Reservoir storing the largest amount of sediment (Table 3.3-2). The sediment stored behind the dams has high water content and 85 percent of its particles are silts and clays (particle size less than 0.063 mm) while 15 percent are sand or coarser (particle size higher than 0.063 mm) (Gathard Engineering Consulting 2006; Stillwater Sciences 2008; Reclamation 2012).

Table 3.3-2. Estimated Volume of Sediment Currently Stored within Hydroelectric Reach Reservoirs (Reclamation 2012)

Reservoir	Current Sediment Volume (yd ³)
J.C. Boyle	1,000,000
Copco 1	7,440,000
Copco 2	0
Iron Gate	4,710,000
Total	13,150,000

Lower Klamath River: Downstream from Iron Gate Dam

Downstream from Iron Gate Dam, channel conditions reflect the interruption of sediment flux from upstream by Klamath Hydroelectric Project dams and the eventual re-supply of sediment from tributaries entering the mainstem Klamath River (PacifiCorp 2004a; Reclamation 2012). The reach from Iron Gate Dam to Cottonwood Creek (RM 182.1) is characterized by coarse, cobble-boulder bars immediately downstream from the dam, transitioning to a cobble bed with pool-riffle morphology farther downstream near Cottonwood Creek (Montgomery and Buffington 1997; PacifiCorp 2004a; Stillwater Sciences 2010a). Cottonwood Creek to the Scott River is a confined channel with a cobble-gravel bed and pool-riffle morphology (PacifiCorp 2004a). The median bed material ranges from 45 to 50 mm, but bar substrates become finer in the downstream direction, with median sizes of 49 mm and 25 mm at the upstream and downstream ends, respectively. Downstream from the Scott River, including through the Seiad Valley, the Klamath River is cobble-gravel bedded with pool-riffle morphology (PacifiCorp 2004a). PacifiCorp (2004a) also noted increasing quantities of sand and fine gravel on the bed surface with distance downstream, likely reflecting the resupply of finer material from tributaries to the Klamath River.

Upper Klamath Lake, Keno Impoundment/Lake Ewauna, and the Klamath Hydroelectric Project dams trap most of the finer sediment produced in the low sediment yielding, young volcanic terrain upstream of the dams, which results in coarsening of the channel bed downstream from the dams until tributaries resupply the channel with finer sediment. Most (~98 percent) of the sediment supplied to the mainstem Klamath River (Stillwater Sciences 2010a) currently is delivered from tributaries downstream from Cottonwood Creek, limiting the effects of interrupting upstream sediment supply to the reach between JC Boyle Reservoir and approximately the Scott River.

This sediment interception has disrupted geomorphic and vegetative processes that form channel habitats and create spawning gravels downstream from Iron Gate Dam (Buer 1981; PacifiCorp 2004a; Klamath River Basin Fisheries Task Force 1991). Since the construction of the Project, sediment and spawning gravel have been intercepted by Project reservoirs and cut off by the Iron Gate Dam. The resultant reduction in spawning gravels downstream from Iron Gate Dam has been identified as one of the causes of the decline in salmonid fry production in this reach of the Klamath River (Buer 1981). In

response to this recognized limiting factor, the California Department of Water Resources initiated gravel augmentation programs for spawning gravel downstream from Iron Gate Dam (Buer 1981).

Reclamation (2011a) used reach average hydraulic properties and previously collected grain size data to estimate the flow magnitude and return period at which sediment mobilization occurs downstream from Iron Gate Dam. The estimates did not include the reach from Iron Gate Dam to Bogus Creek, for which there were no grain size data. Reclamation (2011a) assumed this reach to be fully armored because there has been no sediment supplied to this reach in the past 50 years because the dams capture sediment from upstream. From downstream from Bogus Creek to Willow Creek, flows to mobilize median substrate sizes (D50) ranged from 6,800 to 12,700 cfs, and recur every 2.6 to 7.5 years, on average (Figure 3.3-4).

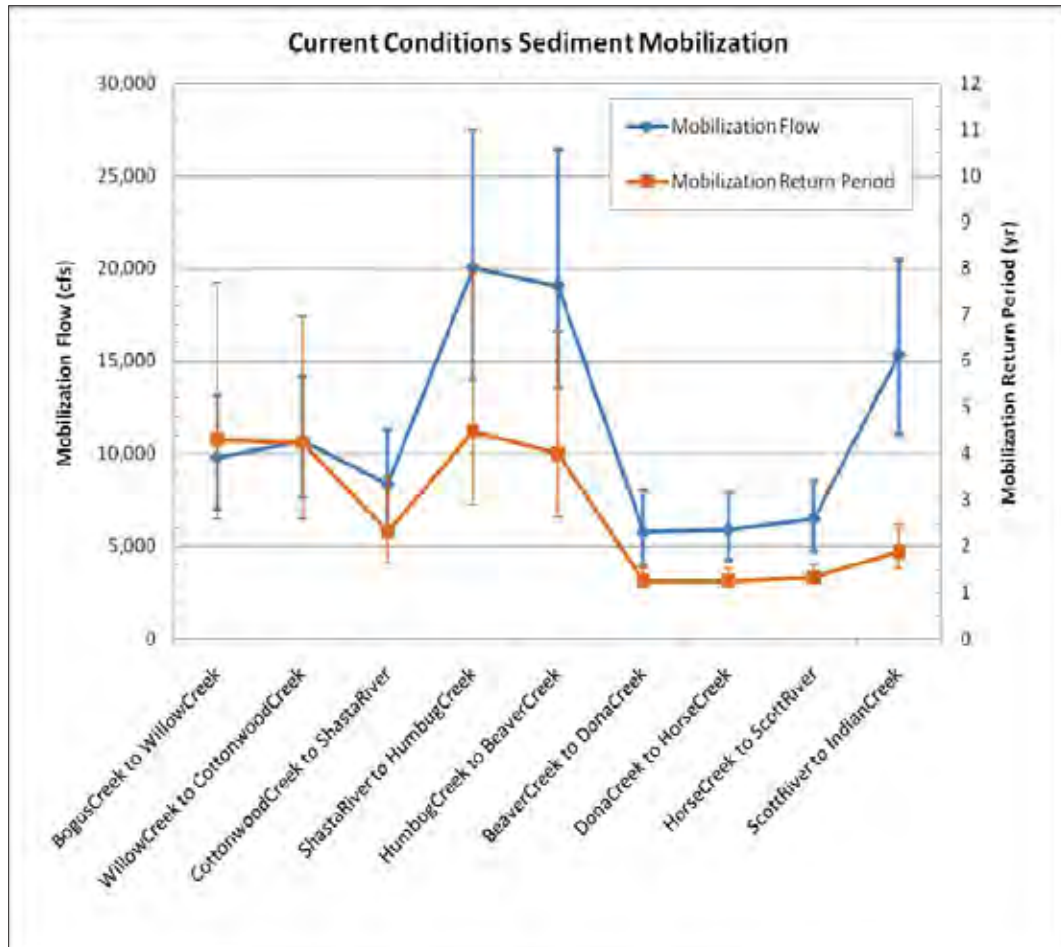

Figure 3.3-4. Mobilization Flow and Return Period at which Sediment Mobilization Occurs (Reclamation 2012).

3.3.3.3.3 Water Quality

Sections 3.2.2 and 3.2.3 provide information regarding regulatory considerations and existing conditions for water quality in the area of analysis, including those that can directly affect beneficial uses for aquatic species (i.e., water temperature, suspended sediments, dissolved oxygen, pH, and algal toxins such as microcystin). As described therein, multiple water bodies in the area of analysis, including the mainstem Klamath River, are listed under Section 303(d) of the Clean Water Act (CWA) for a variety of water quality parameters such as water temperature, sedimentation, nutrients, dissolved oxygen, pH, ammonia, chlorophyll-*a*, and microcystin (Table 3.2-8 in Section 3.2., Water Quality). Existing conditions for water temperature and algal toxins are evaluated in greater detail below with respect to implications on fish health and survival in the Klamath Basin. Microcystin concentrations are also addressed in Section 3.4, Algae.

3.3.3.3.4 Water Temperature

As described in Section 3.2, Water Quality, the entire Klamath River from the Klamath Estuary to Keno Dam has been listed as impaired for water temperature (Table 3.2-8 in Section 3.2, Water Quality). Water temperatures in the Klamath River are of special concern as they are elevated with a greater frequency and they remain elevated for longer periods of time than temperatures in adjacent coastal anadromous streams, and they are seasonally marginal in the lower mainstem for anadromous salmonids (Bartholow 2005). These elevated temperatures are especially detrimental to anadromous species during the warmer portions of the year (ODEQ 2002). Acute thermal effects for salmonids are expected to occur as mean daily water temperatures begin to exceed 20°C (Bartholow 2005). Bartholow (2005) expressed concern that if water temperature trends in the mainstem Klamath River downstream from Iron Gate Dam continue, some stocks may decline to levels insufficient to ensure survival. Klamath River salmonids are generally more tolerant of high water temperatures than salmonids from other basins (FERC 2007, Foott et al. 2012). Moreover, the Administrative Law Judge (2006) found that juvenile steelhead trout can withstand incrementally higher temperatures exceeding 22 °C provided food is abundant and by finding thermal refuge or by living in areas where nocturnal temperatures drop below the thermal threshold. Elevated temperatures can affect the timing of different life-history events, altering migration patterns, delaying and shortening the spawning season, impairing reproductive success, reducing growth, and result in an ongoing lack of temporal diversity (Hamilton et al. 2011). High water temperatures can contribute to low dissolved oxygen events by reducing dissolved oxygen solubility and accelerating oxygen-demanding processes, and can facilitate the spread of disease (Wood et al. 2006). Stress associated with high water temperatures can make cold water species more vulnerable to disease and parasites, and have been associated with fish kills in the Klamath River downstream from Iron Gate Dam during low flow periods in late summer (Hardy and Addley 2001).

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Both Upper Klamath Lake and the Keno Impoundment/Lake Ewauna are relatively shallow; temperatures in Upper Klamath Lake, the Keno Impoundment/Lake Ewauna, and J.C. Boyle Reservoir are generally warm during the late spring through early fall (see Section 3.2.3.2). In the summer, instantaneous maximum water temperatures of 22 to

24 °C are common in the upper 3 to 6 feet of Upper Klamath Lake and temperatures can approach a maximum of 30 °C near the surface (PacifiCorp 2004a). Although prolonged exposure to these high temperatures could be lethal for some species, these temperatures remain within tolerance criteria for migrating adult anadromous salmonids during the period when migration would be expected (Dunsmoor and Huntington 2006, Hamilton et al. 2011). In addition, anadromous salmonids successfully navigated through the lake to spawn in the Upper Klamath Basin prior to their access being blocked by the Project. Temperatures in Upper Klamath Lake are actually cooler than those downstream from Iron Gate Dam in the late summer and early fall when fall-run Chinook salmon are migrating. In addition, thermal refugia are available in this reach where fish can moderate the temperatures they are exposed to. Upper Klamath Lake supports a population of redband trout that move into cooler tributary habitats in the summer, but which have high growth rates while in the lake. Those in the lake over the summer can find thermal refuge in Pelican Bay, which is fed by springs and remains cool (Dunsmoor and Huntington 2006). Wetlands surround this bay and would be expected to provide juvenile salmonids with excellent rearing habitat (Dunsmoor and Huntington 2006).

The Keno Impoundment/Lake Ewauna has generally poor water quality in the summer, with instantaneous maximum water temperatures exceeding 25 °C and low dissolved oxygen (Hamilton et al. 2011). These warm temperatures are also present downstream from Keno Dam. However, from November through mid-June, the reach from Link River Dam to Keno Dam is cooler (below 20 °C) and meets criteria for migrating adult anadromous salmonids (Hamilton et al. 2011). Temperatures in the Link River and the Keno Impoundment/Lake Ewauna tend to increase in the summer; maximum water temperatures (22 to 25 °C) are still within the preferred range for warm- and some cool-water species found in the Upper Klamath Basin (yellow perch, catfish, sunfish, largemouth bass, and spotted bass).

Hydroelectric Reach: Klamath River from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

Water temperatures through the Hydroelectric Reach are generally warm in the reservoirs from late spring through early fall, but tributaries in this reach are generally cool. In addition, numerous cold-water springs contribute flows to both Copco 1 and Iron Gate Reservoirs. Average monthly water temperatures within reservoirs from 2001 to 2004 ranged from just over 5 °C in November to more than 22 °C in June through August (FERC 2007), with thermal stratification in Copco 1 and Iron Gate reservoirs resulting in relatively warm discharge waters during summer months. Water temperatures at the downstream end of the J.C. Boyle Bypass Reach and in the Klamath River upstream of Shovel Creek are consistently cooler than other sites sampled between Link Dam and the Shasta River (PacifiCorp 2004b) (see Section 3.2.3.2). Temperatures in the J.C. Boyle Bypass Reach are cooled by the contribution of 200 to 250 cfs of groundwater within the reach. The cool water input from the bypass reach during the summer results in a relatively lower daily water temperature range in the Klamath River in the J.C. Boyle Peaking Reach (FERC 2007).

Temperature data for tributary reaches are based on a limited study period as described in PacifiCorp (2004a). Fall Creek, which flows into Iron Gate Reservoir, is generally cold year-round and does not exceed 14 °C degrees during the summer (PacifiCorp 2004a). Temperatures in Jenny Creek, which also flows into Iron Gate Reservoir, vary seasonally, ranging from less than 10°C in the spring to more than 22 °C in July and August (PacifiCorp 2004a). Temperatures in Shovel Creek are generally low year-round and do not exceed 15 °C in the summer (PacifiCorp 2004a). Spencer Creek temperatures are low during spring (<15 °C) and are generally below 18°C, but can exceed 20 °C for short durations (PacifiCorp 2004a).

Copco 1 and Iron Gate Reservoirs reach maximum temperatures exceeding 20 °C near their surfaces during the summer while maintaining average temperatures near 8 °C or 10 °C when stratified (PacifiCorp 2004a). These cooler water temperatures at a depth >6–8 m below the surface (see Appendix C, Section C.1.1.4) are a result of the retention of cold water in Copco 1 and Iron Gate reservoirs during the winter, and the relatively shallow outlets of both reservoirs (PacifiCorp 2004a). Summertime thermal stratification in Copco1 and Iron Gate reservoirs is typically accompanied by hypoxia (Appendix C, Section C.4.1.4). Although water temperatures increase in the summer months (see Section 3.2.3.2), temperatures documented in the Hydroelectric Reach are within the tolerance ranges of the species observed there, but would be considered seasonally stressful for cold water species.

Lower Klamath River: Downstream from Iron Gate Dam

Water temperatures in spring in the Lower Klamath Basin downstream from Iron Gate Dam can be slightly cooler from reservoir releases than those upstream of Iron Gate Dam (see Section 3.2.3.2), with this difference diminishing downstream from Iron Gate Dam with no noticeable difference just upstream of the Salmon River confluence. Summer weather conditions, however, can be severe from June through September, and rising ambient air temperatures can lead to increased water temperatures (Hamilton et al. 2011). Downstream from Iron Gate Dam, mean monthly temperatures in the river are 3 to 6 °C in January and 20 to 22.5 °C in July and August (Bartholow 2005). Substantial losses of juvenile salmonids have occurred during their migration through the Lower Klamath River, and were especially severe during low-water years with periods of sustained high water temperatures, which may cause them to crowd into thermal refugia and may reduce the resistance of these fish to disease and other stressors (Scheiff et al. 2001). Summary statistics compiled by the United States Environmental Protection Agency (EPA) indicate that water temperatures at locations between Iron Gate Dam and the Klamath River's confluence with the Scott River range from about 16 to 22 °C in June, and from 16 to 26 °C in July (FERC 2007). The Klamath Basin downstream from Iron Gate Dam (i.e., the Lower Klamath Basin) supports a variety of species of anadromous fish including fall and spring Chinook salmon, coho salmon, steelhead, green sturgeon, and Pacific lamprey. From May through September (peaking in June–August) summer temperatures begin to warm to stressful levels for cold water species such as salmon, steelhead, and Pacific lamprey.

Klamath River Estuary and Pacific Ocean Nearshore Environment

Water temperatures in the estuary range from 5 to 12 °C from December through April (Hiner 2006). Warmer air temperatures and lower flows in summer and fall months result in increased water temperatures ranging from 20 to 24°C (Hiner 2006). Under summer low-flow conditions, water temperatures in the Klamath Estuary exceed those for optimal growth as well as critical thermal maxima for Chinook salmon, coho salmon, and steelhead (Stillwater Sciences 2009a). However, this effect is reduced by input of cool ocean water and a high prevalence of coastal fog.

3.3.3.3.5 Disease and Parasites

Fish diseases, specifically the myxozoan parasites *Ceratomyxa shasta* (*C. shasta*) and *Parvicapsula minibicornis*, periodically result in substantial mortality for Klamath River salmon, (steelhead are generally resistant to *C. shasta*). Additional diseases that may affect fish in the Klamath Basin include *Ichthyophthirius multifis* (Ich) and *Flavobacterium columnare* (“columnaris disease”). These parasites and diseases occur throughout the watershed, but appear to cause the most severe mortality in the Lower Klamath Basin where *C. shasta* has been observed to result in high rates of mortality in salmon. Ich and columnaris occasionally result in substantial mortality (e.g., the 2002 fish kill of primarily adult Chinook salmon). The effects of Ich and columnaris are generally not as harmful on a population level as the myxozoan parasites, although impacts on juvenile salmonids and other species have not been well studied.

Both *P. minibicornis* and *C. shasta* spend part of their life cycle in an invertebrate host and another part in a fish host. Transmission of these parasites is limited to areas where the invertebrate host is present. In the Klamath River, their invertebrate host is the annelid polychaete worm *Manayunkia speciosa* (Bartholomew et al. 1997, 2007). Once the polychaetes are infected, they release *C. shasta* actinospores into the water column. Actinospores are generally released when temperatures rise above 10°C and remain viable from 3 to 7 days at temperatures from 11 to 18°C, with temperatures outside that range resulting in a shorter period of viability (Foott et al. 2007). The longer the period of viability, the wider the distribution of the actinospores within the river, and thus the higher the risk of exposure for salmon (Bjork and Bartholomew 2010). Actinospore abundance, a primary determinant of infectious dose, is controlled by the number of polychaetes and the prevalence and severity of infection within their population.

Salmon become infected when the actinospores enter the gills, eventually reaching the intestines where the parasite replicates and matures to the myxospore stage. Myxospores are shed by the dying and dead salmon, and the cycle continues with infection of polychaete worms by the myxospores (Bartholomew and Foott 2010). The polychaete host for the parasite is present in a variety of habitat types, including runs, pools, riffles, edge-water, and reservoir inflow zones, as well as sand, gravel, boulders, bedrock, aquatic vegetation, and is frequently found among mats of filamentous periphytic algal species (e.g. *Cladophora*) that traps fine sediment and organic detrital matter.

(Bartholomew and Foott 2010). Slow-flowing and more stable, depositional habitats (e.g., pools with sand) may support higher densities of polychaetes, (Bartholomew and Foott 2010), especially if instream flows remain constant. The mobilization of particles on the bed of the channel downstream from Iron Gate Dam depends directly upon the size of the substrate and magnitude of peak flows. The greater the flows, the larger the particles likely to be moved, and the smaller the particle, the lower the flow required for mobilization. Polychaetes are more persistent if the substrate remains immobile for long periods (on the order of years). Under historical conditions frequent flood events and natural sediment supply, combined with considerable intra-annual flow variability, ensured that the substrate was frequently mobilized. Under existing conditions with dams in place, sediment supply is reduced, flow variability is decreased, and conditions supporting the persistence of polychaetes are more prevalent.

Native populations of salmonids in waters where *C. shasta* is endemic generally develop a high degree of resistance to the disease. Stocking et al. (2006) conducted studies of the seasonal and spatial distribution of *C. shasta* in the Klamath River. The study included the exposure of fall Chinook salmon (*Oncorhynchus tshawytscha*; Iron Gate Hatchery strain). The study found the polychaete host, *M. speciosa*, from Upper Klamath Lake to the mouth of the river. Although infection rates were high in non-native, non-resistant, rainbow trout, used as sentinel fish in the upper Klamath River upstream of Iron Gate Dam and downstream from the Williamson River, mortality rates were very low (Stocking et al. 2006). Chinook salmon at this location did not become infected. Minimal mortality in both was likely due to low levels of parasites in this area and a predominance of Type 0 genotype of *C. shasta* (see below). Because the parasites are endemic to the watershed, the native salmonid populations have some level of resistance to the disease. However, an altered river channel downstream from Iron Gate Dam, where the bed has been atypically stable, has provided favorable habitat for the polychaete worm host, likely increasing the parasite load to which the fish are exposed. High parasite loads are believed to lead to higher rates of mortality.

Susceptibility to *C. shasta* is also influenced by the genetic type of *C. shasta* fish encounter. Atkinson and Bartholomew (2010) conducted an analysis of the genotypes of *C. shasta* and the association of these genotypes with different salmonid species, including Chinook and coho salmon, steelhead, rainbow trout, and redband trout. In the Williamson River, although parasite densities had been found to be high, Chinook salmon were resistant to infection because the genotype specific to Chinook salmon was absent. In a genetic analysis, the *C. shasta* genotypes were characterized as Type 0, Type I, Type II and Type III (Table 3.3-3):

Table 3.3-3. *Ceratomyxa shasta* genotypes in the Klamath Basin.

<i>C. shasta</i> Genotype	Distribution	Affected Species	Notes
Type 0	Upper and Lower Klamath Basin	native steelhead, rainbow, and redband trout	Usually occurs in low densities, is not very virulent, and causes little or no mortality
Type I	Lower Klamath Basin	Chinook salmon	If the Type I genotype were carried into the Upper Klamath Basin, only Chinook salmon would be affected
Type II	Klamath Lake, Upper and Lower Klamath Basin	coho salmon and non-native rainbow trout	The “biotype” found in the Upper Klamath Basin does not appear to affect coho salmon, and risks to native rainbow/redband trout are low ¹
Type III	Assumed widespread in Klamath Basin based on presence in fish	all salmonid species	Prevalence of this genotype is low and it infects fish but does not appear to cause mortality

¹ (J. Bartholomew, pers. comm. 2010)

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Fish in the upper Klamath River are exposed to disease and parasites. Many of the diseases and parasites described above can occur here. *C. shasta* and *P. minibicornis* are both known to occur in the Upper Klamath Basin (Administrative Law Judge 2006), and *C. shasta* densities have been reported to be as high in the Williamson River (Hurst et al. 2012) as in the area downstream from Iron Gate Dam (Hallett and Bartholomew 2006). In the section of the river upstream of J.C. Boyle Reservoir, however, *C. shasta* does not have the same serious effects as it does downstream from Iron Gate Dam, because of the genotype of the parasite and the higher resistance of the redband trout to the disease. Historically *C. shasta* and *P. minibicornis* occurred in the Upper Klamath Basin and resident fish above the dams evolved with these parasites. The current infectious zone and high parasite loads below Iron Gate Dam are the result of a synergistic effect of numerous factors (FERC 2007; Hamilton et al. 2011). Factors associated with the current infectious zone and high parasite loads include: 1) close proximity of myxospores-shedding carcasses (concentration of carcasses), 2) abundant polychaete populations that are found in atypically stable habitats, 3) permissible temperatures (>15 C) during periods when juvenile salmonids are present, and 4) low flow variability (Bartholomew and Foott 2010). . This synergy would be unlikely in the Upper Klamath River.

Results from the large amount of recent research on Klamath River fish diseases remain consistent with the previous finding that the movement of anadromous fish above Iron Gate Dam presents a relatively low risk of introducing pathogens to resident fish (Administrative Law Judge 2006, USFWS/NOAA Fisheries Service Issue 2(B)).

Hydroelectric Reach: Klamath River from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

As described above, Stocking et al. (2006) found the polychaete host for *C. shasta* and *P. minibicornis* throughout the mainstem Klamath River, including the reach from J.C. Boyle Reservoir to Iron Gate Dam (the Hydroelectric Reach), and within all four

Project reservoirs. However, these polychaete populations are most abundant at reservoir inflow areas with densities decreasing with distance from reservoir/river interface, but not disappearing entirely (Stocking and Bartholomew 2007). Stocking and Bartholomew (2007) noted that the ability of some polychaete populations to persist through disturbances (e.g., large flow events) indicates that the lotic populations are influenced by the stability of the microhabitat they occupy. In order for an area to develop as an infectious zone, several factors need to coincide, including microhabitats with low velocity, and stable flows (Bartholomew and Foott 2010).

Lower Klamath River: Downstream from Iron Gate Dam

In the Lower Klamath River, the polychaete host for *C. shasta* and *P. minibicornis* is aggregated into small, patchy populations. The reach of the Klamath River from the Shasta River to Seiad/Indian Creek is known to be a highly infectious zone with high actinospores exposure, particularly from May through August (Beeman et al. 2008, Bartholomew and Foott 2010). This portion of the river contains areas of dense populations of polychaetes within low-velocity habitats with *Cladophora* (a filamentous green periphytic algae), sand-silt, and fine benthic organic material in the substrate (Stocking and Bartholomew 2007). As described above, the reduced bedload mobility has increased the persistence of polychaetes under existing conditions. High parasite prevalence in the Lower Klamath River is considered to be a combined effect of high spore input from heavily infected, spawned adult salmon that congregate downstream from Iron Gate Dam and Iron Gate Hatchery and the proximity to dense populations of polychaetes (Bartholomew et al. 2007). The highest rates of infection occur in the Lower Klamath River downstream from Iron Gate Dam, generally the reach from Shasta River to Seiad (Stocking and Bartholomew 2007; Bartholomew and Foott 2010).

Despite potential resistance to the disease in native populations, salmon (particularly juvenile salmon, and more so at higher water temperatures) exposed to high levels of the parasite may be more susceptible to disease. Chinook and coho salmon migrating downstream have been found to have infection rates as high as 90 percent and 50 percent, respectively (Bartholomew and Foott 2010). The number of juvenile salmon that become infected is estimated to be 10 to 70 percent annually based on surveys of fish captured in the river (True et al. 2010). High disease infection rates are apparently resulting in high mortality of outmigrating smolts. Studies of outmigrating coho salmon smolts by Beeman et al. (2008) estimated that disease-related mortality rates were between 35 and 70 percent in the Klamath River near Iron Gate Dam. Their studies suggested that higher spring discharge increased smolt survival (Beeman et al. 2008). In 2008, mortality rates were as high as 85 percent in May (7-day exposure for age 1+ coho smolts), and 96 percent (age 0+ coho smolts) and 84 percent (0+ Chinook smolts) in June (3-day exposure). In May 2004, the USFWS, the Yurok Tribe and the Karuk Tribe, reported high levels of mortality and disease infections among naturally produced juvenile Chinook salmon captured in downstream migrant traps fished in the Klamath River (Nichols and Foott 2005). The symptoms observed included bloated abdominal cavities, pale gills, bloody vents, and pop-eye. Infected fish also exhibited lethargic behavior, poor swimming ability and increased vulnerability to handling stress. The primary cause of the disease was found to be *C. shasta*, with *P. minibicornis* observed as well. The

2004 mortality event was not quantified, because of limited resources and other problems associated with sampling small fish in a large river system. Other recent fish kills include the June 2000 and June 1998 fish kills. CDFG (2000) estimated 10,000 to 300,000 individuals, mostly young-of-year killed in the June 2000 event, believed to be infected with *C. shasta* and columnaris. However in 2010 through 2012, years with lower river temperatures and conditions less conducive to juvenile disease, prevalence of *C. shasta* in emigrant Chinook salmon during the peak migration period was less than 35 percent.

For adult salmon disease risk have been less frequent and of a different nature. Ich and columnaris have occasionally had a substantial impact, particularly when habitat conditions include exceptionally low flows, high water temperatures, and high densities of fish (such as adult Chinook salmon migrating upstream in the fall and holding at high densities in pools). The effects of Ich and columnaris are generally not as harmful as the myxozoan parasites, although the 2002 fish kill in the lower Klamath provided dramatic evidence of the ability of Ich and columnaris to cause significant salmon mortality, with more than 33,000 adult salmon and steelhead were lost during a disease outbreak. Most of the fish affected by the 2002 fish die-off were fall-run Chinook salmon in the lower 36 miles of the Klamath River (CDFG 2004). Based on a review of available literature and historical records, this was the largest known pre-spawning adult salmonid die-off recorded on the Klamath River and possibly the Pacific Coast (USFWS 2003). Subsequent reviews of the 2002 fish kill by CDFG (2004), NRC (2004), and USFWS (2003) determined several factors contributed to the epizootic of Ich and columnaris. An above average number of Chinook salmon entered the Klamath River during this period. Flows in September 2002 were among the lowest recorded in the last 50 years (CDFG 2004), which may have caused crowding in holding areas that increased transmission of disease. Low flows can also be associated with high water temperature and lower than normal dissolved oxygen concentrations (NRC 2004). Low river discharges were apparently unsuitable for migrating adult salmon, resulting in a large number congregating in the warm water of the Lower Klamath River (USFWS 2003). Fish passage may also have been impeded by low flows, contributing to crowding (CDFG 2004). The NRC did not rule out low flows as a contributing factor but hypothesized that high water temperatures may have also inhibited the fish from moving upstream (NRC 2004). Whether inhibited by low flows, high temperatures, or both, fish in the Lower Klamath River stopped migrating upstream, resulting in crowded, stressful conditions and possibly longer residence times in a confined reach of the river.

Although losses of adult salmonids can be substantial when events such as the 2002 fish die-off occur, the combination of factors that leads to adult infection by Ich and columnaris disease are not be as frequent as the annual exposure of juvenile salmon to *C. shasta* and *P. minibicornis*, as many juveniles must migrate each spring downstream past established populations of the invertebrate polychaete worm host.

FERC (FERC 2007) concluded that Klamath Hydroelectric Project has likely contributed to conditions that foster disease losses in the Lower Klamath River by (1) increasing the density of spawning adult fall Chinook salmon downstream from Iron Gate Dam; (2) promoting the development of attached algae beds that provide favorable habitat for

the polychaete alternate host for *C. shasta*, with *P. minibicornis*; and (3) contributing to water quality conditions that increase the stress level of juvenile and adult migrants and increase their susceptibility to disease. The water quality conditions that may increase stress levels include: (1) increased water temperatures in the late summer and fall; (2) elevated ammonia concentrations and swings in DO and pH associated with algal blooms in project reservoirs; and (3) effects of exposure to elevated levels of microcystin produced from microcystis blooms in Project reservoirs, which may also result in direct mortality.

Klamath River Estuary and Pacific Ocean Nearshore

While disease and parasites occur in the Klamath Estuary and Pacific Ocean, these areas are not known to be important source areas for these stressors. Juvenile salmonids that are weakened by disease or parasites upstream may succumb to those diseases once they enter the estuary or ocean as a result of the additional stress created by adapting to the saline environment.

3.3.3.3.6 Algal Toxins

Algae produced in Upper Klamath Lake and the reservoirs in the Klamath Hydropower Reach (Copco 1 and Iron Gate Reservoirs) may be deleterious to the health of aquatic organisms in Upper Klamath Lake and the Klamath River. Some cyanobacteria species, such as *M. aeruginosa*, produce toxins that can cause irritation, sickness, or in extreme cases, death to exposed organisms (see Section 3.2.3.7 and Appendix C, Section C.6). While direct links to fish health are still somewhat unclear, recently collected data from the Klamath Basin indicates that algal toxins bioaccumulate in tissue from fish and mussels at concentrations that may be detrimental to the affected species (Fetcho 2011), as discussed below.

In Upper Klamath Lake, a reconnaissance study was conducted to evaluate the presence, concentration, and dynamics of microcystin exposure by Lost River sucker (*Deltistes luxatus*) and shortnose sucker (*Chasmistes brevirostris*). The U.S. Geological Survey (USGS) collected water samples at multiple lake sites from July to October 2007 and June through September 2008 and found evidence of gastro-intestinal lesions in juvenile suckers sampled from around the lake, although organ damage was also absent from many fish, and most of the affected fish were collected in the northern portion of the lake. The pathology of the lesions was consistent with exposure to microcystin, and evidence of a route of exposure was suggested by gut analysis showing that juvenile suckers had ingested chironomid larvae, which had in turn ingested *A. flos-aquae* and colonies of *M. aeruginosa*. The lesions were observed when liver necrosis was either present or absent suggesting that the gastro-intestinal tract was the first point of toxin contact. The authors hypothesized that the lesions were caused by algal toxins, and that the route of exposure to toxins was an oral route through the food chain, rather than exposure to dissolved toxins at the gills (VanderKooi et al. 2010). However, there were other possible explanations for the lesions, including the potential for an undetected viral infection. Conclusive pathology experiments demonstrating that exposure of juvenile suckers to algal toxins via the described oral routes can cause the types of lesions observed have not yet been done. The pathologies and evidence therefore are consistent

with the hypothesis of exposure to algal toxins but do not constitute proof of a causal mechanism. Additional work to describe the observed pathologies is ongoing.

In the Hydroelectric Reach and the Klamath River downstream from Iron Gate Dam, the occurrence of microcystin toxin in fish and mussel tissue has been studied since 2005 (Fetcho 2006; Kann 2008; CH2M Hill 2009a, 2009b; Prendergast and Foster 2010; Kann et al. 2010 a, b; Fetcho 2011). Samples of muscle and liver tissues from resident fish (i.e., yellow perch [*Perca flavescens*] and crappie [*Pomoxis nigromaculatus*]) in Copco 1 and Iron Gate Reservoirs in 2007 and 2008 indicate that two of eight microcystin congeners (i.e., chemically different forms of microcystin) were detected in muscle and liver tissues of yellow perch (total samples = 36) during September 2007 (Kann 2008) but unbound or “free” microcystin was not detected in muscle tissues of yellow perch and crappie during May-June, July, September, and November 2008 (total samples = 196) (CH2M Hill 2009a). Yellow perch muscle tissue samples collected from Copco 1 and Iron Gate Reservoirs in August and September 2009 (total samples = 43) did not exhibit microcystin (Prendergast and Foster 2010).

Rainbow trout muscle tissue samples collected upstream of Copco 1 Reservoir and immediately downstream from Iron Gate Reservoir during May-June, July, September, and November 2008 (total samples = 76) indicated that no un-bound or “free” microcystin was detected before, during, or after the 2008 bloom period in the reservoirs (CH2M Hill 2009a). Chinook salmon tissue samples from Iron Gate Hatchery in September and October 2005 did not contain detectable levels of microcystin (Fetcho 2006) and Chinook salmon and steelhead liver and muscle samples from the hatchery in October 2007 (total samples = 6) did not contain detectable levels of un-bound or “free” microcystin (CH2M Hill 2009b). However, Kann (2008) reported that one of eight microcystin congeners was detectable in three composite samples of liver, stomach, and muscle tissue from six juvenile Chinook salmon obtained at Iron Gate Hatchery in August 2007.

Further downstream in the Lower Klamath River, Fetcho (2006) reported that liver and muscle tissue samples from five Chinook salmon and two steelhead specimens taken from the Klamath River at or near Weitchpec (near RM 43) in 2005 did not contain detectable levels of microcystin. PacifiCorp collected liver and muscle tissue samples from five Chinook salmon and three steelhead in the middle Klamath River and the Lower Klamath River downstream from the Trinity River in October 2007 and reported that no detectable levels of un-bound or “free” microcystin were found (CH2M Hill 2009b). However, preliminary results from salmonid tissue samples collected in September and October 2010 near Happy Camp show that microcystin was detected in multiple Chinook salmon livers and one steelhead liver at levels which exceeded public health guidelines (Kann et al. 2011). Since livers are not typically consumed, the tested fish did not likely pose a public health concern with respect to consumption. However, results indicate that direct effects to fish health due to microcystin exposure such as stress and/or disease are a possibility (Kann et al. 2011). During the October period that Chinook salmon samples were collected, the 2010 longitudinal microcystin sampling in

river-water showed very high microcystin levels being exported from Iron Gate Reservoir and transported downstream to areas where Chinook salmon were migrating upstream.

Overall, the variation in fish tissue results in Copco 1 and Iron Gate Reservoirs and the Klamath River downstream from Iron Gate Dam indicates that the presence of *M. aeruginosa* and microcystin does not necessarily correlate to microcystin concentrations in fish tissue. Reasons for this lack of correlation may include, but are not limited to, the patchy distribution of algal blooms within the reservoirs, the ability of fish to move in and out of algal bloom areas where microcystin is likely most prevalent, and the fact that uptake of toxins into fish tissue occurs through the food chain and not directly from the water (Prendergast and Foster 2010). Microcystin can also bioaccumulate in mussel tissue in the Lower Klamath River.

Kann (2008) reported on the concentrations of eight individual microcystin congeners in freshwater mussel tissue samples obtained from the Klamath River in July and November 2007. Microcystin congeners were detected in July in composite and individual tissue samples from the Klamath River near the Klamath Highway Rest Area (at RM 178), near Seiad Valley (at RM 129) and at Big Bar (near RM 51). Individual mussel samples taken later in the year in November from the Klamath River near Orleans (at RM 59), near Happy Camp (at RM 108), near Seiad Valley (at RM 129), at the Brown Bear River Access (at RM 157.5), and near the Klamath Highway Rest Area (at RM 178) did not contain detectable levels of microcystin congeners. Overall, for the 2007 *M. aeruginosa* bloom, 85 percent of fish and mussel tissue samples collected during July through September 2007 in the Klamath River, including Iron Gate and Copco 1 Reservoirs, exhibited microcystin bioaccumulation (Kann 2008). Results indicated that all of the World Health Organization (WHO) total daily intake guideline values were exceeded, including several observations of values exceeding acute total daily intake thresholds (Kann 2008). In a retrospective letter to PacifiCorp (August 6, 2008), the California Office of Environmental Health Hazard Assessment (OEHHA) stated that they “would have recommended against consuming mussels from the affected section of the Klamath River, and yellow perch from Iron Gate and Copco Reservoirs, because their average concentrations exceeded 26 nanograms per gram (ng/g),” which is the OEHHA upper bound of advisory tissue levels fish or shellfish consumption (for a single serving per week based on 8 ounces uncooked fish). Additional public health advisories were issued in 2009 and 2010 in Copco 1 and Iron Gate Reservoirs, as well as downstream locations in the Klamath River (including locations on the Yurok Reservation), for microcystin levels in ambient and/or freshwater mussel tissue (Kann et al. 2010a,b, Fetcho 2011).

3.3.3.3.7 Aquatic Habitat

One of factors that influence habitat availability for aquatic species is instream flow. Reclamation manages Upper Klamath Lake to meet the requirements of biological opinions (BOs) from the USFWS (2008) and NOAA Fisheries Service (2010a) and its contract requirements for the Reclamation’s Klamath Project (Reclamation 2010). If implemented, the Proposed Action would result in changes in the operations of Upper Klamath Lake (see Section 2.4.3.9). These changes would affect reservoir elevations in

Upper Klamath Lake, and river flows in downstream reaches. These hydrologic changes would result in changes to instream habitat. Studies to determine how fish habitat changes with flow have been conducted in areas of the Klamath River, including two reaches between J.C. Boyle Reservoir and Iron Gate Dam, for selected life stages of rainbow trout (Bureau of Land Management 2002) and seven locations between Iron Gate Dam and the estuary for selected life stages of Chinook salmon, coho salmon, and steelhead (Hardy et al. 2006).

The following sections describe the amount of flow-related habitat in various portions of the Basin for the species for which information exists. Where specific information is not available for a species or area, the Lead Agencies used hydrologic changes, species habitat requirements, and comparisons with those species for which the Lead Agencies does have specific information to qualitatively assess changes in flow-related habitat. This information was used to evaluate how the Proposed Action and alternatives might result in changes to the amount of flow-related habitat. The Lead Agencies determined that the hydrologic record of the past decade was insufficient for describing the amount of habitat available under existing conditions because of management actions made over the past eight years to protect listed fish species (minimum lake elevations; minimum flows downstream from Iron Gate Dam). These changes are described in BOs from USFWS (2008) and NOAA Fisheries Service (2002, 2010a). The flows under existing conditions and with the various alternatives are described in Section 3.6, Flood Hydrology.

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

This area was not evaluated for flow-related habitat, as no known flow-related habitat relationships exist for the Klamath or Link Rivers in this area. Some changes in flow-related habitat in tributaries to Upper Klamath Lake may occur; however, the location and magnitude of these changes are unknown at this time.

Water surface elevations in Upper Klamath Lake are expected to vary as a result of implementation of the Proposed Action and alternatives. The USFWS BO (2008) provides information on the amount of habitat provided for Lost River and shortnose suckers at different lake elevations, with higher elevations providing increased habitat for all life stages of sucker. It requires that Reclamation maintain the lake at minimum elevations from February through October each year to protect shortnose and Lost River suckers.

Under existing conditions (as indicated by the hydrologic modeling for the No Action/No Project Alternative), lake elevations are maintained at elevations ranging from about 4,138 to 4,142.2 feet in drier conditions (90 percent exceedance) and 4,139.8 to 4,143.3 feet under wetter conditions (20 percent exceedance). Lake elevations increase during the fall and winter, peak in April or May, and then decline until October.

Hydroelectric Reach: Klamath River from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

Under its existing license, PacifiCorp operates the J.C. Boyle Powerhouse in peaking mode, meaning that water is run through the powerhouse to generate electricity cyclically depending on water availability and power demand. Flows through the reach downstream from Copco 2 Dam are only about 5 cfs unless spill is occurring as a result of high runoff or project maintenance (PacifiCorp 2004a). Based on an Indicators of Hydrologic Alteration (IHA) Analyses (Richter et al. 1996) of flows within the reach downstream from J.C. Boyle Powerhouse, Huntington (2004) found a high rate of deviation from conditions that would be expected without the project influencing conditions. Substantial changes in flow (350 to 3,000 cfs) can occur within the course of a single day in the 17-mile long J.C. Boyle Peaking Reach (the reach of the Klamath River between J.C. Boyle Powerhouse and Copco 1 Reservoir). These flow fluctuations can result in temperature fluctuations in this reach ranging 5–15°C during the summer months (ODEQ 2010). These extreme flow fluctuations may also result in stranding of fish and invertebrates (Dunsmoor 2006), reductions in aquatic invertebrate production (City of Klamath Falls 1986, as cited in Hamilton et al. 2011), displacement of fish, and higher energetic costs to fish to maintain their position (FERC 2007). In the Trial-type Hearing for the relicensing of the Klamath Hydroelectric Project (Administrative Law Judge 2006), it was found that this reach had lower macroinvertebrate drift rates, indicating a reduced food base for fish.

Lower Klamath River: Downstream from Iron Gate Dam

A universal feature of the historical hydrographs of the Klamath River and its tributaries is a season of high spring flows, triggered by melting snow, followed by recession to a base flow condition by late summer (NRC 2004). This main feature of the hydrographs has undoubtedly influenced the adaptations of native organisms, as reflected in the timing of their key life-history features (NRC 2004). The natural flow regime of a river is the characteristic pattern of flow quantity, timing, rate of change of hydrologic conditions, and variability across time scales (hours to multiple years), all without the influence of human activities (Poff *et al.* 1997). It is this diverse hydrology, with the range of hydraulic conditions and habitats supported, that allowed the various anadromous fish species and life history strategies to evolve and flourish in the Klamath River over time. Therefore, to fully understand the habitat requirements for anadromous fish species, the historical flow patterns under which these species developed must also be understood.

There is a long history of water development in the Klamath Basin dating back to the late 1800's and early 1900's (See Chapter 1). Farmers introduced irrigation to the Upper Basin as early as 1882. Irrigation was necessary to the farmers because lack of timely and sufficient rain made watering crops a challenge. The earliest irrigation project in the Upper Klamath Basin occurred when residents of the town of Linkville dug a low capacity ditch connecting the town to the Link River, two miles above the present-day town of Klamath Falls. The ditch was later extended and enlarged, turning it into a high capacity canal, known as the Ankeny-Henley Canal. The first hydroelectric facility was constructed 1895 along the east side of Link River, below Upper Klamath Lake, to provide electricity to the town of Klamath Falls. The first major changes to the natural

hydrology of the Klamath River began after Congress authorized Reclamation's Klamath Project in 1905. The A canal was first completed in 1907, however, major diversions of flow from the Klamath River did not begin until after the construction of Link River Dam at the outlet of Upper Klamath Lake in 1921. Further downstream, the first major power peaking hydroelectric facility, Copco No. 1, was constructed in 1918, followed closely by construction of Copco No. 2 just downstream in 1925. JC Boyle Dam, which is the most upstream of the four mainstem dams, was completed in 1958 and also operates as a power peaking facility. Finally, Iron Gate Dam was constructed in 1962 to re-regulate power peaking flow releases from Copco No. 1 and 2 hydroelectric facilities just upstream. For more detail on the physical characteristics of each hydroelectric facility please refer to Chapters 1 and 2, and Section 3.6.3.2, Basin Hydrology.

The following provides a brief description of changes to Klamath River hydrology that have occurred through development of water management features related to irrigation, power generation, and environmental requirements over the years. The major hydrologic time periods discussed include a description of natural hydrology prior to development of major reclamation or hydroelectric facilities (pre 1913); a description of major hydrologic alterations caused by development of power peaking facilities (1913 to 1960); a description of hydrology following construction to Iron Gate Dam through 2000, when ESA flow requirements began to influence water releases downstream from Iron Gate; and finally, a description of more recent events that led up to the development of KBRA flow recommendations (Proposed Action) and the 2010 NOAA Fisheries Service Biological Opinion's, Reasonable and Prudent Alternative (RPA) for flow releases downstream from Iron Gate Dam (No Action Alternative).

Owing to the long history and early development of water resources within the basin, little hydrologic data exist to describe the natural flow patterns that existed prior to construction of Reclamation's Klamath Project. The first streamflow records on the Klamath River began on June 1, 1904, when the United States Geological Survey (USGS) began operating an instream flow gage on the Klamath River at Keno (USGS Gage #11509500). River flow data for the USGS Gage at Keno are available for water years 1905 through 1912, after which the gage was discontinued until 1930. The Lost River Diversion Dam was completed in 1912, which can affect Klamath River hydrology (Hecht and Kamman 1996). Therefore, flow data collected at Keno from 1905 through 1912 provide the best source of information to describe those unaltered hydrologic characteristics that supported the rivers natural ecological processes prior to construction of major irrigation facilities in the upper basin. Although this period is known to be slightly wetter than normal, the general shape of the hydrograph is still useful for illustrating the general timing, magnitude, and duration of flow throughout the year under near natural conditions. Over this eight year period the total annual discharge at Keno ranged from a low of 1,345,000 acre Feet to a high of 1,952,000 acre feet and averaged about 1,558,000 acre Feet. Examination of three different water years, representing conditions that range from dry to wet, provide a sense of the natural flow variation that existed under natural conditions (Figure 3.3-5). Average daily flows for the 1905-1912 water years therefore provide the most reasonable set of data to assess hydrologic

changes in the Klamath Basin through time as various irrigation and hydropower generation facilities were constructed. For the purposes of the following discussion, the

Figure 3.3-5. Mean daily flows (cubic feet per second) for the Klamath River at the USGS Gage at Keno for three different water years, generally representing drier (1908), more normal (1911) and wetter (1907) conditions. Mean daily flows for water years 1905 through 1912 are also displayed to illustrate the natural flow regime that existed prior to development of major Reclamation or hydroelectric projects.

term “natural” applies to the period prior to construction of either the hydroelectric or irrigation systems in the Klamath Basin, with river flows best represented by the 1905-1912 data.

Although there are no empirical river discharge data downstream from Keno prior to implementation of Reclamation’s Klamath Project, modeling results of flows near Iron Gate Dam without Reclamation’s Klamath Project show similar patterns to the natural discharge at Keno (Reclamation 2005). Spring peaks from snowmelt in tributary basins reliably provided an increase in discharge, typically near the end of April (NRC 2004), with base flows subsequently declining to a minimum in the beginning of September.

Under these conditions flows gradually increased during fall and winter months when Chinook salmon, followed closely by coho salmon, migrate upriver and spawn. Their eggs incubate over the winter when sporadic short duration high flows related to storm events typically occur. Fry emerge in late winter and early spring when flows are typically be near their highest level. These spring flows inundate side channel, off channel and backwater habitats along the flood plain creating abundant rearing habitat for salmonids. Fry grow during the spring and many smolt during that first spring and migrate downriver in late spring and early summer. Others seek out suitable rearing areas in colder tributary streams or in spring fed habitats to rear over the summer and smolt the following fall or spring when water temperatures are cool and flows are either increasing or are high once again.

As described in Section 3.6.3.1, a rock reef originally controlled the elevation of Upper Klamath Lake and river flows downstream to Link River. Link River is only 1.3 miles long and ends at the upper extent of Lake Ewauna and the Keno Impoundment. Historical accounts describe the occurrence of extremely low flows in Link River during prolonged dry spells (Dickens & Dickens, 1985). These extremely low flow conditions were most likely caused by strong south winds forming seiches within Upper Klamath Lake which greatly diminished flows to Link River for brief periods of time. The Klamath Indians referred to Link River as “Yulalona” which translates to “back and forth” (Donnelly 2002) and this is probably related to these natural seiches. Inputs from tributary streams and natural springs downstream from Keno would have maintained flow in the Klamath River and prevented it from drying completely further downstream near the current location of Iron Gate Dam. A second rock reef formed a natural hydraulic control for Lake Ewauna and provided an ideal location for the construction of Keno Dam.

Farther downstream in the coastal zone of the Lower Klamath Basin, the hydrologic pattern of the Klamath River is primarily dominated by rainfall events in the fall, winter and spring. In the middle and lower portions of the Klamath River, discharge responds rapidly to rainfall due to the relatively short length of lower tributary sub-basins (*e.g.*, Salmon River). The natural Klamath River hydrology was therefore diverse, with a range of hydraulic conditions affected by both the Upper Klamath Basin patterns previously described (*e.g.* Figure 3.3-5) and lower basin tributary inputs (see Section 3.6.3.3 Historic Stream Flows). As a result, habitats were also diverse, supporting a variety of different anadromous salmonid life history strategies throughout the year (Figure 3.3-6).

Figure 3.3-6. Timeline Depicting the Timing of Salmon Lifecycles in the Mainstem of the Klamath River Coinciding with Dam Removal Plans.

Copco No. 1 and Copco No. 2 facilities were constructed to generate hydroelectric power and their operation greatly altered flow patterns downstream. The USGS installed a gage on the Klamath River near Fall Creek downstream from Copco No. 1 and 2 and began recording flows at this location in October 1923 (USGS Gage #11512500). Flow data is available at this location until 1962 when construction of Iron Gate Dam inundated the river at this location. Hydroelectric power peaking operations at Copco No. 1 and 2 cause major changes to the hydrograph downstream from the powerhouse (Figure 3.3-7). Rapid changes in flow associated with hydropower generation, commonly referred to as power peaking, created both hazardous conditions for recreational fishermen and also created inhospitable conditions for aquatic species downstream. Rapid changes in flow associated with daily hydropower generation, commonly referred to as power peaking, created both hazardous conditions for recreational fishermen and also created difficult conditions for aquatic species downstream. Fish studies have shown considerable biological impacts due to Project peaking (City of Klamath Falls 1986; FERC 2007; BLM 2002; Wales and Coots 1950). From June 1948 to May 1949, Wales and Coots (1950) estimated that Project peaking operations resulted in the loss of over 1.8 million salmonid fingerlings downstream from Copco No. 1 and 2 facilities. Mean daily flows fell below 100 cubic feet per second in the Klamath River near Fall Creek (USGS Gage #11512500), downstream from Copco No. 2 Dam, on fifty occasions between water years 1931 and 1937. Instantaneous flow levels may have been lower. Thus, hydropower peaking between 1918 and the construction of Iron Gate Dam to re-regulate flows in 1962 may explain some anecdotal accounts of the occurrence of low flows in the Klamath River in the past that were submitted by several citizens during public scoping.

Iron Gate Dam was completed in 1962 to re-regulate peaking flow releases from the Copco facilities upstream. At that time minimum flow releases downstream were stipulated by the Federal Energy Regulatory Commission (FERC) under Article 52 of the FERC License for operation of Project No. 2082. Article 52 required the following minimum flows downstream from Iron Gate Dam: September 1 through April 30, 1,300 cfs; May 1 through May 31, 1,000 cfs; June 1 through July 31, 710 cfs; and August 1 through August 31, 1,000 cfs. These requirements provided more stable flow conditions downstream, however, they also altered the timing of base flows and did not attempt to restore or simulate the natural “pre-project” hydrograph. Fall flows were slightly increased while spring and summer flows were substantially reduced compared to natural flows.

Figure 3.3-7. Mean daily flows (cubic feet per second) for the Klamath River at the USGS Gage near Fall Creek (Gage #11512500) for three different water years, generally representing drier (1937), normal (1936) and wetter (1943) conditions.

Hecht and Kamman (1996) analyzed the hydrologic records for similar water years (pre- and post-Project) at several locations along the Klamath River. The authors concluded that the timing of peak and base flows changed significantly after construction of Reclamation’s Klamath Project, and that the operation of Reclamation’s Klamath Project increases flows in October and November and decreases flows in the late spring and summer as measured at Keno, Seiad, and Klamath USGS gage sites. Comparison of mean daily flows recorded at Keno (USGS Gage #11509500) from 1905 to 1912 with mean daily flows recorded at Keno and Iron Gate (USGS Gage #11516430) in more recent years (1961-2000) provide visual confirmation of these findings (Figure 3.3-8).

Figure 3.3-8. Comparison of mean daily flows recorded at Keno (USGS Gage # 11509500) historically (1905-1912) with more recent conditions (1961-2000). Mean daily flows recorded at Iron Gate (USGS Gage #11516530) are shown to depict both the mean daily accretions and similarities that exist in the hydrograph between Keno and Iron Gate.

As shown in Figure 3.3-8, for the period from 1961 through 2000, the timing and magnitude of average flows in the Klamath River at Keno have changed relative to the natural flow regime. Reclamation's Klamath Project diverts water from the Klamath River beginning in the spring and significantly reduces flow volumes in the Klamath River from April until September. The extraction of water significantly accelerates the decline of flow rates during the spring runoff and has the effect of moving the spring runoff peak from the end of April and beginning of May to the middle of March, a shift of more than one month. Although most of the diverted water remains within the basin, about 30,000 acre feet of water is diverted from Jenny Creek (tributary to the Klamath River at Iron Gate Reservoir) to the Rogue River Valley annually. Under natural conditions, river discharge did not reach base (minimum) flow, until September. Operation of Reclamation's Klamath Project has caused a shift in the onset of minimum base flow levels by about two months earlier in the summer from September to July. Tributary inflows and spring flow accretions, the most prominent being Big Springs (about 250 cfs) in the JC Boyle bypass reach, would account for difference in mean daily

flow between Keno and Iron Gate were it not for the operation Reclamation’s Klamath Project.

The Southern Oregon Northern California Coast (SONCC) coho salmon Evolutionarily Significant Unit (ESU) was listed as threatened under the Federal Endangered Species Act (ESA) on May 6, 1997 (62 FR 24588). In 2001, NOAA Fisheries Service determined that the operation of Reclamation’s Klamath Project jeopardized the continued existence of SONCC coho salmon. To reduce impacts to levels that avoid jeopardy to SONCC coho salmon, NOAA Fisheries Service proposed Reasonable and Prudent Alternative (RPA) flows for the Klamath River downstream from Iron Gate Dam (NOAA Fisheries Service 2001). Because of the expectation that additional information and analyses relevant to the relationship between Iron Gate Dam flows and suitable salmonid habitat (e.g., the Hardy Phase II Report) would become available within a few months following the issuance of the NOAA Fisheries Service 2001 Biological Opinion, the RPA only included minimum Iron Gate Dam flows for the April through September 2001 period. In the 2001 Opinion (NOAA Fisheries Service 2001), NOAA Fisheries Service stated their intention to prepare a supplemental biological opinion and RPA, addressing all water year types. In addition, NOAA Fisheries Service stated that the supplemental biological opinion could include a more refined minimum Iron Gate Dam flow regime for future “critically dry” water years, based on any new information or analyses that may become available in the near future. NOAA Fisheries Service’s reasonable and prudent alternative for 2001 included the following instantaneous minimum flow releases to the Klamath River downstream from Iron Gate Dam, by time step, for the April through September period:

Time Step	Iron Gate Dam Discharge (CFS)
April	1,700
May	1,700
June 1-15	2,100
June 16-30	1,700
July	1,000
August	1,000
September	1,000

In 2002, Reclamation requested formal consultation under ESA for ongoing operation of the Klamath Reclamation Project from 2002 through 2012. In the Biological Opinion, NOAA Fisheries Service (2002) found that the operation of Reclamation’s Klamath Project as proposed in Reclamation’s Biological Assessment would likely jeopardize the continued existence of SONCC coho salmon and would also adversely modify their critical habitat. To avoid the likelihood of jeopardizing the continued existence of SONCC coho salmon or cause adverse modification to their critical habitat, NOAA Fisheries Service developed a reasonable and prudent alternative which included development of a water bank and water supply enhancement program to improve flows to benefit coho salmon habitat and long-term flow targets (Table 3.3-A).

Table 3.3-A. Summary of the Iron Gate Dam long-term flow targets expected to be achieved by water year 2010 unless modified by study results. These flow targets are instantaneous minimum flows (Table 9, NOAA Fisheries Service 2002).

* Convene “Between Year Transition Group”

Recommended Long Term Iron Gate Dam Discharge By Water year Type					
Month	Dry	Below Average	Average	Above Average	Wet
October	1,300*	1,300*	1,300	1,300	1,300
November	1,300*	1,300*	1,300	1,300	1,300

September	1,000	1,000	1,000	1,000	1,000

Concerns over the health of anadromous fish populations and their habitat in the Klamath River downstream from Iron Gate Dam lead the Department of the Interior (DOI) to fund development of a study to determine instream flows required to support the ecological needs of aquatic resources, with particular attention given to anadromous fish species. After several years of data collection, development of various draft reports, and extensive review of the biological findings by agency and public scientists, the final report “Evaluation of Instream Flow Needs in the Lower Klamath River, Phase II” was completed by Hardy et al. in July, 2006. Subsequent to its release, the National Research Council’s Committee on Hydrology, Ecology, and Fishes of the Klamath River Basin also conducted a thorough review of the report (NRC 2008). The report, commonly referred to as the Hardy Phase II Report, provides recommendations for flow releases downstream from Iron Gate Dam to provide for the long-term protection, enhancement and recovery of the aquatic resources. The recommendations are intended to benefit all anadromous species and life stages on a seasonal basis and are not focused on a single species or life stage (Hardy et al. 2006). The recommendations were intended to provide guidance to the Department of the Interior in meeting their Public and Tribal Trust responsibilities, as well as meeting responsibilities described under the Endangered Species Act. A summary of the Hardy Phase II flow recommendations are presented in Table 3.3-B. It is important to note that these recommendations are for base flows only.

Hardy recommendations include higher flows levels to satisfy important physical and ecological requirement to provide diverse habitat and floodplain maintenance. These components were broadly defined by NRC (2004) as: Over Bank Flows (infrequent high flow event that overtops the riverbanks); High Pulse Flows (short duration high flow within the stream channel during or immediately after storm events); Base Average Flows (base flows in the absence of significant precipitation or runoff event); and, Subsistence Minimum Flows (stream flows needed to maintain tolerable water quality conditions and provide minimal aquatic habitat).

Table 3.3-B. Instream flow recommendations by annual exceedence* levels for net inflows to Upper Klamath Lake on a monthly basis below Iron Gate Dam (Table 27, Hardy et al. 2006)

* For example, a 10 percent exceedence would be equivalent to the inflow value to Upper Klamath Lake that is exceeded 10 percent of the time for the existing hydrologic record, a more wet condition.

The Hardy Phase II flow exceedence recommendations incorporate the principles of “Ecological Base Flow” requirements. Ecological Base Flows are intended to provide adequate protection for aquatic resources. Human induced reductions in flow below this level are believed to result in unacceptable levels of risk to the health of aquatic resources

(Hardy et al. 2006). Flow volumes equal to those identified for the 95 percent exceedance flows listed in Table 3.3-A (Table 27, Hardy et al. 2006) are intended to be representative of Ecological Base Flows for the Klamath River downstream from Iron Gate Dam under conditions with dams in place. It is important to recognize that the monthly column headings in Table 27 in the Hardy Phase II Report are not intended to be interpreted as monthly time steps for implementation of instream flows. Under real time management, the exceedance flow recommendations would ideally be implemented using daily time steps as recommended in Hetrick et al (2009) and discussed by Hardy (2008). The findings of Hardy et al. (2006) provide the best available science on the relationship between anadromous fish habitat and instream flow in the Klamath River at this time.

During the negotiation of the Klamath Basin Restoration Agreement (KBRA) a Technical Team consisting of staff from the U.S. Fish and Wildlife Service, National Marine Fisheries Service, the California Department of the Fish and Game as well as technical experts from other participants in the negotiation, was formed to evaluate potential impacts that may occur to either anadromous fish or listed suckers during the interim period (between the dates of a positive Secretarial Determination, should one occur, and dam removal) for various management alternatives that were under consideration by the negotiating parties. This Technical Team should not be confused with the Technical Advisory Team (TAT) described in Section 20.4.3 of the KBRA or the Federal Team for the Secretarial Determination assembled to conduct technical studies requested in the KHSA or to conduct the environmental analysis required under the National Environmental Policy Act (NEPA) or the California Environmental Quality Act (CEQA). A full description of the analytical methods used by the Technical Team is described in detail in Hetrick et al. (2009). The Technical Team's approach to development of instream flow recommendations for the Klamath River considered both the Hardy Phase II instream flow recommendations in conjunction with instream flows that provide a minimum of 80 percent of the maximum habitat values for priority species and life stages for five different water year types ranging from dry to wet (Hetrick et al. 2009). The resulting flow recommendations were labeled Alt X by the Technical Team.

An alternative to the Alt X flow recommendations was proposed for KBRA by biologists from the Yurok Tribe, labeled the ALT-X Yurok flow schedule. The ALT-X Yurok schedule was designed to increase water storage in the fall and winter to increase the likelihood of filling Upper Klamath Lake. Filling the lake early in the water year increases the probability of spill and the availability of water to maximize, to the extent possible, river flows in the spring and early summer to provide better habitat conditions for Chinook salmon emergence and Chinook and coho salmon fry and juvenile rearing during the critical spring months of March through June. To accomplish this objective within the management regime described under the KBRA, the ALT-X Yurok flow schedule would maintain steady flows from October through February at 1,000 cfs for 90% exceedance years and 1,100 cfs for 70% exceedance years, and at levels reduced from the ALT-X schedule for the October to December period during higher inflow conditions (see Figure I-3 in Hetrick et al. 2009). The ALT-X Yurok flow schedule adopts the ALT-X flow schedule throughout the remainder of the water year. While the conservative fall/winter flow period of the ALT-X Yurok flow schedule increases the

likelihood of spill occurring later in the year, it does not provide flow variability through a substantial portion of the fall/winter period, nor does it mimic the natural flow regime as recommended throughout the current literature regarding instream flow management (Poff et al. 1997). Differences in total flow volume between the ALT-X and ALT-X Yurok flow schedules during this period were, however, not considered to be of a magnitude that would preclude a real-time approach to water management that would provide desired variability in fall/winter flows.

The Technical Team used the Water Resources Integrated Modeling System (WRIMS) to provide the hydrologic data (river flow and lake levels) necessary to analyze potential impacts to anadromous fish habitat in the river and sucker habitat in Upper Klamath Lake under numerous water management scenarios (Hetrick et al. 2009). The WRIMS model is capable of simulating river flows at Iron Gate Dam as they would have happened under various management scenarios and allows for comparisons to be made between alternatives and historical conditions. The analysis was limited to hydrologic conditions present during water years 1961 – 2000. The WRIMS Run-32 Refuge model run provides simulated Klamath River flows at Iron Gate and Upper Klamath Lake elevations using target flows provided by Alt X Yurok, Upper Klamath Lake elevation targets (Alt Y) described in Hetrick et al. (2009), and management objectives provided in the KBRA with the model priorities set to provide agricultural irrigation deliveries to Klamath Reclamation Project irrigators as described in Part IV of the KBRA. This also includes those benefits associated with both the Water Use Retirement Program (additional 30,000 acre feet) and increased water storage capacity in Upper Klamath Lake through restoration of Williamson River Delta, Agency Lake and Barnes Ranches, and Wood River wetlands. The model results do not include any additional benefits that may occur as a result of the implementation of a drought plan, which had not been developed at the time of this analysis. The results of WRIMS Run 32 Refuge are presented in Table I-5 and I-7 in Hetrick et al. (2009). Appendix E-5 of the KBRA also provides the results for three similar WRIMS (referred to as KLAMSIM) model simulations for Klamath River flows at Iron Gate and Upper Klamath Lake elevations.

As described in Hetrick et al. (2009), percent habitat area available using the flow-habitat relationships in the Hardy Phase II Report, for WRIMS Run-32 Refuge model output flows, were consistently higher than percent habitat area calculated for actual flow releases observed below Iron Gate Dam during water years 1961-2000 for the March – May emergence and rearing life stages of Chinook salmon, and for the June juvenile rearing period for coho salmon for exceedences greater than 10 percent (extremely wet years or drier). Percent habitat areas calculated for the WRIMS Run-32 Refuge model output flows and Hardy Phase II flow recommendations for the March – April period differed little, if at all, for all exceedence levels with the exception of the March time step for a 10 percent (extremely wet year) exceedence level, in which case the habitat value for the Hardy Phase II flow was about 25 percent higher than the habitat value calculated for the WRIMS Run-32 Refuge model output flows. Chinook salmon spawning percent habitat areas in October and November from WRIMS Run-32 Refuge were generally higher for the 10 percent (extremely wet year) exceedence level, similar for the 30, 50, and 70 percent (wet, normal, and dry) exceedences, and less at the 90 percent (critically

dry year) exceedence level than the percent habitat areas calculated for actual flows downstream from Iron Gate from 1961-2000 and Hardy Phase II flow recommendations. Both the WRIMS Run-32 Refuge modeled flow outputs and the Hardy Phase II flow recommendations provide habitat values above 70 percent of the maximum available habitat for priority anadromous fish species and life stages for a greater length of time (more time steps) than were provided under the actual flows below IGD during water years 1961-2000. For Upper Klamath Lake, the WRIMS Run 32 Refuge model run predicted that, in general, the lake would fill to elevations necessary to allow Lost River and shortnose sucker unrestricted access to critical spawning locations (Hetrick et al. 2009).

Results of the WRIMS Run 32 Refuge simulation indicate that in critically dry water years (similar to 1992 and 1994) there is a substantial reduction in Upper Klamath Lake elevations resulting in corresponding reductions in habitat that would negatively impact anadromous fish in the Klamath River and suckers in Upper Klamath Lake (Hetrick et al. 2009). These results demonstrated the critically important need for the development and effective implementation of a drought plan capable of reducing these potential impacts to both anadromous fish and suckers when critically dry conditions at the 95 percent exceedence level exist. Section 19.2 of the KBRA describes the process used for development of a drought plan (KBCC. 2011) that may reduce some of these potential impacts.

Appendix E of Reclamation (2011a) contains a description of the methods and assumptions that were incorporated into the hydrology simulations for the No Action Alternative (2010 Biological Opinion flows) and the Dam Removal Alternative (KBRA flows) used in the analysis. Previous hydrology simulations conducted by the Technical Team using the WRIMS (WRIMS Run 32 Refuge) model and described by Hetrick et al. (2009) were used to simulate conditions during the interim period prior to dam removal and did not incorporate several aspects of the KBRA (Drought Plan), and therefore were not appropriate for use in the EIS/EIR analysis of the Proposed Action or other alternatives. At the time when the Technical Team was conducting their analysis, the KBRA was still being developed and the Drought Plan had not been written. Under KBRA, the Technical Advisory Team (TAT) would also implement management of environmental water in real time; therefore, simulation of unknown future hydrologic and biological conditions is problematic. In addition, the previous analysis only addressed flows downstream from Iron Gate and did not consider flow needs that would likely be required for anadromous fish that would have access to areas upstream of Iron Gate Dam after proposed dam removal in 2020 as well as protections that may be required in future Biological Opinions under the ESA. Therefore, the Federal Team for the Secretarial Determination needed to incorporate several assumptions into the KBRA hydrology model simulations that attempt to provide adequate protections for anadromous fish and suckers that may be representative of potential recommendations by the TAT in the future that would include additional conservation measures that could be anticipated through implementation of a Drought Plan in critically dry water years. To meet these requirements the following assumptions, which are also described in Appendix E of Reclamation (2011a), were incorporated into the KBRA flow simulations:

- Incorporation of a minimum flow of 100 cfs at Link River to provide adequate passage through the fish ladder and stream channel.
- Incorporation of a minimum flow at Keno Dam of 300 cfs to provide adequate fish passage.
- Minor adjustment of KBRA flow targets for use in the hydrology model for the time steps from July 1 through the end of September to improve flow conditions for adult migration and reduce the potential for fish die off. The changes that were implemented include reducing the target from 921 to 840 cfs for July 1 to 15, increasing the target from 806 to 840 cfs for July 16 to 31, increasing the target from 895 to 1110 cfs in August, and increasing the targets from 1010 to 1110 cfs in September.
- Incorporation of minimum Ecological Base Flow (EBF) levels during the periods from March 1 through June 30 and during the months of August and September. The EBF volumes are those proposed by the Hardy Phase II 95% exceedence flow levels.
- Incorporation of pulse flows into the disaggregated daily data to realize potential benefits of these flows to reduce disease infection rates through disruption of the parasite's life cycle.
- Minor adjustment to the flow targets for the month of March for water years represented by the 70% Exceedence. These adjustments include reductions in the targets from 2358 to 2085 cfs (March 1-15) and from 2343 to 2149 cfs (March 16-31). The change is consistent with rate of change for wetter water years.
- Incorporation of minimum base flows of 800 cfs during the months of October through February. The minimum of 800 cfs is considered to be necessary to prevent adverse impacts to salmonids during the winter months.
- Redistribution of irrigation and refuge supplies during shortage years to reflect KBRA language. KPSIM does adjustments on annual basis as a post process. Monthly adjustments are done as a post process in a workbook by the data manager which runs both models.
- Minor adjustments were made to UKL elevation criteria in association with shortage adjustments.
- Net evaporation and riparian evapotranspiration gain was added.
- A method was implemented to create imperfect knowledge of forecasts. Because operational decisions are made based upon forecasts and not perfect knowledge of future flows, it is necessary to simulate this process in the model.

The Hardy et al. (2006) Phase II flow exceedence recommendations do not consider physical, biological, and chemical alterations to the Klamath system resulting from dam removal. The anticipated future changes to the system that would occur under the KHSA and KBRA led Hardy (2008) to conclude that future flow releases as described in the KBRA are a logical extension of the Hardy Phase 2 Flow recommendations, balancing multiple needs, including those of anadromous salmonids. Improved water quality conditions (primarily increased minimum dissolved oxygen and more natural water temperatures), restoration of sediment transport processes, potential reductions in disease,

restored access to thermal refugia and instream habitats upstream are all factors that led Hardy (2008) to conclude “that the threshold flow at which significant concerns over thermal and disease factors will drop well below 1000 cfs to something on the order of 700 to 800 cfs.” Consistent with these findings the Federal Team for the Secretarial Determination incorporated minimum base flows of 800 cfs into the KBRA flow simulations during the period from October through February (Reclamation 2011, Appendix E). Base flows of 800 cfs at Iron Gate Dam, along with tributary accretions downstream, currently provide greater than 75 percent of the available Chinook salmon spawning habitat from the R-Ranch study site downstream to the Brown Bear study site (Hardy et al. 2006) and flow levels of this magnitude would be adequate for adult coho salmon to migrate freely upstream. However, real time flow management envisioned by Hetrick et al. (2009) under KBRA would create variable flows during the spawning season that would actually have potential to increase the abundance of spawning habitat above what could be provided under a single static flow condition (Hetrick et al. 2009).

In the mid 2000s, NOAA Fisheries Service, FWS and Reclamation worked together to better understand and consider the conservation needs of listed fish (SONCC coho salmon, Shortnose and Lost River suckers) that reside in the Klamath River or in the Upper Klamath Basin. The agencies worked to improve inter-agency cooperation to promote efficient utilization of limited water resources for listed species, refuges and Project water users and to better harmonize the analyses and any potential conditions imposed by the final biological opinions prepared by the FWS and NOAA Fisheries Service. In October of 2007 Reclamation requested formal consultation under section 7 of the ESA for operation of Reclamation’s Klamath Project from 2008 through 2018. In the years immediately following, NOAA Fisheries Service worked collaboratively with Reclamation and FWS, and met with technical experts from Klamath Basin Tribes, to develop a reasonable and prudent alternative to avoid jeopardizing listed coho salmon. The final biological opinion which includes a reasonable and prudent alternative that addresses instream flow needs for SONCC coho salmon was released in 2010 (see Section 3.6.3.2 and Table 3.6-1 for additional description).

Under the No Action Alternative, Klamath River flows were simulated following the instream flow requirements established for operation of Reclamation’s Klamath Project under the reasonable and prudent alternative (RPA) described with in the 2010 Biological Opinion (NOAA Fisheries Service 2010a). In developing the RPA, NOAA Fisheries Service concluded that the implementation of Hardy Phase II flow exceedence recommendations at Iron Gate Dam will sufficiently provide fluvial conditions necessary for the conservation of coho salmon. NOAA Fisheries Service also adopted flows for certain time periods that reflect Hardy Phase II flows and determined that this action provided both a reasonable and prudent approach consistent with avoiding jeopardy of Southern Oregon and Northern California Coast (SONCC) coho salmon. As a result, the hydrology simulation results used in the analysis of the EIS/EIR for the No Action Alternative (NOAA Fisheries Service 2010a BO flows) and the Proposed Project (KBRA Flows) are similar in many aspects as described in Reclamation (2011a).

However, one aspect of the RPA flows that could not easily be incorporated into the hydrologic model for the No Action Alternative is the requirement to include a fall and winter flow variability program. The purpose of the Fall Winter Flow Variability Program, included in the RPA, is to enhance flow variability that would result from additional tributary inflow during fall and winter rainfall events. To accomplish this purpose, the RPA sets aside 18,600 acre feet of water for this purpose (NOAA Fisheries Service 2010a). In projection of the no-action Alternative, rather than attempt to simulate uncertain future implementation of this fall and winter flow variability program, the hydrologic modeling increased the base flow for the month of October from 1,000 cfs to 1,300 cfs which is roughly equivalent to the 18,600 acre feet provided under the RPA. Incorporation of this assumption increases simulated flows during the month of October under the No Action Alternative.

Klamath River Estuary and Pacific Ocean

Flow-related habitat has not been described for the Klamath River estuary.

3.3.3.3.8 Critical Habitat

The ESA requires that USFWS and NOAA Fisheries Service designate critical habitat² for the listed species they manage. Critical habitat has been designated for three species within the area of analysis: coho salmon, green sturgeon, and bull trout, and has been proposed for an additional two: shortnose and Lost River suckers. An endangered population of killer whales that includes Klamath River salmon in its diet is also discussed here.

Coho Salmon

Critical habitat for the SONCC Coho ESU was designated on May 5, 1999 and includes all river reaches accessible to listed coho salmon between Cape Blanco, Oregon and Punta Gorda, California, and includes water, substrate, and adjacent riparian zones of estuarine and riverine reaches, including off-channel habitat. “Accessible reaches” are defined as those within the historical range of the ESU that can still be occupied by any life stage of coho salmon. Specifically, in the Klamath Basin, all river reaches downstream from Iron Gate Dam on the Klamath River and Lewiston Dam on the Trinity River are designated as critical habitat (NOAA Fisheries Service 1999b).

Features of critical habitat considered essential for the conservation of the SONCC ESU (NOAA Fisheries Service 1997b) include (1) substrate, (2) water quality, (3) water quantity, (4) water temperature, (5) water velocity, (6) cover/shelter, (7) food, (8) riparian vegetation, (9) space, and (10) safe passage conditions. Primary Constituent Elements (PCEs) for SONCC coho salmon are described in NOAA Fisheries Service (1999b) as follows: “In addition to these factors, NOAA Fisheries Service also focuses on the known physical and biological features (PCEs) within the designated area that are

² The ESA defines critical habitat as “the specific areas within the geographical area occupied by the species, at the time it is listed, on which are found those physical or biological features (I) essential to the conservation of the species and (II) which may require special management considerations or protection; and specific areas outside the geographical area occupied by the species at the time it is listed that are determined by the Secretary to be essential for the conservation of the species.”

essential to the conservation of the species and that may require special management considerations or protection. These essential features may include, but are not limited to, spawning sites, food resources, water quality and quantity, and riparian vegetation.”

Shortnose Sucker and Lost River Sucker

Critical habitat was originally proposed but not finalized by the USFWS for the Lost River sucker and shortnose sucker in 1994 (USFWS 1994). Critical habitat for the two species was re-proposed on December 7, 2011 (USFWS 2011b). The proposed new critical habitat area is within Klamath and Lake Counties, Oregon, and Modoc County, California. The two proposed critical habitat units include: (1) approximately 146 stream miles (234 km) and 117,848 acres (47,691 ha) of lakes and reservoirs for Lost River sucker; and (2) approximately 128 stream miles (207 km) and 123,590 acres (50,015 ha) of lakes and reservoirs for shortnose sucker (USFWS 2011b). The USFWS considers the physical and biological features essential to the conservation of the species which may require special management considerations or protection when proposing critical habitat. These include, but are not limited to: (1) space for individual and population growth and for normal behavior; (2) food, water, air, light, minerals, or other nutritional or physiological requirements; (3) cover or shelter; (4) sites for breeding, reproduction, or rearing (or development) of offspring; and (5) habitats that are protected from disturbance or are representative of the historical, geographical, and ecological distributions of a species. PCEs are the specific elements of physical and biological features that are essential to the conservation of the species. The PCEs identified in the critical habitat proposal are as follows: (1) water in sufficient depths and quantity; (2) spawning and rearing habitat; and (3) areas contain abundant food (USFWS 2011b). A revised draft recovery plan was released in 2011 (USFWS 2011a) and is expected to be finalized with the new critical habitat in 2012 once public comments are addressed. The draft recovery plan cites predominant threats to these suckers as lack of spawning habitat, continued loss of habitat, lake elevation fluctuations that reduce access to vegetative habitat, water diversions, competition and predation by introduced species, hybridization with other sucker species, isolation of remaining habitats, and drought (USFWS 2011a). Decreases in water quality resulting from timber harvest, dredging activities, removal of riparian vegetation, and livestock grazing may also cause problems for these species (USFWS 2011a).

Green Sturgeon

In 2009, NOAA Fisheries Service designated critical habitat for the Southern DPS of green sturgeon, which encompasses all coastal marine waters of the United States less than 60 fathoms deep (approximately 110 m) from Monterey Bay, California north to Cape Flattery, Washington. The estuary portion of the Eel and Klamath/Trinity Rivers was specifically excluded from the critical habitat designation (NOAA Fisheries Service 2009b).

Bull Trout

Critical habitat designations for bull trout were finalized in 2005, but were then remanded in 2009 and republished in 2010. The final 2010 rule designates 277 miles of stream shoreline and 9,329 acres of reservoirs or lakes as critical habitat within the Klamath

River Recovery Unit. This habitat includes Agency Lake and its tributaries and an assortment of headwater streams. A designated critical habitat map is available from the USFWS (http://www.fws.gov/oregonfwo/Species/Data/BullTrout/Maps/final_krb.pdf). Critical habitat areas have at least one PCE essential to the conservation of bull trout. These features are the PCEs laid out in the appropriate quantity and spatial arrangement for conservation of the species. These include: (1) Space for individual and population growth and for normal behavior; (2) Food, water, air, light, minerals, or other nutritional or physiological requirements; (3) Cover or shelter; (4) Sites for breeding, reproduction, or rearing (or development) of offspring; and (5) Habitats that are protected from disturbance or are representative of the historical, geographical, and ecological distributions of a species.

Eulachon

Critical habitat for the Southern DPS eulachon in the Klamath River was designated by the NOAA Fisheries Service on 20 October 2011 (NOAA Fisheries Service 2011). NOAA Fisheries Service designated approximately 539 miles of riverine and estuarine habitat in California, Oregon, and Washington within the geographical area occupied by the southern DPS of eulachon. The designation includes 16 rivers and creeks extending from and including the Mad River, California to the Elwha River, Washington. NOAA Fisheries Service did not identify any unoccupied areas as being essential to conservation and thus, did not designate any unoccupied areas as critical habitat. NOAA Fisheries Service excluded from designation all lands of the Lower Elwha Tribe, Quinault Tribe, Yurok Tribe, and Resighini Rancheria. In the Klamath River, designated critical habitat extends from the mouth of the Klamath River upstream to Omogar Creek, a distance of 10.7 miles, and includes only the Federal, State, and private lands within the Yurok Reservation and Resighini Rancheria. The physical or biological features essential for conservation of this species include: (1) Freshwater spawning and incubation sites with water flow, quality, and temperature conditions and substrate supporting spawning and incubation, (2) Freshwater and estuarine migration corridors free of obstructions with water flow, quality and temperature conditions supporting larval and adult mobility, and with abundant prey items supporting larval feeding after the yolk sac is depleted, and (3) nearshore and offshore marine foraging habitat with water quality and available prey, supporting juveniles and adult survival.

Southern Resident Killer Whale

In November 2006, NOAA Fisheries Service designated critical habitat for Southern Resident Killer Whales (NOAA Fisheries Service 2006b). Critical habitat includes all waters relative to a contiguous shoreline-delimited by the line at a 20-foot depth relative to extreme high water within three designated areas: (1) the Haro Strait and waters around the San Juan Islands; (2) Puget Sound; and (3) the Strait of Juan de Fuca. Coastal and offshore areas have not been designated as critical habitat, though they are recognized as important for the Southern Resident Killer Whales and NOAA Fisheries Service anticipates additional information on coastal habitat use from research projects in the coming years (NOAA Fisheries Service 2006b).

Based on the natural history of the Southern Residents and their habitat needs, the following physical or biological features were identified as essential to conservation: (1) water quality to support growth and development; (2) prey species of sufficient quantity, quality, and availability to support individual growth, reproduction, and development, as well as overall population growth; and (3) passage conditions to allow for migration, resting, and foraging (71 FR 69054). There is the potential for Southern Resident Killer Whales to feed on Klamath River salmonids during the period from about September through May when they spend more time in outer coastal waters and may range from central California to northern British Columbia (Hanson et al. 2010). Southern Resident Killer Whales would not be expected to be affected by any of the alternatives, apart from their effects on salmon production.

3.3.3.3.9 Essential Fish Habitat

EFH is designated for commercially fished species under the Magnuson-Stevens Fishery Conservation and Management Reauthorization Act (Magnuson-Stevens Act). The Magnuson-Stevens Act requires Federal fishery management plans, developed by NOAA Fisheries Service and the Regional Fishery Management Councils, to describe the habitat essential to the fish being managed and to describe threats to that habitat from both fishing and nonfishing activities. To protect EFH, Federal agencies are required to consult with the NOAA Fisheries Service on activities that may adversely affect EFH.

EFH has been designated for 3 species of salmon, 83 groundfish species, and 5 pelagic species. Descriptions of EFH within the area of analysis are provided below.

Chinook and Coho Salmon

Coho salmon are also managed under the Magnuson-Stevens Act, under the authority of which EFH for coho salmon is described in Amendment 14 to the Pacific Coast Salmon Fishery Management Plan (50 CFR 660.412). EFH for Chinook salmon is also described in the same management plan, and is identical to that for coho salmon in the Klamath Basin. EFH has been designated for the mainstem Klamath River and its tributaries from its mouth to Iron Gate Dam, and upstream to Lewiston Dam on the Trinity River. EFH includes the water quality and quantity necessary for successful adult migration and holding, spawning, egg-to-fry survival, fry rearing, smolt migration, and estuarine rearing of juvenile coho and Chinook salmon.

Groundfish

The Magnuson-Stevens Act defines EFH to include those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity (16 USC 1802 (10)). EFH for Pacific Coast groundfish includes all waters and substrate within areas with a depth less than or equal to 3,500 m (1,914 fm) shoreward to the mean higher high water level or the upriver extent of saltwater intrusion (defined as upstream and landward to where ocean-derived salts measure less than 0.5 ppt during the period of average annual low flow). The Klamath River Estuary, which extends from the river's mouth upstream to near the confluence with Ah Pah Creek, is included in the Pacific groundfish EFH (50 CFR § 660.395).

Pelagic Fish

EFH for coastal pelagic species, including finfish (northern anchovy, Pacific sardine, Pacific (chub) mackerel, and jack mackerel) and market squid occurs from the shorelines of California, Oregon, and Washington westward to the exclusive economic zone and above the thermocline where sea surface temperatures range from 10 to 26°C. During colder winters, the northern extent of EFH for coastal pelagic species may be as far south as Cape Mendocino, and during warm summers it may extend into Alaska's Aleutian Islands. In each of these seasonal examples the Klamath Estuary and coastline would be included as EFH for these species.

3.3.4 Environmental Consequences

3.3.4.1 Environmental Effects Determination Methods

This section provides a brief overview of the methods used in the evaluation of important factors to aquatic resources. More complete descriptions are provided in the Methods and Criteria Technical Memorandum (Reclamation 2012), Appendix E for suspended sediment and Appendix F for bedload sediment.

3.3.4.1.1 Suspended Sediment

As described in Appendix E, the potential effects of suspended sediment on anadromous fish species for the Proposed Action and alternatives were assessed using SRH-1D (Huang and Greimann 2010, as summarized in Reclamation 2011). The SRH-1D model provides an estimate of SSCs at different points on the river on a daily average estimate. This information is used to assess the impacts of SSCs on fish based on the concentration and duration of exposure using Newcombe and Jensen's (1996) approach. Duration of exposure is based on the time a species and lifestage would be exposed to elevated SSCs. These effects are compared to those that fish would be expected to encounter under baseline conditions. Estimated existing conditions were also simulated using the SRH-1D model, to provide a comparison of what SSCs would be with and without dam removal in the years 2020 and 2021 (No Action/No Project Alternative). This approach is similar to that used in Stillwater Sciences (2008, 2009a, 2009b).

Daily durations of SSC concentrations were modeled assuming the Proposed Action occurred within each of the 48 years in the available hydrology record since 1961. For each simulation year in the 48 year record, the duration of SSCs over a given threshold was calculated for each species and life-history stage (e.g., duration of SSC over 1,000 mg/L during spring-run Chinook salmon adult upstream migration). The results of modeling all potential years were summarized for each life-stage of each species assessed. Because the suspended sediment varies with hydrology, and in order to account for (and compare) the range of results and impacts that might occur under each alternative, two scenarios were analyzed for the Proposed Action, and for action alternatives, with the goal of predicting the potential impacts to fish that has either a 50 percent (likely to occur) or 10 percent (unlikely, or worst case) probability of occurring, defined as follows:

3.3.4.1.2 For Existing Conditions and the No Action/No Project Alternative:

- **Normal conditions:** SSCs and durations with a 50 percent exceedance probability for the mainstem Klamath River downstream from Iron Gate Dam (i.e., the probability of these concentrations and durations being equaled or exceeded in any one year is 50 percent). Exceedance probabilities were based on modeling SSC for all water years subsequent to 1961 with facilities in place. To assess “normal conditions” the median (50 percent) SSC and duration from these results was estimated (Appendix II, Volume E, page E-3). “Normal conditions” is a description of the SSCs that commonly occur under existing conditions during most years, such as during typical winter flows.
- **Extreme conditions:** SSCs and durations with a 10 percent exceedance probability (i.e., the probability of these concentrations and durations being equaled or exceeded in any 1 year is 10 percent). “Extreme conditions” is a description of infrequent SSCs events in the Klamath River under existing conditions, such as a flood (Appendix II, Volume E, page E-4).

3.3.4.1.3 For the Proposed Action– Full Facilities Removal of Four Dams:

- **Most likely scenario:** SSCs and durations with a 50 percent exceedance probability for the mainstem Klamath River downstream from Iron Gate Dam (i.e., the probability of these concentrations and durations being equaled or exceeded for each assessed species and life-stage in any one year is 50 percent). Exceedance probabilities were based on the results of modeling suspended sediment in the Klamath River downstream from Iron Gate Dam in all water years observed since 1961 with facility removal. To predict the “most likely scenario” that will occur under the Proposed Action, the median (50 percent exposure concentration) was estimated.
- **Worst-case scenario:** SSCs and durations with a 10 percent exceedance probability (i.e., the probability of these concentrations and durations being equaled or exceeded for each assessed species and life-stage in any 1 year is 10 percent). “Worst-case scenario” is a prediction of an unlikely, but potential scenario of high SSCs that could occur under if the Proposed Action occurs under a sequence of rare hydrologic conditions.

3.3.4.1.4 Bedload Sediment

As described in Appendix F, the analysis of potential changes to bedload sediment also relied upon output from the SRH-1D model (Huang and Greimann 2010). The changes in bedload were evaluated for a range of hydrologic conditions for short-term (2-year) and long-term (5-, 10-, 25-, 50-year) changes using a range of flows taken from historical hydrology. A long-term simulation was not conducted for the Klamath River upstream of Iron Gate Dam under the assumption that the bedload sediment conditions at the end of 2 years are representative and would persist through time, allowing for mild fluctuations as a function of hydrology (Reclamation 2012).

The effects determination used results from the analysis and knowledge of habitat requirements of affected fish species to determine how changes in bed elevation and

substrate composition would affect aquatic resources (e.g., pool habitat, spawning gravel, benthic habitat). Changes in substrate composition occurring as a result of dam removal that decreased habitat suitability were assumed to be deleterious to salmonids. Bedload transport in the area upstream of the influence of J.C. Boyle Reservoir are not anticipated to be affected by dam removal and are not expected to be substantially affected by the Proposed Action, and are not evaluated further in this document. Link and Keno Dams would remain in place and would continue to affect hydrology and sediment transport in much the way they do currently.

3.3.4.1.5 Water Quality

The analysis of potential short- and long-term water quality-related effects on fish is based on the corresponding water quality effects determinations (see Section 3.2, Water Quality) for parameters to which fish are most sensitive (i.e., water temperature, sediment and turbidity, dissolved oxygen, pH, and ammonia toxicity), as well as effects determinations for State and approved tribal designated beneficial uses that are directly related to fish (see Table 3.2-3).

As described in Section 3.2., Water Quality, implementation of the Oregon and California Total Maximum Daily Loads (TMDLs) is considered to be a reasonably foreseeable action associated with water quality during the period of analysis (i.e., 50 years) (see Section 3.2.4.1, Environmental Effects Determination Methods), and is expected to generally improve water quality conditions in the Klamath River. Modeling efforts for development of the TMDLs included four simulated scenarios and both “dams in” and “dams out” conditions (see Appendix D, Section D.1 for additional detail on modeling scenarios). TMDL model results for water temperature, dissolved oxygen, pH, and nutrients provide one set of quantitative, predictive information under the alternatives and so these results are discussed as part of the water quality analysis (Section 3.2.4.3, Effects Determinations) and the corresponding aquatics analysis (below). However, since no one existing model captures all of the elements analyzed for water quality in this Klamath Facilities Removal EIS/EIR, where possible, model outputs are used in combination to assess similar spatial and temporal trends in predicted water quality parameters (Section 3.2.4.1, Environmental Effects Determination Methods).

Potential effects of sediment-associated toxins on fish under the dam removal alternatives were evaluated using the results of multiple screening level comparisons of sediment contaminant levels identified in reservoir sediments that are currently trapped behind the dams. These water quality methods are described in greater detail in Section 3.2.4.1.7.

3.3.4.1.6 Water Temperature

Potential impacts of water temperature on species within each analysis area were evaluated using available modeled water temperatures (PacifiCorp 2004c; Dunsmoor and Huntington 2006; FERC 2007; Tetra Tech 2009, Perry et al. 2011). Because model results were not developed for scenarios covering each of the alternatives, this evaluation assumes that the Partial Facilities Removal Alternative would result in temperatures similar to those that would occur under the Proposed Action. It is assumed that the Fish Passage at Four Dams Alternative would result in similar temperatures to existing

conditions. The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative was assumed to result in temperatures intermediate to the Proposed Action and existing conditions. Because the remaining reservoirs are small relative to Copco 1 and Iron Gate Reservoirs, with correspondingly lower amounts of thermal heating and residence time, the temperatures under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would likely be more similar to those under the Proposed Action than they would be to the No Action/No Project Alternative. Water temperature data were compared to the thermal tolerances of focal species and associated life stages as determined from the literature to determine relative suitability for these species under the various alternatives.

No one available water temperature model includes all of the reasonably foreseeable actions associated with water temperature. Implementation of TMDLs is included in the TMDL models (Tetra Tech 2009) and climate change and KBRA hydrology are incorporated into the RBM10 model (Perry et al. 2011) (see Section 3.2.4.1.1 and Appendix D for additional detail). Neither implementation of total maximum daily loads (TMDLs) nor climate change was incorporated into the existing models, including the Chinook salmon life cycle model (EDRRA) developed by Hendrix (2011). For purposes of the water quality and aquatics analyses it is assumed that TMDL water temperature objectives can be met; however the timeframes for achieving allocations required under the TMDLs will depend on the measures taken to improve water quality conditions (see Section 3.2.4.3.1). It is also assumed that climate change would result in 1.0 to 3.0°C warming of median air temperature by the end of the analysis period (Snyder et al. 2004; Bartholow 2005; Perry et al. 2011) (see also Section 3.2.4.1.1).

3.3.4.1.7 Fish Disease and Parasites

Fish diseases, specifically *C. shasta* and *P. minibicornis*, can contribute to mortality and have periodically contributed to substantial mortality for Klamath River salmon. Generally, Klamath River steelhead are resistant to *C. shasta* (Administrative Law Judge 2006). Environmental variables such as temperature, flow, sediment (bedload composition and stability), plankton (high quality food abundance), and nutrients are thought to affect the abundance of *P. minibicornis* and *C. shasta* via habitat for the intermediate host; therefore, differences in river habitat conditions that could occur under the Proposed Action and alternatives could affect the abundance of these parasites and their infection rates in Klamath Basin salmon. Bartholomew and Foott (2010) prepared a compilation of available information regarding Myxozoan disease relative to the Klamath River and, in their analysis they considered several factors that could, if co-occurring, lead to high disease infection rates of fish:

- Physical habitat components that support the invertebrate host species (pools, eddies, sediment, mats of filamentous green algae [periphyton])
- Microhabitats with low velocity and unnaturally stable flows
- Close proximity to spawning areas
- Water temperatures higher than 15 °C

3.3.4.1.8 Aquatic Habitat

Changes to habitat area were assessed for each life stage qualitatively, using knowledge of habitat requirements and expected changes under the alternatives. Quantitative descriptions of the relationship between fish habitat and flow are available for the current channel configuration at some locations (Bureau of Land Management 2002; Hardy et al. 2006). However, extrapolation of these relationships to describe the habitat changes that would be anticipated under each of the proposed alternatives would not provide an appropriate method to assess the effects of the project alternatives because the channel configuration itself is anticipated to change as a result of alterations to sediment supply and the temporal resolution (mean monthly or biweekly time steps) of modeled flows would not accurately represent daily flow conditions. Qualitative analyses relied on data evaluated for other affected factors (water temperature and fish passage) and expected changes in geomorphic processes, such as short- and long-term changes in sediment transport and deposition, to determine increases or decreases in habitat relative to existing conditions for the different species and life stages in the various reaches.

3.3.4.1.9 Critical Habitat

NOAA Fisheries Service has designated critical habitat for coho salmon, Southern Resident Killer Whales, and eulachon, and the USFWS has designated critical habitat for bull trout. Within critical habitat, NOAA Fisheries Service has determined that the PCEs essential for the conservation of these species are those sites and habitat components that support one or more life stage. Critical habitat for Southern Resident Killer Whales does not extend into coastal or offshore habitats (71 FR 69054). The effects of each alternative on critical habitat were based on evaluation of the physical, chemical and biological changes that were expected to occur to designated critical habitat within the area of analysis and how those changes would affect the PCEs for that critical habitat in the short and long term.

3.3.4.1.10 Essential Fish Habitat

The effects of each alternative on EFH were based on evaluation of the physical, chemical and biological changes that were expected to occur to EFH within the area of analysis and whether those changes would have beneficial effects on this habitat in terms of its quantity and quality in the short and long term.

3.3.4.1.11 Freshwater Mussels

Increased levels of fine sediment, both suspended in the water column and along the channel bed, can inhibit the growth, production, and abundance of freshwater mussels and clams. Therefore, the analysis of impacts associated with dam removal focused on short- and long-term changes in SSCs (Aldridge et al. 1987, as cited in Henley et al. 2000) and stream substrate texture (Howard and Cuffey 2003; Vannote and Minshall 1982). The evaluation focuses on freshwater mussels because of the lack of information regarding the effects of SSCs and sediment transport on clams. Suspended sediment impacts on freshwater mussel species were evaluated using output from the SRH-1D (Huang and Greimann 2010) sediment transport model as discussed above for suspended and bedload sediment.

Aldridge et al. (1987, as cited in Henley et al. 2000) showed that exposure to SSCs of 600-750 mg/L led to reduced survival of freshwater mussels found in the eastern United States. No duration of exposure was cited in the study. No comparable data are available for the species in the Klamath River. Using 600 mg/L as the minimum SSCs that would be detrimental to freshwater mussels, alternatives were compared to each other by determining the number of days during which this criterion threshold would be exceeded.

Analysis of impacts due to changes in bedload transport on the four species of freshwater mussels considered modeled changes in median sediment size, under the Proposed Action and each project alternative. The effects of changes in water quality on freshwater mussels were evaluated in the same manner as described for fish. The analysis presented here, focuses on effect on freshwater mussels because of their longer lifespan and a lack of information on the effects of water quality on clams.

3.3.4.1.12 Benthic Macroinvertebrates

Suspended sediment and turbidity can cause stress to benthic macroinvertebrates (BMI) populations through impaired respiration, reduced feeding, growth, and reproductive abilities, and reduced primary production (Lemly 1982; Vuori and Joensuu 1996). Therefore, potential short-term and long-term effects of the Proposed Action and alternatives on BMIs were evaluated for both short- and long-term changes in SSCs and bedload sediment. Suspended sediment impacts on BMIs were evaluated using output from the SRH-1D (Huang and Greimann 2010) sediment transport model as discussed above for suspended and bedload sediment.

Changes in substrate size or embeddedness may influence the distribution, abundance, and community structure of BMIs (Bjornn et al. 1977; McClelland and Brusven 1980; Ryan 1991). Bed texture changes that would occur under the Proposed Action and alternatives were qualitatively evaluated to determine whether changes in substrate composition would likely decrease macroinvertebrate abundance or alter the community composition to the extent that these communities could no longer support sufficient fish populations in the Klamath system.

The effects of changes in water quality, Biochemical Oxygen Demand/Immediate Oxygen Demand, and toxicity effects on BMIs were based on water quality determinations (see Section 3.2, Water Quality) and evaluated in the same manner as described for fish and mollusks. Potential toxicity to BMIs was also evaluated using the results of bioassays.

3.3.4.2 Significance Criteria

The Proposed Action and alternatives could affect aquatic resources directly or indirectly through a variety of mechanisms, as described in the preceding section. These effects could be additive or offsetting. For purposes of this evaluation, the Lead Agencies considered the total effect of the factors described above on native fish populations and their habitat. These impacts could vary substantially in intensity, geographic extent, and duration. The intensity of an impact refers to how severely it affects an organism. This severity can range from sublethal behavioral adaptations such as avoidance of a specific

condition, to mortality. The geographic extent refers to how much of the species' potential habitat and what proportion of the total population is expected to be affected. The temporal duration refers to how long the effect is anticipated to persist (hours, days, months, or years). The Lead Agencies considered effects in the short term (less than 2 years) and the long term (more than 2 years), but either short- or long-term impacts could be significant.

For the analysis of Aquatic Resources in this EIS/EIR, the following determinations were considered:

- No from existing conditions: Effect would not result in alterations to existing conditions.
- Significant: As defined below.
- Less-than-significant: Effect influences an aquatics species, but does not result in a significant effect.
- Beneficial: Results in a substantial increase in the abundance of a year class in the short or long term.

For the purposes of this EIS/EIR, effects would be significant if they would result in the following:

Short term:

- Substantially reduce the abundance of a year class in the short term.
- Substantially decrease the habitat quality or availability for a native species over a large proportion of the habitat available to it in the short term.
- Substantially decrease the quality or availability of a large proportion of critical habitat under the ESA or EFH under the Magnuson-Stevens Fishery Conservation and Management Act in the short term.

Long term:

- Substantially reduce the population of a native species for more than two generations after removal of all dams (if removed all at once) or after the last dam (if removed sequentially).
- Substantially decrease the habitat quality or availability for a native species or community in the long term.
- Substantially decrease the habitat quality or availability for a native species over a large proportion of the habitat available to it in the long term.
- Substantially decrease the habitat quality or availability of a large proportion of critical habitat under the ESA or EFH under the Magnuson-Stevens Fishery Conservation and Management Act in the long term.
- Continue or worsen conditions that are currently causing a species to decline in the long term.
- Eliminate a year class of salmon or steelhead, thereby impacting the long-term viability within the Klamath Basin. Because of the fixed, 3-year timing of the

coho salmon life cycle, which has little to no plasticity, this criterion was added for the protection of coho salmon in particular.

3.3.4.3 Effects Determinations

3.3.4.3.1 Alternative 1: No Action/No Project

Under this alternative, none of the actions under consideration would be implemented. The Klamath Hydroelectric Project would continue current operations under the terms of an annual license until a long-term license is finalized. Annual licenses would not include actions associated with the KHSA and KBRA. Several Interim Measures (IMs) from the KHSA would be implemented through other PacifiCorp's Habitat Conservation Plan or other means; these measures are included in the No Action/No Project Alternative. In addition, continued expenditures of \$10 to 20 million a year on various basin-wide restoration projects (e.g., stream habitat improvements), and other basin conservation plans will continue to provide aquatic habitat improvements. Some KBRA actions have already been initiated and would continue under the No Action/No Project Alternative. These include the Williamson River Delta Project, the Agency Lake and Barnes Ranch Project, fish habitat restoration work, and ongoing climate change assessments. The TMDLs would be implemented under all alternatives as they are an unrelated regulatory action; however, TMDL goals would likely be met at a later date than under alternatives with KBRA. Hydroelectric operations would continue as they have been, providing peaking power generation during the summer as demand requires and conditions allow. Iron Gate Hatchery would continue to operate at current levels of production in order to meet mitigation requirements.

Key Ecological Attributes

Suspended Sediment

Suspended sediment effects under the No Action/No Project Alternative are described in detail in Appendix E, and summarized here. Under the No Action/No Project Alternative, suspended sediment would be the same as under existing conditions. Most suspended sediment is supplied by tributaries; Iron Gate Dam currently interrupts both fine and coarse sediment transport, so suspended sediment generally increase in a downstream direction. The Lower Klamath River downstream from the Trinity River confluence (RM 40.0) to the estuary mouth is listed as sediment impaired under Section 303(d) of the CWA (see Table 3.2-8). Under both normal and extreme conditions, the magnitude and duration of the SSCs modeled for the No Action/No Project Alternative are expected to cause major stress to migrating adult and juvenile salmonids primarily during winter, with a Newcombe and Jensen (1996) Severity Index predicted to be higher than 8 for most of the winter (see Appendix E for detailed analysis).

Bedload Sediment

Bedload sediment effects under the No Action/No Project Alternative are described in detail in Appendix F, and summarized here.

Hydroelectric Reach: from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

Under the No Action/No Project Alternative, the Klamath Hydroelectric Project dams would continue to trap fine and coarse sediment. The No Action/No Project

Alternative would have no effects associated with bedload sediment relative to existing conditions for any aquatic species in this reach.

Lower Klamath River: Downstream from Iron Gate Dam Under the No Action/No Project Alternative, the Project dams would continue to interrupt the transport of bedload. These periodic inputs of bedload sediments are necessary for the long-term maintenance of aquatic habitats. As a result of the interception of sand, gravel and coarser sediment supply from sources upstream of Iron Gate Dam the channel downstream from Iron Gate Dam would continue to coarsen and decrease in mobility (Reclamation 2012), providing fewer components of habitat, in particular spawning habitat, and decreased quality habitat over time. This effect would gradually decrease in the downstream direction as coarse sediment is resupplied by tributary inputs (Hetrick et al. 2009), and would be substantially reduced at the Cottonwood Creek confluence (PacifiCorp 2004b). As occurs under existing conditions, the coarser bed material is mobilized at higher flows that occur less frequently, resulting in channel features that are unnaturally static and provide lower value aquatic habitat (Buer 1981).

Klamath River Estuary The No Action/No Project Alternative would not change bedload transport to the estuary or Pacific Ocean, relative to existing conditions.

Water Quality

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir As described in Section 3.2, Water Quality, long-term dissolved oxygen levels under the No Action/No Project Alternative would continue to exhibit seasonal variability. Dissolved oxygen levels are particularly low during the summer in this reach, with typical levels ranging from <1 mg/L to 5 mg/L. Such low levels do not meet Oregon water quality objectives for dissolved oxygen, and they do not consistently support designated beneficial uses in Oregon for cold-water aquatic life, cool-water aquatic life, warm-water aquatic life, and spawning.

Full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly increase dissolved oxygen in this reach. Klamath TMDL model results for riverine conditions between Link River Dam and the upstream end of J.C. Boyle Reservoir predict that dissolved oxygen concentrations would meet the 6.5 mg/L objective year round, including the warm summer and fall months (see subsection to Section 3.2.4.3.1, Upper Klamath Basin). Full attainment could require decades to achieve and it is highly dependent on improvements in dissolved oxygen in Upper Klamath Lake.

Additionally, restoration activities such as floodplain rehabilitation, riparian vegetation planting, and purchase of conservation easements/land related to nutrients under the No Action/No Project Alternative are currently ongoing in the Upper Klamath Basin and are expected to continue to improve long-term dissolved oxygen in the Upper Klamath Basin. These restoration actions and implementation of water quality improvement measures under Oregon TMDLs to address water quality impairments are also expected

to improve pH during the period of analysis (50 years) by decreasing algal bloom populations and rates of photosynthesis and correspondingly decreasing observed pH maximums in the Upper Klamath Lake and its tributaries.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Under the No Action/No Project Alternative, continued high rates of algal photosynthesis in the two largest reservoirs in the Hydroelectric Reach (Copco 1 and Iron Gate) would result in dissolved oxygen and pH values that would not consistently meet applicable ODEQ and California Basin Plan water quality objectives (see Section 3.2, Water Quality). The bottom waters (i.e., hypolimnion) of Copco 1 and Iron Gate Reservoirs would continue to have very low oxygen levels (< 1 mg/L to 5 mg/L) during summer stratification periods (FERC 2007). Based on existing conditions, pH during summer through fall in Copco 1 and Iron Gate Reservoirs would continue to range from just above neutral (7) to greater than 9 (slightly basic), with the highest values occurring during algal blooms. The ongoing presence of the two largest reservoirs in the Hydroelectric Reach (Copco 1 and Iron Gate) would also continue to provide the conditions necessary for large seasonal blue-green algae blooms, including *M. aeruginosa*, which can produce a toxin and contribute to reduced health and increased mortality rates for fish and other aquatic resources both within the reservoirs and in areas downstream. As with the upstream reach, full attainment of the Oregon and California TMDLs (implementation mechanism and timing unknown) would significantly improve seasonal dissolved oxygen and pH levels in the Hydroelectric Reach. Full attainment could require decades to achieve and it is highly dependent on improvements in dissolved oxygen in Upper Klamath Lake and the Keno Impoundment/Lake Ewauna.

Lower Klamath River: Downstream from Iron Gate Dam Ongoing efforts to improve water quality conditions are underway through the TMDL process and considerable efforts to improve habitat are also underway (Hamilton et al. 2011). Once implemented, these efforts could reduce existing conditions that contribute to reduced health and increased mortality rates for aquatic resources (described below) to some extent, but this process would be slower and more challenging than with the dams removed. In the interim, water quality conditions that may reduce survival of fish and other aquatic resources would persist downstream from Iron Gate Dam.

Given existing conditions, long-term dissolved oxygen levels under the No Action/No Project Alternative would continue to exhibit seasonal variability and would not consistently meet California Basin Plan and Hoopa Valley Tribe water quality objectives for dissolved oxygen and they would not consistently support designated beneficial uses in the Lower Klamath River downstream from Iron Gate Dam.

Modeling conducted for development of the California Klamath River TMDL indicates that under the No Action/No Project Alternative, dissolved oxygen concentrations immediately downstream from Iron Gate Dam, without additional mitigation, would not meet the North Coast Basin Plan water quality objective of 85 percent saturation (see Tables 3.2-4 and 3.2-5) during August–September and the 90 percent saturation objective from October–November (Figure 3.2-18). Further downstream, near the confluence with

the Shasta River, dissolved oxygen concentrations under the No Action/No Project Alternative would not meet the 90 percent saturation objective from October–November (Figure 3.2-19). In the Klamath River at Seiad Valley, concentrations would be mostly in compliance, with the exception of modeled values in November that are just above the 90 percent saturation objective (Figure 3.2-20). By the Salmon River (RM 66.0) confluence, with full attainment of TMDL allocations, predicted dissolved oxygen concentrations would remain at or above the 85 percent saturation objective (as well as the 90 percent saturation objective, where applicable), meeting the North Coast Region Basin Plan requirements.

Under the No Action/No Project Alternative, continued high rates of algal photosynthesis in the reservoirs would result in high pH values in the Lower Klamath River downstream from Iron Gate Dam (see Section 3.2, Water Quality). Under the No Action/No Project Alternative, pH would continue to be elevated with high diurnal variability during summer and early fall months.

The overall anticipated effect on dissolved oxygen in the Lower Klamath River under the No Action/No Project Alternative would be an increasing trend toward compliance with water quality objectives and support of designated beneficial uses, but with possible continued seasonally low dissolved oxygen downstream from Iron Gate Dam, and so would not consistently meet California Basin Plan and Hoopa Valley Tribe water quality objectives for dissolved oxygen. The No Action/No Project Alternative would continue to periodically result in dissolved oxygen levels that may be deleterious to aquatic resources downstream from Iron Gate Dam, but this effect would be similar to or less than that which currently occurs.

Water Temperature

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the No Action/No Project Alternative, water temperature in the upper Klamath River would remain similar to existing conditions in the near term, but would be expected to show a gradual cooling trend through implementation of the TMDLs. However, climate change would partially offset temperature improvements (see also the subsection of Section 3.2.4.3.1). Climate change impacts on the Klamath River and Estuary are based on current estimates of potential future changes in air temperature and precipitation patterns for the California North Coast hydrologic region (Stillwater Sciences 2009a). Regional climate models estimate that median annual air temperature would increase 1.0 to 3 °C by 2050 (Snyder et al. 2004). These ambient air temperatures could in turn raise water temperatures. Additionally, decreases in snowpack from higher air temperatures from January to March are also predicted, resulting in a more modest spring runoff peak. In the Klamath Basin as a whole, increasing air temperatures and decreasing flows in the summer months would be expected to cause general increases in summer and fall water temperatures on the order of 2–3 °C (3.6–5.4 °F) (Bartholow 2005). Despite climate predictions, temperatures in Upper Klamath Lake have exhibited a downward trend from 1990 to 2009 (Jassby and Kann 2010).

As described in the subsection of Section 3.2.4.3.1, based on a programmatic assessment the Williamson River Delta Project and the Agency Lake and Barnes Ranches Project represent a reasonably foreseeable set of actions under the No Action/No Project Alternative that would provide favorable springtime water temperatures for rearing fish in the Upper Klamath Basin. Specific options for both projects still need to be developed and studied as part of a separate project-level National Environmental Policy Act (NEPA) evaluation and ESA consultation.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Under the No Action/No Project Alternative, the effects of ongoing and future upstream water quality improvements under the TMDLs would improve water temperatures below Keno Dam. However, climate change would partially offset anticipated temperature improvements. The river's thermal regime downstream from the reservoirs would continue to be out of phase with the natural temperature regime (Hamilton et al. 2011). Unnatural temperature fluctuations would continue downstream from the J.C. Boyle Bypass Reach, from the mixture of cold-water inflow from Big Springs and the warmer water discharge from the J.C. Boyle Powerhouse (Hamilton et al. 2011). Similar impacts from climate change as described above are also predicted to occur in this reach; therefore, water temperatures are expected to remain similar to existing conditions.

Lower Klamath River: Downstream from Iron Gate Dam The Lower Klamath River downstream from Iron Gate Dam would continue to have elevated water temperatures in the summer and fall in the near term. The reservoirs have the effect of changing the timing and magnitude of the thermal regime by increasing water temperatures in the fall as a result of the increased hydraulic residence time and thermal mass (Bartholow et al. 2005). Bartholow et al. (2005) and PacifiCorp (2004a) showed that the reservoirs delay seasonal thermal signatures by 18 days. Implementation of the TMDLs in these mainstem and tributaries is expected to result in lower water temperatures over time; however, these improvements would be partially offset by the effects of climate change, as described above. In the long term, water temperatures in the mainstem and tributaries are expected to remain similar to existing conditions.

Under the No Action/No Project Alternative, dams would continue to increase late summer and early fall water temperatures in the Klamath River downstream from Iron Gate Dam (subsection of Section 3.2.4.3.1). Under existing conditions in the fall, the dams do not decrease temperatures of water that is transported downstream from Upper Klamath Lake. This is due to the fact that powerhouse withdrawals for Copco 1 and Iron Gate Dams are primarily from the epilimnion (surface waters) (see Appendix C, Section C.1.1.4) which is heated by ambient air under existing reservoir operations. Unlike Shasta Dam or other deep reservoirs that support downstream tailwater fisheries by release of cool water from low level outlets, the location of dam outlets in the Klamath River cannot be adjusted to access large volumes of cool water in the bottom of the reservoirs (hypolimnion).

Under this alternative, the current phase shift and lack of temporal temperature diversity will persist, including current warm temperatures in late summer and fall (Hamilton et al. 2011). This phase shift and warm fall temperatures results in delayed adult upstream migration, which is speculated to delay fall spawning (Dunsmore and Huntington 2006). Current cooler temps in spring likely delay emergence, and reduce growth rates of juveniles (Hardy et al. 2006). In addition, juveniles and adults migrating in late summer and fall would continue to experience warm temperatures that could be deleterious to health and survival, including increased risk of disease, and high rates of delayed spawning and prespawn mortality (Hetrick et al. 2009).

In addition, the decrease in diel temperature variation compared with historical conditions is deleterious for salmonids. Historically, diel temperature variation would result in regular nighttime cooling of water, offering daily relief with significant bioenergetic benefits that helped fish persist under marginal conditions (NRC 2004). The current lack of diel temperature variation reduces the value of thermal refuge habitat (Dunsmoor and Huntington 2006) and reduces the suitability of rearing habitat in the mainstem Klamath River (NRC 2004).

In addition to direct thermal stress, the potential for continued elevated water temperatures in the late summer/fall (due to potential for climate change to offset anticipated TMDL temperature improvements) could result in indirect stressors on salmonids including an increased intensity and duration of algal blooms, decreased dissolved oxygen levels, and conditions conducive to disease (Bartholomew and Foott 2010). These effects would adversely impact cold-water fish communities and would be deleterious to warm-water fish communities as well.

Klamath River Estuary and Pacific Ocean Nearshore Environment Under the No Action/No Project Alternative, water temperatures in the Klamath River Estuary and Pacific Ocean would remain similar to the existing conditions and climate change would continue to play a role in future temperatures as described above.

Fish Disease and Parasites

The ongoing presence of the dams under the No Action/No Project Alternative would continue to contribute to the static flows, immobile substrate, seasonally warm water temperatures, and planktonic food sources that are favorable for polychaetes and for *C. shasta* and *P. minibicornis* (Hetrick et al. 2009). Salmon carcasses would continue to concentrate downstream from Iron Gate Dam, where the polychaete hosts are abundant, facilitating the cross infection between the fish and the polychaetes. Based on this scenario, mortality associated with *C. shasta* and *P. minibicornis* would be expected to worsen or remain similar to existing conditions. In particular these conditions would continue to adversely affect outmigrants from tributaries downstream from Iron Gate Dam, including those from the Shasta and Scott rivers. If temperatures warm over time with climate change, these infection rates could increase. The No Action/No Project Alternative would result in continued substantial deleterious effects on salmon in terms of fish disease.

Algal Toxins

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the No Action/No Project Alternative, high nutrient inputs supporting the growth of toxin-producing nuisance algal species such as *M. aeruginosa* in Upper Klamath Lake would remain similar to existing conditions for decades into the future. This would result in the potential for continued bioaccumulation of microcystin in suckers in Upper Klamath Lake and could be deleterious to fish health. Upon full attainment of the TMDLs (implementation mechanism and timing currently unknown), nutrients and toxin-producing nuisance algal species would likely decrease (see Sections 3.2.4.3.1.6 Chlorophyll-a and Algal Toxins – Lower Klamath Basin and 3.4.4.3.1 Alternative 1: No Action/No Project Alternative –Phytoplankton for additional detail regarding TMDLs and algal growth). Accordingly, with full attainment of the TMDLs, improvements to microcystin tissue levels in suckers in the lake would be expected.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Continued impoundment of water at the Four Facilities under the No Action/No Project Alternative would support growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa* in Copco 1 and Iron Gate Reservoirs, resulting in high seasonal concentrations of algal toxins in the Hydroelectric Reach for decades into the future. This would result in continued bioaccumulation of microcystin in fish tissue for species in the Hydroelectric Reach and could be deleterious to fish health. Upon full attainment of the TMDLs (implementation mechanism and timing currently unknown), nutrients and toxin-producing nuisance algal species would likely decrease in the Hydroelectric Reach (see subsection of Section 3.2.4.3.1, Chlorophyll-a and Algal Toxins – Upper Klamath Basin, and Section 3.4.4.3.1, Alternative 1: No Action/No Project Alternative –Phytoplankton, for additional detail regarding TMDLs and algal growth in the Hydroelectric Reach). Accordingly, with full attainment of the TMDLs, improvements to microcystin tissue levels in fish in the Hydroelectric Reach would be expected.

Lower Klamath River: Downstream from Iron Gate Dam Continued impoundment of water at the Four Facilities under the No Action/No Project Alternative would continue to support growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa* in Copco 1 and Iron Gate Reservoirs and subsequent transport of high seasonal concentrations of algal toxins to the Klamath River downstream from Iron Gate Dam. This would also support continued bioaccumulation of microcystin in fish and mussel tissue for species downstream from the dam. Upon full attainment of the TMDLs (implementation mechanism and timing currently unknown), nutrients and toxin-producing nuisance algal species would decrease in the Hydroelectric Reach (see subsection of Sections 3.2.4.3.1, Chlorophyll-a and Algal Toxins – Lower Klamath Basin, and Section 3.4.4.3.1, Alternative 1: No Action/No Project Alternative – Phytoplankton, for additional detail regarding TMDLs and algal growth in the Klamath River downstream from Iron Gate Dam). Accordingly, with full attainment of the TMDLs, improvements to microcystin tissue levels in fish in the Klamath River downstream from Iron Gate Dam would be expected.

Aquatic Habitat

Under the No Action/No Project Alternative, hydrology and aquatic habitat of the Klamath River from its headwaters to the estuary would generally remain the same as under existing conditions, subject to the influence of climate change (discussed under Section 3.10, Greenhouse Gases/Global Climate Change). As described in the subsection of Section 3.3.3.3.7, Under the No Action Alternative, Klamath River flows were simulated following the instream flow requirements established for operation of Reclamation's Klamath Project under the reasonable and prudent alternative (RPA) described with in the 2010 Biological Opinion (NOAA Fisheries Service 2010a).

Activities currently underway to improve aquatic habitat and recover salmonid and sucker populations within the Klamath Basin would continue at their current levels. The ongoing Wood River Wetland Restoration, Agency Lake and Barnes Ranches Project, and the Williamson River Delta Project would likely improve resident fish habitat in the Upper Klamath Basin. Recovery actions to improve aquatic habitat under the Klamath River Coho Salmon Recovery Plan would continue, depending on available funding. These actions are anticipated to improve aquatic habitat conditions over time relative to current conditions. However, anadromous fish would continue to be blocked from access to historical habitat.

Under the No Action/No Project, PacifiCorp would need to obtain a long-term operating license for the Klamath Hydroelectric Project from FERC to continue operating the Project (FERC 2007). Until a new license is issued, operations would continue under the annual license terms, and effects on aquatic habitat would continue as described in Section 3.3.3.3.7.

Aquatic Resources Effects

Critical Habitat

As described below, continued impoundment of water within reservoirs under the No Action/No Project Alternative could alter the water quality and habitat suitability within critical habitat.

Coho Salmon As described above in detail, under the No Action/No Project Alternative, habitat supporting PCEs for coho salmon will continue to be degraded (NOAA Fisheries Service 1999b, NOAA Fisheries Service 2010a). Spawning habitat would continue to be impaired by sediment and instream flows within tributary streams, with little mainstem spawning. Rearing habitat with food resources would continue to be impaired as result of habitat degradation, high water temperature, and disease within tributaries and the mainstem. Water quantity supporting PCEs would continue to be depleted both within tributaries and within the mainstem. The quality of PCEs would likely improve gradually over time, through the actions undertaken under the Klamath River Coho Salmon Recovery Plan. TMDL implementation is anticipated to result in improved water quality to meet PCEs; however, this could take decades to achieve, and water quality initially would be reduced and remain poor similar to that under existing conditions. Also, full attainment of the water temperature TMDLs would be partially offset by climate

change. **The effect of the No Action/No Project Alternative would be no change from existing conditions for coho salmon critical habitat in the short and long term.**

Bull Trout Because bull trout are restricted in distribution to the headwaters of limited number of streams, under the No Action/No Project Alternative, PCEs of critical habitat supporting bull trout are not expected to be affected by implementation of the Oregon TMDL processes. Over the long-term, climate change would be expected to result in warmer temperatures, although the headwater streams supporting bull trout may be affected less than other environments due to influence of groundwater. **The effect of the No Action/No Project Alternative would be no change from existing conditions for bull trout critical habitat in the short and long term.**

Southern Resident Killer Whale The Klamath River may affect PCEs of critical habitat for Southern Resident Killer Whales through its potential contribution of Chinook salmon to the food supply for Southern Resident Killer Whales, the survival and fecundity of which appears dependent upon the abundance of this species (Ward et al. 2009; Ford et al. 2009). Chinook salmon originating from the Fraser River are the dominant prey of resident killer whales in the summer months when they are usually in inland marine waters (Hanson et al. 2010). Less is known of their diet during the remainder of the year (September through May) when they spend much of their time in outer coastal waters, but it is believed likely that they preferentially feed on Chinook salmon when available, and roughly in proportion to their relative abundance (Hanson et al. 2010). The contribution of Klamath-origin salmonids to the diet of Southern Residents is unknown, but during this period they may travel from central California to northern British Columbia (Krahn et al. 2004, as cited in Hanson et al. 2010). No change from existing conditions is expected in the short term.

TMDL implementation in the Basin is expected to improve water quality conditions over time although they could take decades to achieve. Such improvements in water quality might result in increased Chinook salmon production over time. However, full attainment of the water temperature TMDL would be partially offset by climate change. **The effect of the No Action/No Project Alternative would be no change from existing conditions for Southern Resident Killer Whale critical habitat in the short and long term.**

Eulachon

Under the No Action/No Project Alternative, PCEs of critical habitat supporting eulachon are not anticipated to change relative to existing conditions. **The effect of the No Action/No Project Alternative would be no change from existing conditions for Eulachon critical habitat in the short and long term.**

Essential Fish Habitat

Dams and the continued impoundment of water within reservoirs under the No Action/No Project Alternative could alter the availability and suitability of EFH.

Chinook and Coho Salmon EFH Under the No Action/No Project Alternative, EFH for Chinook and coho salmon would be expected to remain similar to its current condition. Access to habitat would be limited to its current levels; water quality would improve through TMDL implementation, but would be partially offset by warming expected as a result of climate change. The amount of suitable habitat in currently accessible tributaries would likely be reduced by climate change. Conditions under the No Action/No Project Alternative would continue to contribute to elevated concentrations of disease parasites and would provide the conditions required for the cross infection of fish and polychaetes (Hetrick et al. 2009; Hamilton et al. 2011). These interacting factors could decrease the viability of Chinook and coho salmon populations in the future (Hetrick et al. 2009; Hamilton et al. 2011). **The effect of the No Action/No Project Alternative would be no change from existing conditions for Chinook and coho salmon EFH in the short and long term.**

Groundfish EFH Under the No Action/No Project Alternative, sediment and habitat conditions in the estuary and nearshore ocean would remain the same as they are under existing conditions. **The effect of the No Action/No Project Alternative would be no change from existing conditions for groundfish EFH in the short and long term.**

Pelagic Fish EFH Under the No Action/No Project Alternative, sediment and habitat conditions in the estuary and nearshore ocean would continue to be the same as they are under existing conditions. **The effect of the No Action/No Project Alternative would be no change from existing conditions for pelagic fish EFH in the short and long term.**

Species-Specific Impacts

As described below, continued impoundment of water within reservoirs under the No Action/No Project Alternative, and the continued blockage of habitat access at project dams, could affect aquatic species.

Species-specific impacts are based upon existing conditions for key ecological attributes summarized above.

Fall-Run Chinook Salmon To help determine if the Proposed Action will advance restoration of the salmonid fisheries of the Klamath Basin, a Chinook Salmon Expert Panel was convened to attempt to answer specific questions that had been formulated by the project stakeholders to assist with assessing the effects of the Proposed Action compared with existing conditions (Goodman et al. 2011). In response to comments the Panel stated with certainty that under the No Action/No Project Alternative, fall-run Chinook salmon within the Klamath River will continue to decline³. However, as described in detail in Section 3.3.3.1.1.1, although abundances are low compared to historical numbers (Table 3.3-1), in a recent review of the population status of Chinook salmon, the BRT (Williams et al. 2011) concluded that the current population (which includes hatchery fish) appear to have been fairly stable for the past 30 years and is not currently in decline.

³ Page 69 of Appendix C of the July 20, 2011 Addendum to Goodman et al. 2011.

As described in Section 3.2, Water Quality, long-term dissolved oxygen levels under the No Action/No Project Alternative would continue to exhibit seasonal variability. These dissolved oxygen levels would not consistently meet Oregon and California Basin Plan water quality objectives for dissolved oxygen, and would not consistently support designated beneficial uses in Oregon for cold-water aquatic life, cool-water aquatic life, warm-water aquatic life, and spawning and in California for cold freshwater habitat, warm freshwater habitat, and spawning habitat beneficial uses. In addition, the thermal regimes downstream from Iron Gate Dam would continue to be altered as a result of project facilities and operations, particularly retention time of water in the reservoirs. As a result, fall-run Chinook salmon spawning downstream from Iron Gate Dam would likely continue to be delayed, and prespawn mortality will continue to occur (Hetrick et al. 2009).

Under the No Action/No Project Alternative, Iron Gate Dam would continue to block fall-run Chinook salmon access to hundreds of miles of historical habitat, which used to extend upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005). This includes around 76 miles of potential habitat within the Klamath Hydroelectric Project, based on approximately 53 miles of potential anadromous fish (steelhead) habitat in the Project Reach (Administrative Law Judge 2006)⁴, taking into consideration the more limited distribution of Chinook salmon relative to steelhead (United States Department of the Interior (DOI) 2007), and including over 22 miles inundated by Klamath Hydroelectric Project reservoirs (Cunanan 2009). The current reservoirs inundate sections of the river that had high sinuosity and complex channels that historically provided excellent salmonid spawning and rearing habitats (Hetrick et al. 2009). The consequences of this ongoing loss of habitat to the population could include reduced resilience to recover from catastrophic disturbances of natural or anthropogenic origin, such as wildfire or chemical spills. Under the No Action/No Project Alternative access to cold water habitat would continue to be severely limited. Because areas upstream of the Iron Gate Dam include cold-water refugia, refugia for outmigrating smolts, and opportunities for the population to adapt to changing temperatures are reduced, whether these temperatures are a result of short- or long-term changes. Under the No Action/No Project Alternative, the system of reservoirs and dams in the hydroelectric reach will continue to create conditions conducive to the spread of parasites among the fall-run Chinook salmon population downstream from Iron Gate Dam, especially where adults (and carcasses) tend to congregate in high numbers, just downstream from Iron Gate Dam (Stocking and Bartholomew 2007, Bartholomew and Foott 2010), but also in other locations further downstream. Additional factors related to the project would continue to exacerbate the situation downstream from Iron Gate Dam, including increased water temperatures and dampened flow and thermal variability, reduced dissolved oxygen concentrations, loss of sediment transport through the reach due to capture of sediment by the dams, and reservoirs contributing plankton to the filter-feeding polychaete hosts of the myxozoan parasites (Hamilton et al. 2011). Under the No Action/No Project Alternative, downstream-migrating juvenile Chinook salmon may

⁴ This also takes into consideration slight differences in the Administrative Law Judge (2006) definition of the Project Reach from what is used in this report.

continue to have high disease infection rates (Bartholomew and Foott 2010) during summer months in some years. Heavy parasite loads may increase disease-related mortality in outmigrant smolts, particularly when water temperatures are high, or may reduce ocean survival by affecting growth or fitness.

Effects of suspended sediment on fall-run Chinook salmon under the No Action/No Project Alternative and existing conditions are described in Appendix E, Section E.3.1.1. Overall, fall-run Chinook salmon use the mainstem Klamath River for spawning, rearing, and as a migratory corridor. Although SSCs under existing conditions and the No Action/No Project Alternative are relatively high in the mainstem downstream from Orleans, and even more so downstream from the Trinity River (California State Water Resources Control Board [SWRCB] 2006, NCRWQCB 2010) (see Section 3.2.3), they are relatively low in the reach downstream from Iron Gate Dam where most mainstem spawning occurs. Suspended sediment concentrations and durations during upstream and downstream migration, even under extreme conditions, are low enough that they have limited effects on fish, although physiological stress and reduced growth rates are possible. In general, fall-run Chinook salmon appear relatively unaffected by current SSCs because smolt outmigration primarily occurs when SSCs are naturally low.

Under the No Action/No Project Alternative, ongoing hatchery operations would continue to mitigate for habitat lost due to construction of Iron Gate Dam by releasing millions of juvenile and yearling Chinook salmon annually. These fish may compete with the progeny of naturally spawned fish for food and other limited resources, such as thermal refugia. In addition, hatchery releases can increase disease infection rates through crowding and, where mortality occurs, concentrated release of myxospores on top of the area of highest polychaete densities. In addition, some adult fish may stray and spawn with wild fish, which can reduce genetic and phenotypic diversity and reproductive success within the wild population (McLean et al. 2003, Araki et al. 2007, Araki et al. 2009, all as cited in Hamilton et al. 2011).

Under the No Action/No Project Alternative, the interruption of sediment transport processes by the dams would continue, reducing spawning gravel supply to downstream reaches and changing the dynamics of channel morphology and riparian vegetation communities that create and maintain rearing habitats for fry and juvenile fall-run Chinook salmon. Lack of sediment transport is also likely to be contributing to the high densities of polychaetes downstream from Iron Gate Dam that host salmonid parasites, through reduction of scour that would otherwise help limit periphyton growth (FERC 2007; Hetrick et al. 2009).

The effect of the No Action/No Project Alternative would be no change from existing conditions for fall-run Chinook salmon in the short and long term.

Spring-Run Chinook Salmon In a recent review of the population status of Chinook salmon, the BRT (Williams et al. 2011) concluded that the current Chinook population (which includes hatchery fish) appear to have been fairly stable for the past 30 years and is not currently in decline, despite dramatic reductions in comparison to historical

abundance (Table 3.3-1). However, the BRT was concerned about the relatively few populations of spring-run Chinook salmon and the low numbers of spawners within those populations (Williams et al. 2011).

Under the No Action/No Project Alternative, poor water quality conditions caused partly by nutrient enrichment during spring-run Chinook salmon upstream and downstream migration may cause high stress. Water quality in the mainstem Klamath River downstream from Iron Gate Dam is characterized by altered seasonal water temperature patterns, dissolved oxygen, and increased nutrient input, as well occasional blooms of *M. aeruginosa*. Although water quality tends to improve downstream from the Salmon River (current upstream extent of spring-run distribution in the Klamath River), the effect of water quality alterations is that conditions (especially water temperature and dissolved oxygen) are critically stressful for spring-run Chinook salmon for much of the summer if they were present during the period June through September. Maximum temperatures often reach 25 °C during summer, considered lethal for most Pacific salmon (Sullivan et al. 2000). Spring Chinook salmon that are stressed by high temperatures, whether adults or juveniles, likely have lower survival rates, especially when challenged by additional water quality factors, such as low dissolved oxygen, the presence of toxic blue-green algae (*M. aeruginosa*) and fish diseases, and high pH and unionized ammonia. Under the No Action/No Project Alternative, downstream-migrating juvenile Chinook salmon may continue to have high disease infection rates (Bartholomew and Foott 2010) during summer months in some years. Heavy parasite loads may increase disease-related mortality in outmigrant smolts, particularly when water temperatures are high, or may reduce ocean survival by affecting growth or fitness.

High water temperatures during summer may also reduce the growth of juvenile fish that are rearing and migrating downstream to the ocean due to greater metabolic requirements. Because size is correlated with ocean survival, this could lead to reduced smolt survival and subsequently, reduced escapement. Finally, high temperatures can selectively reduce the survival of fish migrating later in the summer (the “summer run”), thus reducing genetic and life-history diversity. High water temperatures likely limit adult holding and summer rearing habitat for spring Chinook salmon in main spawning tributaries, the Salmon and Trinity Rivers, which would likely reduce overall production. Low flows in dry years can cause migration barriers to form, reducing habitat available to spawning and rearing fish.

Under the No Action/No Project Alternative, Iron Gate Dam would continue to block spring-run Chinook salmon access to their historical habitat, which used to extend upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005). This includes around 76 miles of potential habitat within the Project reach, based on approximately 53 miles of potential anadromous fish (steelhead) habitat in the Project Reach (Administrative Law Judge 2006)⁵, taking into consideration the more limited distribution of Chinook salmon relative to steelhead (DOI 2007), and including over 22 miles inundated by Klamath Hydroelectric Project reservoirs (Cunanan 2009), and

⁵ This also takes into consideration slight differences in the Administrative Law Judge (2006) definition of the Project Reach from what is used in this report.

habitat within the bypass reaches. The current reservoirs inundate sections of the river that had high sinuosity and complex channels that historically provided excellent salmonid spawning and rearing habitats (Hetrick et al. 2009). In addition, access would continue to be blocked to hundreds of miles of habitat upstream of J.C. Boyle Reservoir (Hamilton et al. 2005). The consequences of this ongoing loss of habitat to the population could include reduced resilience to recover from catastrophic disturbances of natural or anthropogenic origin, such as wildfire or chemical spills. Because areas upstream of Iron Gate Dam include cold-water refugia, opportunities for the population to adapt to changing climate are reduced, whether these changes are a result of short- or long-term cycles or trends.

Effects of suspended sediment on spring-run Chinook salmon under the No Action/No Project Alternative and existing conditions are described in Appendix E, Section E.3.1.2. Overall, spring-run Chinook salmon mostly use the mainstem Klamath River as a migratory corridor during adult migration, and downstream smolt migration. Although suspended sediment under existing conditions and the No Action/No Project Alternative is relatively high in the mainstem Klamath River downstream from Orleans, and especially downstream from the Trinity River (Appendix E), increases in suspended sediment in the mainstem Klamath River during critical migratory periods are low enough in concentration and short enough in duration that effects are limited to physiological stress and possibly inhibited growth, even during extreme conditions.

One of the main spawning streams for spring-run Chinook salmon, the Salmon River has dramatically increased sediment production over historical conditions as a result of road construction, timber harvest, and wildfire disturbance (Elder et al. 2002). Habitat degradation is believed to be the primary cause of the decline of the spring-run salmon population in the Klamath River system. Under the No Action/No Project Alternative, spawning and rearing habitat would continue to be reduced in both quantity and quality, and production may be low in some years.

As described in the subsection of Section 3.3.3.1.1, the extirpation of at least seven spring-run populations from the Klamath-Trinity River system has been attributed to dams, overfishing, irrigation, and commercial hydraulic mining operations (Coots 1962; Snyder 1931; Myers et al. 1998). Under this alternative, dams would continue to block access to historical habitat, and spring-run Chinook salmon are likely to remain at significantly suppressed levels over the years of analysis (50 years).

The effect of the No Action/No Project Alternative would be no change from existing conditions for spring-run Chinook salmon in the short and long term.

Coho Salmon As described in Section 3.2, Water Quality, long-term dissolved oxygen levels under the No Action/No Project Alternative would continue to exhibit seasonal variability. These dissolved oxygen levels would not consistently meet Oregon and California Basin Plan water quality objectives for dissolved oxygen, and would not consistently support designated beneficial uses in Oregon for cold-water aquatic life, cool-water aquatic life, warm-water aquatic life, and spawning and in California for cold

freshwater habitat, warm freshwater habitat, and spawning habitat beneficial uses. In addition, the thermal regimes downstream from Iron Gate Dam would continue to be altered as a result of project facilities and operations, particularly due to retention time of water in the reservoirs.

Under the No Action/No Project Alternative, Iron Gate Dam would continue to block coho salmon to historical habitat which used to extend upstream at least as far as Spencer Creek (Hamilton et al. 2005), including an estimated 76 miles of potential habitat within the Klamath Hydroelectric Project, based on approximately 53 miles of potential anadromous fish (steelhead) habitat in the Project Reach (Administrative Law Judge 2006),⁶ taking into consideration the more limited distribution of coho salmon relative to steelhead (DOI 2007), and including over 22 miles inundated by Klamath Hydroelectric Project reservoirs (Cunanan 2009), and habitat within the bypass reaches. The current reservoirs inundate sections of the river that had high sinuosity and complex channels that historically provided excellent salmonid spawning and rearing habitats (Hetrick et al. 2009). The consequences of this ongoing loss of habitat to the population would include reduced resilience to recover from catastrophic disturbances of natural or anthropogenic origin, such as wildfire or chemical spills (Hamilton et al. 2011). Under the No Action/No Project Alternative access to cold water habitat would continue to be severely limited. Because areas upstream of the Iron Gate Dam include cold-water refugia, refugia for outmigrating smolts, and opportunities for the population to adapt to changing temperatures are reduced, whether these temperatures are a result of short- or long-term changes. The above factors could reduce the natural genetic and life-history diversity found in Klamath Basin subpopulations of coho salmon that make them ideally suited to adapting to changing watershed conditions.

Under the No Action/No Project Alternative, upstream-migrating adult coho salmon will continue to be exposed to high water temperatures and poor water quality in the mainstem Klamath River, which can cause physiological stress, delay migration, reduce coldwater refugia, and increase mortality from disease. Low flows and increased sedimentation in tributaries can create barriers at the mouths of spawning streams, which would reduce spawning habitat area and production under the No Action/No Project Alternative in some years.

Effects of suspended sediment on coho salmon under the No Action/No Project Alternative and existing conditions are described in Appendix E Section E.3.1.3. Overall, under existing conditions and the No Action/No Project Alternative, SSCs in the mainstem are sufficiently high and of long enough duration that major physiological stress and reduced growth of coho salmon are anticipated in most years. Suitable rearing habitat for juvenile coho salmon under the No Action/No Project Alternative would continue to be restricted by high temperatures in some areas. High water temperatures may promote higher incidence of disease or parasitism, which may increase direct and indirect mortality (Stutzer et al. 2006, NOAA Fisheries Service 2010a). During a 2008 PIT-tag study of juvenile coho salmon in the Shasta River, Chesney et al. (2009) found

⁶ This also takes into consideration slight differences in the Administrative Law Judge (2006) definition of the Project Reach from what is used in this report.

juvenile coho salmon only in areas where temperatures were moderated by cold springs; the remainder of potential rearing habitat was too warm (>20°C). Rearing habitat would continue to be compromised by livestock grazing and the legacy of logging impacts in riparian habitat that simplify channel and floodplain interactions that are conducive to creating habitat for rearing coho salmon in the winter.

Under historical, unregulated conditions, an annual spring pulse flow occurred in the Klamath River and in its tributaries (NRC 2004). Under current conditions a spring pulse still occurs, but is altered by water management. The magnitude of the spring flow is believed to have historically resulted in higher survival of coho salmon juvenile outmigrants and smolts relative to current conditions through several mechanisms, including (1) reduced rates of infection in juvenile salmon by *C. shasta* and *P. minibicornis*, (2) a reduced period of residency spent in the mainstem prior to smolting, and (3) greater habitat availability in the mid-Klamath River (Hardy et al. 2006), especially in the reach between Shasta River and Scott River where survival is particularly poor (Beeman et al. 2008). It is speculated that this low outmigrant survival limits habitat restoration efforts on the Shasta and Scott rivers from realizing their potential to increase population abundance.

High numbers of hatchery fish may affect wild coho salmon in the Klamath Basin under the No Action/No Project Alternative. The vast majority of coho salmon that spawn in the Klamath Basin are believed to be of hatchery origin, although the percentage varies among years (Ackerman et al. 2006).

Coho salmon populations in the Klamath Basin are in decline; less than 70 percent of streams historically used by coho salmon in the Basin still contain small populations (NRC 2004). The No Action/No Project Alternative would likely continue to produce the types of habitat alterations that have helped to cause this decline.

More detail on current conditions for coho salmon can be found in NOAA Fisheries Service's (2010a) *BO on operation of the Klamath Project between 2010 and 2018*.

The effect of the No Action/No Project Alternative would be no change from existing conditions for coho salmon from all populations within the Klamath River watershed in the short and long term.

Steelhead As described in Section 3.2, Water Quality, long-term dissolved oxygen levels under the No Action/No Project Alternative would continue to exhibit seasonal variability. These dissolved oxygen levels would not consistently meet Oregon and California Basin Plan water quality objectives for dissolved oxygen, and would not consistently support designated beneficial uses in Oregon for cold-water aquatic life, cool-water aquatic life, warm-water aquatic life, and spawning and in California for cold freshwater habitat, warm freshwater habitat, and spawning habitat beneficial uses. In addition, the thermal regimes downstream from Iron Gate Dam would continue to be altered as a result of project facilities and operations, particularly by the retention time of water in the reservoirs.

Summer steelhead use the mainstem Klamath River primarily as a migration corridor because most spawning and rearing occurs in the tributaries. Under the No Action/No Project Alternative, summer steelhead spawning and rearing habitat availability and distribution would continue to be restricted during summer and fall to reaches downstream from Seiad Valley by high water temperatures farther upstream. Conditions in the mainstem are generally suitable for adult upstream migration; however, high water temperatures in the late summer and fall may restrict movements and spawning distribution of later-arriving adults. Under a more normative flow regime, temperatures would be cooler in the summer and fall months for adult migrating fish (Bartholow et al. 2005; FERC 2007). Altered flow patterns downstream from Iron Gate Dam may thus be affecting the population by selecting for earlier-arriving fish, potentially reducing life-history diversity in the population. In addition, this represents an ongoing loss of habitat that might otherwise be contributing to smolt production, survival, and escapement. Water temperatures are likely to rise over the next decades as a result of climate change, which could result in further reduction of suitable habitat, with potential consequences for steelhead population abundance.

Fall and winter steelhead are more widely distributed than any other anadromous salmonid downstream from Iron Gate Dam. Under the No Action/No Project Alternative, they would continue to be restricted from 360 miles of historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood Rivers (Huntington 2006), including access to cold-water refugia that could buffer the population to effects from climate change (Hamilton et al. 2005). In addition, there are around 80 miles of potential habitat within the Klamath Hydroelectric Project, based on around 53 miles of anadromous habitat with the Project reach (Administrative Law Judge 2006), including over 22 miles inundated by Klamath Hydroelectric Project reservoirs (Cunanan 2009), and habitat within the bypass reaches. The current reservoirs inundate sections of the river that had high sinuosity and complex channels that historically provided excellent salmonid spawning and rearing habitats (Hetrick et al. 2009). As with summer steelhead, fall and winter steelhead use the mainstem primarily as a migration corridor to access tributaries for spawning. Increases in fine sediment in tributaries used by steelhead for spawning could be reducing egg-to-emergence survival in some tributaries. Under the No Action/No Project Alternative, high summer water temperatures in the summer months can cause density-independent mortality on juveniles that have left spawning tributaries to rear in the mainstem.

Effects of suspended sediment on steelhead under the No Action/No Project Alternative and existing conditions are described in Appendix E, Section E.3.1.4. Overall, steelhead use the mainstem Klamath River as a migratory corridor during adult migration, and downstream smolt migration, and for juvenile rearing. Although SSCs under existing conditions and the No Action/No Project Alternative are relatively high in the mainstem Klamath River downstream from Orleans, and especially downstream from the Trinity River (SWRCB 2006, NCRWQCB 2010) (see Section 3.2.3), SSC in the mainstem Klamath River during critical migratory periods, even during extreme conditions, are low enough and exposure times short enough that effects are likely limited to physiological stress and possibly reduced growth rate. Conditions for fish rearing in the mainstem are

likely worse, but in general steelhead appear resilient to suspended sediment regimes under existing conditions and the No Action/No Project Alternative.

Habitat conditions for juvenile steelhead rearing in the mainstem are generally suitable, except for reaches upstream of Seiad Valley where summer water temperatures are considered stressful. Juvenile outmigration peaks in the spring and extends through the summer and fall. Growth during their rearing and outmigration may be reduced by high temperatures due to increased metabolism, which can reduce ocean survival. High summer water temperatures causing physiological stress to fish can also make them more vulnerable to mortality from disease or other compounding factors.

The effect of the No Action/No Project Alternative would be no change from existing conditions for steelhead in the short and long term.

Pacific Lamprey Pacific lamprey populations appear to have been in decline since the late 1980s in the Klamath Basin; (Larson and Belchik 1998; Moyle et al. 2009; all as cited in Hamilton et al. 2011), and are considered “vulnerable” throughout their range by the American Fisheries Society (Jelks et al. 2008, as cited in Hamilton et al. 2011). Major factors believed to be affecting their populations include barriers to upstream migration at dams; dewatering of larval habitat through flow regulation; reducing larval habitat by increasing water velocity and/or reducing sediment deposition areas; and susceptibility to contaminants in the larval stage (Close et al. 2002, as cited in Hamilton et al. 2011).

Under the No Action/No Project Alternative, Iron Gate Dam would continue to form a barrier to Pacific lamprey migration, which represents an ongoing loss of available habitat and productive capacity. Although the exact upstream extent of suitable habitat for Pacific lamprey prior to the completion of the Four Facilities is unknown, it is believed that Pacific lamprey would have migrated at least as far as Spencer Creek (Hamilton et al. 2005, as cited in Hamilton et al. 2011). The loss of this portion of spawning and larval rearing habitat reduces the Basin’s population viability through contracting their distribution within the watershed and reducing abundance.

Under the No Action/No Project Alternative, the dams would continue to reduce sediment supply to the mainstem Klamath River downstream from Iron Gate Dam, which may limit availability of gravel-cobble substrates for nest building and fine sediment for burrowing; armoring of substrate would also be expected to reduce spawning habitat quality. The overall effect on the Basin population is likely to be small because (1) the effects of the dam on fine sediment and gravel/cobble substrates diminish with distance downstream because of input from tributaries and become less significant downstream from Cottonwood Creek (RM 182.1), and (2) a large proportion of the population may spawn and rear in large tributaries to the mainstem, such as the Trinity, Salmon, Shasta, and Scott Rivers.

Effects of suspended sediment on Pacific lamprey under the No Action/No Project Alternative and existing conditions are described in Appendix E, Section E.3.1.5. Overall, under both normal and extreme conditions, Pacific lamprey are anticipated to

suffer from stressful levels of suspended sediment while rearing and migrating through the mainstem Klamath River, with exposure durations generally much longer under extreme conditions. Because there are multiple year-classes of lamprey in the mainstem Klamath River at any given time, and since adults may migrate upstream throughout the year, Pacific lamprey populations may be well-adapted to persisting through years when SSCs are high, especially since they remain within the sublethal range.

The effects of dams and reservoirs would continue to affect water quality downstream from Iron Gate Dam under the No Action/No Project Alternative, which may reduce habitat quality for spawning and rearing Pacific lamprey, as well as reproductive success. Stone et al. (2002) found dissolved oxygen to be positively associated with lamprey presence at the reach scale ($P = 0.0002$). Meeuwig et al. (2005) reported that survival of larval Pacific lamprey under laboratory conditions was optimal at 18°C, but declined sharply at 22°C, with eggs and larvae at these higher temperatures also exhibiting deformities. Under existing conditions and the No Action/No Project Alternative water quality would improve through TMDL implementation, but would be partially offset by warming expected as a result of climate change.

Flow management under a No Active/No Project Alternative would continue to modify temperature and instream flow patterns from pre-project conditions. Movements of adult, ammocoete, and macrophthalmia Pacific lamprey life stages tend to occur in association with discharge, while temperature and day length may be of less importance as life-history cues (Stone et al. 2002, Luzier et al. 2009). Stone et al. (2002) observed downstream migration of macrophthalmia (juvenile phase) in Cedar Creek in association with summer low flows, with larger ammocoetes also moving downstream during this period as well, indicating that such movements were voluntary. In contrast, Beamish and Levings (1991, as cited in Stone et al. 2002) found that macrophthalmia downstream movements to be associated with high flows, but also observed greater downstream movement of larger, older ammocoetes during these periods.

High discharge appeared to result in involuntary downstream displacement of ammocoetes (especially of smaller individuals) and macrophthalmia outside of their normal migration period, which may reduce survival (Stone et al. 2002).

Under the No Action/No Project Alternative, Pacific lamprey populations in the Klamath Basin may remain at current levels or population numbers may continue to decline over the long term (Close et al. 2010). Because so little is known of Pacific lamprey life history and habitat requirements compared to those of anadromous salmonids, it is more difficult to predict the potential effects of alternatives on their abundance and distribution. **The effect of the No Action/No Project Alternative would be no change from existing conditions for Pacific lamprey in the short and long term.**

Green Sturgeon Green sturgeon spend a majority of their lives in estuaries, bays, and nearshore waters, with adults only returning to fresh water to spawn after more than

15 years, and spawning every 4 years on average (Klimley et al. 2007). In the Klamath River mainstem, green sturgeon spawn and rear in the lower 67 miles, downstream from Ishi Pishi Falls.

The Klamath Basin supports the largest spawning population of Northern Green Sturgeon (Moyle 2002), so it plays a critically important role in the viability and persistence of the entire DPS. Concentration of spawning to only a very few areas renders these spawning populations vulnerable to local catastrophic impacts. A loss of any of the few spawning areas would have much greater effects than the loss of a spawning population of salmon that spawn in other streams throughout their range.

Under the No Action/No Project Alternative, temperatures in the Lower Klamath River in dry years may be reducing reproductive success of green sturgeon (Van Eenennaam et al. 2005). Studies conducted by Van Eenennaam et al. suggest that temperatures above 17–18 °C are suboptimal for hatching and embryonic development, with temperatures from 23 °C to 26 °C resulting in 100 percent pre-hatching mortality. Cech et al. (2000) put the lethal temperature for embryos at 20 °C.

Effects of suspended sediment on green sturgeon under the No Action/No Project Alternative and existing conditions are described in Appendix E. Overall, under existing conditions and the No Action/No Project Alternative, green sturgeon in the Klamath River mainstem are regularly exposed to SSCs documented to cause major physiological stress, reduced growth, and mortality in other fish species, especially during their egg and larval stages, and the year-round juvenile rearing period. However, based on the persistence of their population under these conditions, these metrics likely overestimate effects on green sturgeon.

The effect of the No Action/No Project Alternative would be no change from existing conditions for green sturgeon in the short and long term.

Lost River and Shortnose Sucker

Upper Klamath Lake, one of the primary habitats of Lost River and shortnose suckers, has long been recognized as eutrophic, characterized by extremely high temperatures and pH in the summer, accompanied by huge daily fluctuations in dissolved oxygen and high ammonia concentrations. Recent land use disturbances and changes in hydrology have led to hypereutrophic conditions in Upper Klamath Lake that frequently violate water quality standards and place designated beneficial uses in the lake and in the receiving waters of the Klamath River at risk (Section 3.2.3.4). Although eutrophic conditions in Upper Klamath Lake have caused fish die-offs since the late 1800s, these have become more frequent and severe in recent years with the hypereutrophic conditions, with chubs and suckers being perhaps the hardest hit species (Perkins et al. 2000, Buchanan et al. 2011a, as cited in Hamilton et al. 2011). Upper Klamath Lake inflows and outflows have declined since the 1960s while demand for water has increased for both agriculture and endangered fish species recovery. Along with direct mortality, poor water quality in

Upper Klamath Lake affects endangered sucker species through suppressing growth, reducing resistance to disease and parasites, and reducing reproductive success (Hamilton et al. 2011).

Under current conditions, suckers in reaches of the Four Facilities suffer mortality by entrainment in hydroelectric project turbines (Gutermuth et al. 2000). (Partially effective fish screens at J.C. Boyle facility would continue to contribute to entrainment (Administrative Law Judge 2006)). Suckers would continue to be stranded due to Four Facilities operations and peaking.

Shortnose and Lost River suckers would continue to be subject to poor water quality within reservoirs. However, with little or no successful reproduction (Buettner et al. 2006), populations downstream from Keno Dam contribute minimally to conservation goals and insignificantly to recovery (Hamilton et al. 2011). Under the No Action/No Project Alternative this population would persist, providing some additional insurance, no matter how small, that fish would be available for recolonization efforts if for some reason their primary populations underwent catastrophic decline. This would only be feasible with a species of this type, which is extremely long-lived.

Under the No Action/No Project Alternative, existing efforts to restore habitat for shortnose and Lost River sucker and improve water quality conditions would continue. These actions would be expected to improve conditions for these species over time and their populations would be expected to increase. **The effect of the No Action/No Project Alternative would be no change from existing conditions for Lost River and shortnose sucker populations in the short and long term.**

Redband Trout Resident trout upstream of Iron Gate Dam are considered to be redband trout. Before construction of the Four Facilities, redband trout in the area belonged to one population, with no migration barriers isolating populations from one another (Administrative Law Judge 2006). Under the No Action/No Project Alternative, genetic exchange and movement between reaches would continue to be limited by the J.C. Boyle fish ladder (Administrative Law Judge 2006) and lack of fish ladders at the Copco 1 and 2 Dams, as will access to productive spawning habitat in Spencer Creek by redband trout in the J.C. Boyle Bypass and Peaking Reaches (Administrative Law Judge 2006). The isolation of this population into several smaller subpopulations renders each more vulnerable to extinction due to stochastic events (wildfire, landslides, disease outbreaks, etc.) and limits genetic exchange among subpopulations.

Redband trout populations in the Four Facilities reaches and reservoirs are generally isolated from the larger populations upstream of Upper Klamath Lake, such as in the Williamson and Wood Rivers; little to no natural recruitment from the Upper Klamath Basin to populations in project-affected reaches can occur, as may have occurred historically.

Under the No Action/No Project Alternative, water quality in the Keno Reach would continue to be influenced by Keno Impoundment/Lake Ewauna upstream. In the

summer, problems with low dissolved oxygen, high nutrients, and warm temperatures (occasionally exceeding 21°C) may increase physiological stress on redband trout, making them more vulnerable to mortality from other stressors. Measures implemented to meet TMDL targets would likely improve water quality in this area to some degree.

Under the No Action/No Project Alternative, habitat connectivity for redband trout in the Klamath River would continue to be compromised by structural features of the Four Facilities as well as project operations. Fish downstream from J.C. Boyle Dam would continue to be hindered or obstructed from migrating to spawning grounds in Spencer Creek by requiring them to ascend a fish ladder at J.C. Boyle Dam (Hamilton et al. 2011). Spencer Creek is a highly productive spawning and rearing habitat for rainbow/redband trout. The stock of rainbow/redband trout in the bypass and peaking reaches below J.C. Boyle Dam is currently restricted from Spencer Creek and other suitable habitat upstream of the J.C. Boyle Dam (Administrative Law Judge 2006). Factors influencing their movements include the necessity of passage at the J.C. Boyle Dam fish ladder as well as stresses resulting from power peaking operations downstream from the dam. Migration over the Copco 1 and 2 Dams is in the downstream direction only, as there is no fishway at this Project feature.

The lack of functioning fish screens at Iron Gate, Copco 1 and 2 Dams minimizes recruitment of redband trout to downstream reaches, another factor adding to isolation of subpopulations in the Four Facilities area. At the J.C. Boyle facility, the partially effective fish screens would continue to contribute to entrainment (Administrative Law Judge 2006). The J.C. Boyle facility uses Francis turbines, at an operational head of 440 feet. A 1987 report prepared by the Electric Power Research Institute (EPRI) concluded that fish mortality from entrainment at hydroelectric projects using Francis turbines averaged 24 percent. The EPRI report found that entrainment mortality at hydroelectric projects using Francis turbines with operational head greater than 335 feet ranged from 33-48 percent (Administrative Law Judge 2006). It is estimated that “several tens of thousands of resident fish” are annually entrained at “each of the Projects” facilities (Administrative Law Judge 2006).

The health and productivity of redband trout in the J.C. Boyle Peaking Reach and J.C. Boyle Bypass Reach would continue to be affected under the No Action/No Project Alternative. Obstruction of sediment transport at J.C. Boyle Dam has altered substrates and channel features in the peaking and bypass reaches. High flows have mobilized and removed sediment from storage sites and transported them downstream, reducing habitat quality for redband trout as well as for the macroinvertebrates they feed on. In the J.C. Boyle Peaking Reach, redband trout numbers would continue to be subject to large fluctuations in flows that: (1) cause fluctuations in water temperature and pH, (2) strand fish, (3) displace fish downstream, (4) reduce fry habitat along channel margins, (5) reduce access to suitable gravels where they are affected by flow fluctuations, and (6) reduce macroinvertebrate food production by reducing the area of the channel suitable for their survival (City of Klamath Falls 1986, Addley et al. 2005, as cited in Hamilton et al. 2011). All of these conditions could result in substantial declines in redband trout abundance in this reach.

Diversion of water at Keno Diversion Dam would continue to alter flows downstream, reducing base flows in the summer when water quality is a concern, and reducing the magnitude and frequency of high flows important for creating and maintaining physical and ecological processes that affect habitat for trout, their macroinvertebrate food, and other aquatic organisms. Reduced flows in the 1.4 mile long Copco 2 Bypass Reach would continue to prevent redband trout from using what would otherwise be complex habitat suitable for spawning and rearing. Productivity of redband trout in the bypass and peaking reaches would continue to be suppressed by Four Facilities effects that limit spawning and rearing habitat in these reaches (Hamilton et al. 2011). Under existing conditions, spawning of redband trout in the Bypass Reach appears limited to an area just downstream from the emergency canal spillway (Hamilton et al. 2011). Patches of gravel that might otherwise be suitable for spawning are rendered inaccessible to redband trout by reductions in instream flows (ODFW 2003, Administrative Law Judge 2006, all as cited in Hamilton et al. 2011).

Reduced redband trout abundance and distribution upstream of Iron Gate Dam attributable to Four Facilities features and operations would continue under the No Action/No Project Alternative. Habitat connectivity and suitability are substantially reduced in some reaches, which also suppresses the full range of life-history options formerly available to them. Other features of the redband trout populations in these reaches would likely be sustained under the No Action/No Project Alternative, such as declines in size (Jacobs et al. 2008, as cited in Hamilton et al. 2011) and condition factor (ODFW 2003, as cited in Hamilton et al. 2011).

The effect of the No Action/No Project Alternative would be no change from existing conditions for redband trout in the short and long term.

Bull Trout The distribution and numbers of bull trout are believed to have declined in the Klamath Basin due to habitat isolation, loss of migratory corridors, poor water quality, and the introduction of nonnative species. The geographic isolation of the Klamath populations places them at greater risk of genetic effects and extirpation (NRC 2004).

The effect of the No Action/No Project Alternative would be no change from existing conditions for bull trout in the short and long term.

Eulachon The southern population of Pacific eulachon consists of populations spawning in rivers south of the Nass River in British Columbia, Canada, to and including the Mad River in California (NOAA Fisheries Service 2009a). On March 18, 2010, NOAA Fisheries Service listed the southern DPS of eulachon as threatened under the ESA (NOAA Fisheries Service 2010b). Historically, the Klamath River was described as the southern limit of the range of eulachon (Gustafson et al. 2010). Moyle (2002) indicates that eulachon have been scarce in the Klamath River since the 1970s, with the exception of three years: they were plentiful in 1988 and moderately abundant again in 1989 and 1998. After 1998, they were thought to be extinct in the Klamath Basin, until a small run was observed in the estuary in 2004. Under the No Action/No Project Alternative,

habitat conditions in the estuary for eulachon would remain the same as they are under existing conditions. However, very little is known about the factors leading to decline of the eulachon.

The effect of the No Action/No Project Alternative would be no change from existing conditions for eulachon in the short and long term.

Longfin Smelt Longfin smelt are a State-listed threatened species throughout their range in California, but the USFWS denied the petition for Federal listing because the population in California (and specifically San Francisco Bay) was not believed to be sufficiently genetically isolated from other populations (USFWS 2009). The importance of ocean rearing is unknown. Little is known about longfin smelt populations in the Klamath River, except that they are presumably small.

The effect of the No Action/No Project Alternative would be no change from existing conditions for longfin smelt in the short and long term.

Introduced Resident Species Introduced resident species occur in Lake Ewauna, Upper Klamath Lake, within reservoirs upstream of Iron Gate Dam, and infrequently downstream from Iron Gate Dam. Under the No Action/No Project Alternative, conditions favorable for introduced species would continue to occur within the Four Facilities reservoirs (Buchanan et al. 2011a). Because these species were introduced and they occur in other nearby water bodies, their abundance is not considered a benefit from a biological perspective.

The effect of the No Action/No Project Alternative would be no change from existing conditions for introduced resident species in the short and long term.

Freshwater mussels The Klamath River appears unusual compared to other Pacific Northwest rivers in that western ridged mussels (*G. angulata*) dominate the freshwater mussel community; of the species found on the mainstem Klamath River, the western ridged mussel seems to be the most abundant and is widely distributed between Iron Gate Dam and the confluence of the Trinity River; (Westover 2010). The floater species (*Anodonta spp.*) are less abundant, with the largest single bed found immediately downstream from Iron Gate Dam (Westover 2010). The western pearlshell (*Margaritifera falcata*) is the least abundant freshwater mussel found in the Klamath River and seems to be mostly found downstream from the confluence of the Salmon River (Westover 2010).

The effect of the No Action/No Project Alternative would be no change from existing conditions for freshwater mussels in the short and long term.

Benthic Macroinvertebrates Under existing conditions, Klamath Hydroelectric Project peaking operations kill, through stranding, large numbers of young fish and aquatic invertebrates that are the primary prey food for resident trout (Administrative Law Judge 2006). Current peaking operations reduce the production of sessile organisms, like

macroinvertebrates, by 10 to 25 percent (Administrative Law Judge (2006)). Macroinvertebrate drift rates, a measure of food availability for trout, in the non-peaking Keno Reach were five to six times greater than in the peaking reach. Fluctuations in the peaking reach are considered to be a contributing factor to the lower macroinvertebrate drift rates (Administrative Law Judge (2006)).

The effect of the No Action/No Project Alternative would be no change from existing conditions on macroinvertebrates in the short and long term.

Interim Measures

Implementation of J.C. Boyle Gravel Placement and/or Habitat Enhancement and the Coho Enhancement Fund could result in alterations to habitat availability and habitat quality, and affect aquatic species. Under the J.C. Boyle Gravel Placement and/or Habitat Enhancement suitable spawning gravel would be placed in the J.C. Boyle Bypass and Peaking Reaches beginning in the fall of 2011 for one year (it is assumed that work would cease in the event of a Negative Determination). This IM would involve placing gravel using a passive approach before high flow periods, or developing other habitat enhancement measures to provide equivalent fishery benefits in the Klamath River upstream of Copco Reservoir. These actions would provide improvements in habitat quality for resident fish prior to dam removal, and for resident and anadromous species following dam removal.

The Coho Enhancement Fund would provide funding for specific projects or actions that would create, maintain, and improve access by coho salmon to important tributary habitats downstream from Iron Gate Dam that are within the potential range of the Upper Klamath coho salmon population. The projects would involve removal of existing fish passage barriers, gravel augmentation, improving/maintaining habitat cover and complexity at coldwater refugia sites, increasing the duration and/or extent of coldwater refugia sites, enhancing habitat in rearing tributaries, restoring connectivity of juvenile rearing habitat in tributaries of the Upper Klamath, Scott, and Shasta Rivers, funding a program to provide flow augmentation in key reaches used for coho spawning and juvenile rearing in the Upper Klamath, Scott, and Shasta Rivers, enhancing habitat in rearing tributaries of the Upper Klamath, Scott, and Shasta Rivers, and protecting summer rearing habitat in tributaries of the Upper Klamath, Scott, and Shasta Rivers (PacifiCorp 2011). **Based on anticipated improvements in habitat availability and habitat quality, implementation of J.C. Boyle Gravel Placement and/or Habitat Enhancement and the Coho Enhancement Fund under the No Action/No Project Alternative would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, redband trout, and benthic macroinvertebrates. These actions would also be beneficial for coho salmon from the Upper Klamath River Population Unit, and less-than-significant for all other population units in the Basin. Effects on bull trout, freshwater mussels, shortnose and Lost River suckers would be less-than-significant. Effects on green sturgeon, eulachon, and Southern Resident Killer Whales would not change from existing conditions.**

Implementation of J.C. Boyle Bypass Barrier Removal could result in alterations to habitat availability, and affect aquatic species. Under this IM, the sidecast rock barrier located approximately three miles upstream of the J.C. Boyle Powerhouse in the J.C. Boyle Bypass Reach would be removed. The objective of this IM is to provide for the safe, timely, and effective upstream passage of Chinook and coho salmon, steelhead, Pacific lamprey, and redband trout. This action would provide improvements in habitat availability for resident fish prior to dam removal, and for resident and anadromous species following dam removal. **Based on anticipated improvements in habitat availability, implementation of J.C. Boyle Bypass Barrier Removal under the No Action/No Project Alternative would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, and redband trout. These actions would also be beneficial for coho salmon from the Upper Klamath River Population Unit, and less-than-significant for all other population units in the Basin. Effects on bull trout, shortnose and Lost River suckers would be less-than-significant. Effects on macroinvertebrates, freshwater mussels, green sturgeon, eulachon, and Southern Resident Killer Whales would not change from existing conditions.**

3.3.4.3.2 Alternative 2: Full Facilities Removal of Four Dams (the Proposed Action)

As described in detail in Section 2.4.3, this alternative includes the removal of the Four Facilities along with the ancillary facilities of each installation in a 20-month period which includes an 8-month period of site preparation and partial drawdown at Copco 1 and a 12-month period for full drawdown and removal of facilities. This includes the entire dam, the powerhouses, spillways, and other infrastructures associated with the power generating facilities, as well as the transfer of the Keno Dam facilities to the Department of the Interior (DOI), and the implementation of the KBRA. Under the Proposed Action, hatchery production would continue for eight years following the removal of Iron Gate Dam. The Proposed Action would result in effects on key ecological attributes that could affect aquatic resources, as summarized below. More detailed technical descriptions of the effects on suspended sediment, bedload sediment, and potential impacts on aquatic species, can be found in Appendices F and G.

Key Ecological Attributes

Suspended Sediment

Suspended sediment effects under Proposed Action are described in detail in Appendix E, and summarized here.

Lower Klamath River: Downstream from Iron Gate Dam Under the Proposed Action, full facility removal would result in the release of 5.3 to 8.6 million yd³ (1.2 to 2.3 million tons) of sediment stored in the reservoirs into the Klamath River downstream from Iron Gate Dam (Reclamation 2012), resulting in higher SSCs than would normally occur under existing conditions (Figure 3.3-9). Reservoir drawdown (lowering of reservoir water surface elevation) is expected to commence in November 2019 for Copco Reservoir and in December 2019 for J.C. Boyle and Iron Gate Reservoirs. Based on the suspended sediment modeling conducted to analyze each alternative (including facility

removal) (Reclamation 2012), SSCs are expected to exceed 1,000 mg/L for weeks, with the potential for peak concentrations exceeding 5,000 mg/L for hours or days, depending on hydrologic conditions during facility removal. SSC would be highest during the period of greatest reservoir drawdown (January through mid-March 2020), as erodible material behind the dams is mobilized downstream (Reclamation 2012). During normal to dry water years, SSC concentrations would begin to decline in late March 2020 and would continue declining through early summer 2020 (Reclamation 2012). If it is a wet year, it may take longer to drain the reservoirs and the high concentrations may extend until June. The SSCs will be near background conditions for all water year types within the first year following removal. At Iron Gate Dam (Figure 3.3-9), where SSCs are artificially low under current conditions (because of sediment trapping by the dam) SSCs would remain elevated above existing conditions throughout the first 2 years. At Orleans (Figure 3.3-10), where SSCs under existing conditions is higher because of inputs of many tributaries, under a most-likely-to-occur scenario the effects of the Proposed Action would be similar to existing conditions by late April when SSCs from the Proposed Action are predicted to decrease. Under a worst case scenario SSCs are projected to remain somewhat elevated above existing conditions until October.

Figure 3.3-9. Comparison of SSCs under Proposed Action and Existing Conditions at Iron Gate Dam, as Predicted Using SRH-1D Model.

Figure 3.3-10. Comparison of SSCs under Proposed Action and Existing Conditions at Orleans, as Predicted Using SRH-1D Model.

Klamath River Estuary and Pacific Ocean Under the Proposed Action, sediment would be released from Iron Gate Dam, and would decline in concentration in the downstream direction as a result of dilution by input from downstream tributaries. Also, SSCs under existing conditions at Klamath Station are higher than at the upstream sites as a result of sediment input from tributaries. As a result, the difference of SSCs from the Proposed Action relative to existing conditions would be smallest in the Klamath River Estuary (Figure 3.3-11). The SSCs under the most-likely-to-occur scenario would be similar to those that occur under existing extreme conditions, and so resemble those that would be expected to occur about 1 year in 10 on average. Under the worst-case simulation, SSCs concentrations are only marginally higher than those for the existing extreme conditions. Therefore, effects on aquatic species from SSCs within the estuary are not anticipated to be distinguishable from existing conditions.

Figure 3.3-11. Comparison of SSCs under Proposed Action and Existing Conditions at Klamath Station, as Predicted Using SRH-1D Model.

Pacific Ocean Nearshore Environment In contrast to the Lower Klamath River, modeled short-term SSCs following dam removal are not available for the nearshore marine environment adjacent to the Klamath River. Substantial dilution of the high (>1,000 mg/L) mainstem river SSCs is expected to occur in the nearshore under the Proposed Action; based on data from 110 coastal watersheds in California, where nearshore SSCs were measured at >100 mg/L during the El Nino winter of 1998 (Mertes and Warrick 2001), peak SSCs leaving the Klamath River Estuary may be diluted by 1 to 2 orders of magnitude from >1,000 mg/L to >10-100 mg/L. Based on the modeled SSCs at Klamath Station presented above, the SSCs in the nearshore ocean would be expected to be similar to what would occur during existing extreme conditions. As described in detail in the subsection of Section 3.2.4.3.2, during several large flood events on the geographically proximal Eel River in the winter of 1997 and 1998, Geyer et al. (2000) found the following: flood conditions were usually accompanied by strong winds from the southern quadrant. The structure of the river plume was strongly influenced by the wind-forcing conditions. During periods of strong southerly (i.e., downwelling favorable) winds, the plume was confined inside the 50-m isobath (i.e., sea floor contour at 50-m below the water surface), within about 7 km of shore. Based upon Eel River plume studies and current knowledge of northern California oceanographic patterns, the fine

sediment discharged to the marine nearshore environment under the Proposed Action would likely be delivered to the ocean in a buoyant river plume that hugs the shoreline as it is transported northward. However, since the flushing of sediments from behind the dams will occur over a number of weeks to months (and perhaps to some degree over 1-2 years), the plume carrying reservoir sediments would likely be influenced by a range of meteorological and ocean conditions (e.g., storm and non-storm periods, differing storm directions). Therefore, some of the time the plume would likely be constrained to shallower nearshore waters, while at other times it would likely extend further offshore and spread more widely. While elevated SSCs (i.e., 10–100 mg/L) created in the nearshore plume would affect physical water quality characteristics specified in the Ocean Plan (i.e., visible floating particulates, natural light attenuation, the deposition rate of inert solids [Table 3.2-7]), the effects are likely to be within the range caused by historical storm events.

River plumes and the associated habitat conditions they create are considered to be areas of high productivity for marine organisms (Grimes and Funucane 1991, Morgan et al. 2005), and create abrupt changes in marine water quality conditions (e.g., water temperature, salinity, sediment) that support salmonids (Schabetsberger et al. 2003, DeRobertis et al. 2005). Due to the relatively small magnitude of SSCs released to the nearshore environment, the anticipated rapid dilution of the sediment plume as it expands in the ocean, and the relatively low rate of deposition of sediments to the marine nearshore bottom substrates, any SSCs elevations associated with the Proposed Action are not anticipated to have effects on species distinguishable from existing conditions.

Bedload Sediment

Bedload sediment effects under Proposed Action are described in detail in Appendix F, and summarized here. As a result of the Proposed Action, the bedload transport processes currently interrupted by the Project that salmon evolved with and depend upon to provide substrate suitable for spawning and early rearing in streams and rivers would be restored.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Dams in the Hydroelectric Reach currently store 13,150,000 yd³ of sediment (Reclamation 2012). No sediment is stored within the Copco 2 Reservoir, Copco 1 Reservoir stores the greatest amount, and J.C. Boyle Reservoir stores the least. Sediment would continue to accrue from existing conditions through 2020, when the dams would be removed. The SRH-1D model estimated 36 to 57 percent (5.3 to 8.6 million yd³) of dam-stored sediment would be eroded the first year after dam removal depending on simulation type (wet, median, or dry) (Figure 3.3-12). Of this sediment, about 15 percent would be transported as bedload. Sediment not eroded from the reservoirs during the first year would be stored in gravel bars and terraces. Some of this material would then be released more slowly through surficial and fluvial processes, but a large portion of the sediment left on the terraces is expected to remain indefinitely (Stillwater Sciences 2008).

SRH-1D model results indicate decreases in bed elevation and increases in median substrate size within the reservoirs during drawdown (January 2020 to May 2020)

(Figure 3.3-13). Within the reservoirs, SRH-1D modeling data for the first two years after dam removal show decreases in fine sediment and increases in median substrate size after completion of drawdown that stabilize as the bed returns to pre-dam elevation. The proportion of fine sediment decreases from 50 to 80 percent to near zero within 2 months after drawdown; the proportion of sand initially increases to 30 to 50 percent then decreases to 10 to 25 percent; the proportion of gravel changes (mostly increases) to 20 to 35 percent; and the proportion of cobble increases to 50 to 70 percent, depending on the reservoir and simulation water year type (i.e., wet, median, or dry). These changes would stabilize within six months as the bed within the historical river channel reaches pre-dam elevations (Reclamation 2012). These river sections are expected to revert to and maintain a pool-riffle morphology due to restoration of riverine processes along the Hydroelectric Reach (PacifiCorp 2004a). Still, after dam removal, channels currently inundated by reservoirs would likely vary from narrow, single-threaded channels to wide and sinuous channels with the potential to form complex features, such as meander cut-offs and vegetated islands (Reclamation 2012).

The river reaches upstream of J.C. Boyle Reservoir and from Copco 1 Reservoir to J.C. Boyle Dam show little change in bed composition or median substrate size during drawdown (Figure 3.3-13) (Reclamation 2012). Currently, these reaches are predominantly cobble (90 percent) with small fractions of gravel and sand. Very little temporal change in substrate size would be expected to occur in response to dam removal (Appendix F).

Figure 3.3-12. Sediment Erosion from Dams in the Hydroelectric Reach During 2020 Drawdown Beginning in January (Reclamation 2012).

Figure 3.3-13. Reach-Averaged Erosion in the Hydroelectric Reach during Wet Year (Reclamation 2012).

The Copco 2 Dam to Iron Gate Reservoir reach shows decreases in the combined proportion of sand and fine: the dry simulations show decreases to approximately 35 percent two years after drawdown (Figures 3.3-14).

Figure 3.3-14. Simulated Bed Composition from Copco 2 to Iron Gate Reservoirs during Two Successive Dry Water Years during and after Drawdown (Based on simulation results provided by Reclamation, March 2012).

Lower Klamath River: Downstream from Iron Gate Dam Since the construction of the lower four PacifiCorp dams, there has been approximately 3.6 million tons of deposition within these reservoirs. Dam construction has interrupted the transport of sediment, including spawning gravel, below Iron Gate Dam necessary for the long-term maintenance of aquatic habitats (Buer 1981). Under the Proposed Action the streambed downstream from Iron Gate Dam would be affected by dam-released sediment and reconnection of the natural sediment supply from upstream. The sediment stored within the reservoirs has a high water content and 85 percent of the particles are silts and clays (less than 0.063 mm) while 15 percent are sand or coarser (larger than 0.063 mm) (Gathard Engineering Consulting 2006; Stillwater Sciences 2008; Reclamation 2012). As such, most sediment eroded from the reservoirs would be silt and clay (less than 0.063 mm) with smaller fractions of sand (0.063 to 2 mm), gravel (2 to 64 mm), and cobble (64 to 256 mm) (Gathard Engineering Consulting 2006; Stillwater Sciences 2010a; Reclamation 2012). A large portion of the silt and finer substrate would likely be transported as suspended sediment and would travel to the ocean shortly after being eroded and mobilized (Stillwater Sciences 2010a). As described below, coarser (larger than 0.063 mm) sediment, including sand, would travel downstream more slowly, attenuated by channel storage and the frequency and magnitude of mobilization flows.

Short-term (2-year) SRH-1D model simulations estimate up to 1 ft of reach-averaged deposition of fine and coarse sediment between Iron Gate Dam and Bogus Creek (RM 189.8) (0.3 to 1 feet and up to 0.8 ft of deposition between Bogus Creek and Willow Creek (RM 185.2) (0.4 to 0.8 ft). Reaches farther downstream showed no apparent change (<0.5 ft) Figure 3.3-15, Reclamation 2012). In the long-term (from 5 to 50 years), after downstream translation of dam released sediment, bed elevation would adjust to a new equilibrium, which includes sediment supplied by upstream tributaries that was formerly trapped by dams within the Hydroelectric Reach. The average bed elevation increase predicted over the next 50 years is 1.5 ft in the reach from Bogus to Willow Creek and less than 1 foot downstream from there (Reclamation 2012). Reclamation (2011a) expects 2 to 3 feet of aggradation between Iron Gate Dam and Cottonwood Creek over the next 50 years.

Under the Proposed Action, the flow magnitude required to mobilize sediment would likely decrease from existing conditions. Reclamation (2011a) estimated the magnitude and return period of flows required to mobilize sediment downstream from Iron Gate Dam 50 years after dam removal using reach averaged, predicted grain sizes from long-term SRH-1D simulations. The estimates show that under the Proposed Action, sediment mobilization flows from Bogus Creek (RM 190.2) to Willow Creek (RM 185.5) and from Willow Creek to Cottonwood Creek (RM 182.5) would range from 3,000 to 7,000 cfs (1.5 to 2.5 year return period) and 5,000 to 9,000 cfs (1.5 to 3.2 year return period), respectively, lower than Existing Conditions. This would have the effect of increasing bed mobilization at least down to the Shasta River (RM 177) under the Proposed Action.

Downstream from the Shasta River, there would be no significant difference in the flow required to mobilize the bed because the bed elevations of this reach are primarily controlled by relatively immobile large cobbles, boulders, and bedrock. Sediment is expected to quickly move through the reach with or without dam removal. However, there is expected to be higher transport of sand, silt, and clay transport through this reach because of the removal of the Project dams.

The effect of dam-released sediment and sediment resupply would likely extend from Iron Gate Dam to Cottonwood Creek (Reclamation 2012). Estimates of reach-averaged stream power (the ability of the river to move sediment) show a decrease from Iron Gate Dam to Cottonwood Creek, with stream power then increasing again downstream from Cottonwood Creek. The increase suggests that short- or long-term sediment deposition, either from dam release or sediment resupply, is unlikely downstream from Cottonwood Creek. However, while the area of significant sediment release and resupply of gravel and cobble under the Proposed Action is from Iron Gate Dam downstream to Cottonwood Creek, sediment transport rates of sand, silt and clay will increase downstream from Cottonwood Creek as well (Reclamation 2012).

Figure 3.3-15. Reach Averaged Bed Elevation Change for Two Successive Wet, Median, or Dry Water Years Following Reservoir Drawdown (Based on simulation results provided by Reclamation, March 2012).

In the short term (within 2 years), SRH-1D model output indicates dam released sediment and sediment resupply would increase the proportion of sand in the bed and decrease median bed substrate size (Figure 3.3-16 and Figure 3.3-17) (Reclamation 2012). Under wet, median and dry simulations, sand within the bed would increase to 30 to 35 percent by March to June 2020 following drawdown, gradually decreasing to 10 to 20 percent by September 2021, while median substrate size (D50) would fluctuate slightly before finally stabilizing to approximately the initial condition with a D50 of 100 mm (Appendix F). Longer-term (5, 10, 25, and 50 years) simulations show increases in the proportion of sand to 5 to 22 percent and decreases in D50 to approximately 50 to 55 mm (Appendix F) after 5 years that stabilize and continue through to year 50. In general, the effect of the Proposed Action will be a more dynamic and mobile bed downstream from Iron Gate Dam, with increased transport of sediment, and increased sediment supply, including spawning gravel.

Figure 3.3-16. Simulated Bed Composition from Iron Gate Dam to Bogus Creek during Two Successive Dry Water Years Following Reservoir Drawdown (Based on simulation results provided by Reclamation, March 2012).

Figure 3.3-17. Simulated D50 (mm) from Iron Gate Dam to Bogus Creek during Successive Wet, Median, and Dry Water Years Following Reservoir Drawdown (Based on simulation results provided by Reclamation, March 2012).

Water Quality

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Dam removal activities under the Proposed Action would not affect water quality in the following areas of the Upper Klamath Basin: Wood, Williamson, and Sprague Rivers, Upper Klamath Lake, and Link River to the upstream end of J.C. Boyle Reservoir.

Water quality problems (e.g., excessive water temperatures and low dissolved oxygen) in the Keno Impoundment/Lake Ewauna during late spring, summer, and early autumn, led NOAA Fisheries Service and the DOI to prescribe interim trap-and-haul measures to transport primarily adult fall-run Chinook salmon past Keno Impoundment/Lake Ewauna during periods when conditions would be harmful to salmonids. During most years, the Keno Impoundment/Lake Ewauna reach of the Klamath River (Link River Dam to Keno Dam) exhibits dissolved oxygen concentrations greater than 6 mg/L from mid-November through mid-June. These measurements are generally acceptable for migrating adult anadromous salmonids (USEPA 1986) for these months and are typically above the ODEQ water quality objective for cool water aquatic life (6.5 mg/L minimum, see Table 3.2-3). Under the Proposed Action, interim, seasonal, upstream trap and haul for primarily fall-run adult Chinook salmon around the Keno Impoundment/Lake Ewauna would be necessary when dissolved oxygen and water temperature do not meet the applicable criteria (i.e., typically during July through October), since migrating salmonids would have access to this reach of the Klamath River. As described under the No Action/No Project Alternative (see subsections of Section 3.2.4.3.1, Water Quality, and

Section 3.3.4.3.1, Aquatics), seasonal dissolved oxygen in the Keno Impoundment/Lake Ewauna would also be expected to improve under the Proposed Action following full attainment of the TMDLs, potentially eliminating the need for trap and haul activities.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam As described in the subsection of Section 3.2.4.3.2, Water Quality, the Proposed Action would cause long-term increases in dissolved oxygen in the Hydroelectric Reach . Dissolved oxygen in the current river reaches and the free-flowing river reaches replacing the reservoirs would no longer be affected by hydropower peaking flows or the extreme conditions of super-saturation (i.e., >100% saturation) in surface waters and hypolimnetic oxygen depletion in bottom waters of Copco 1 and Iron Gate Reservoirs during the April/May through October/November period. This would increase the likelihood of consistently supporting beneficial uses during this period.

As described in the subsection of Section 3.2.4.3.2, Water Quality, under the Proposed Action, pH in the Hydroelectric Reach would no longer experience daily variation due to hydropower peaking flows or the high levels (pH > 9) resulting from seasonal algal growth in the surface waters of Copco 1 and Iron Gate Reservoirs. pH in the free-flowing reaches of the river replacing the reservoirs would not exhibit such extremes, instead possessing a more typical riverine signal. While slight increases in pH and daily fluctuation could occur due to increased periphyton growth in the river reaches previously occupied by reservoirs, the increases are expected to consistently meet the Oregon water quality objective to support beneficial uses and would therefore be less than significant (see Section 3.2.4.3.2).

Lower Klamath River: Downstream from Iron Gate Dam Sediment release associated with the Proposed Action could cause short-term increases in oxygen demand and reductions in dissolved oxygen. As described in the subsection of Section 3.2.4.3.2, Water Quality, predicted short-term increases in oxygen demand under the Proposed Action generally result in dissolved oxygen concentrations greater than 5 mg/L. Exceptions to this would occur four to eight weeks following reservoir drawdown (i.e., in February 2020) for median and dry year hydrologic conditions, when dissolved oxygen would drop to levels below 5 mg/L from Iron Gate Dam to near the confluence with the Shasta River (RM 176.7). Recovery to the North Coast Basin Plan water quality objective of 90 percent saturation (i.e., 10–11 mg/L) would occur in the reach from Seiad Valley to the mainstem confluence with Clear Creek, and would therefore not affect dissolved oxygen in the estuary or the nearshore environment.

Facility removal under the Proposed Action could cause long-term overall increases in dissolved oxygen, as well as increased diel variability in dissolved oxygen, in the Lower Klamath River, particularly for the reach immediately downstream from Iron Gate Dam. Effects would diminish with distance downstream from Iron Gate Dam, such that no effects on dissolved oxygen would occur by the confluence with the Trinity River.

Water Temperature

Upper Klamath Basin Upstream of the Influence of J.C. Boyle Reservoir Dam removal activities under the Proposed Action would not affect water temperature in the following areas of the Upper Klamath Basin: Wood, Williamson, and Sprague Rivers, Upper Klamath Lake, and Link River to the upstream end of J.C. Boyle Reservoir. KBRA implementation would have some effects on water temperature in these areas, which are discussed in the subsection of Section 3.2.4.3.2, Water Quality.

Water quality problems (e.g., excessive water temperatures and low dissolved oxygen) in the Keno Impoundment/Lake Ewauna during late spring, summer, and early autumn, led NOAA Fisheries Service and the DOI to prescribe interim trap-and-haul measures to transport primarily adult fall-run Chinook salmon past Keno Impoundment/Lake Ewauna during periods when conditions would be harmful to salmonids. Under the Proposed Action, interim, seasonal, upstream trap and haul for primarily fall-run adult Chinook salmon around the Keno Impoundment/Lake Ewauna would be necessary when dissolved oxygen and water temperature exceed the EPA criteria of 20 ° C (typically during July through October), since migrating salmonids would have access to this reach of the Klamath River. As described for water temperature under the No Action/No Project Alternative (see subsection of Section 3.2.4.3.1, Water Quality, and Section 3.3.4.3.1.1.3, Aquatics), seasonal water temperature in the Upper Klamath Basin are expected to improve following full attainment of the Oregon TMDLs, potentially eliminating the need for trap and haul activities. However, TMDL-related improvements to water temperature in the upper basin would be partially offset by climate change.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Under the Proposed Action, the Klamath River would no longer be dominated by hydropower peaking events and flows in the former Hydroelectric Reach would more closely mimic the natural hydrograph.

In the absence of the reservoirs, hydraulic residence time in this reach would likely decrease from several weeks to less than a day, and water quality would also be improved (Hamilton et al. 2011). Removal of the Project reservoirs will result in a slight increase in flow as the evaporative losses would be reduced. Evaporation from the surface of the reservoirs is currently about 11,000 acre-feet/year and after dam removal the evapotranspiration in the same reaches is expected to be approximately 4,800 acre-feet/year, resulting in a gain in flow to the Klamath River of approximately 6,200 acre-feet/year (Reclamation 2011). The reservoir drawdowns would allow tributaries and springs such as Fall, Shovel, and Spencer Creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). Water quality conditions would also improve further downstream in the Hydroelectric Reach. From Copco 1 to Iron Gate Reservoir, removal of the Four Facilities would result in a 2-10°C decrease in water temperatures during the fall months and a 1-2.5°C increase in water temperatures during spring months (PacifiCorp 2004a, Dunsmoor and

Huntington 2006, NCRWQCB 2010, Perry et al. 2011; see also subsection of Section 3.2.4.3.2). The effects of changes in temperature regimes within this reach will be similar to those discussed in detail below for the reach downstream from Iron Gate Dam.

Removing the dams would allow access to at least 49 tributaries upstream of Iron Gate Dam that could provide hundreds of miles of habitat for anadromous fish (DOI 2007), including groundwater-fed areas resistant to water temperature increases caused by changes in climate (Hamilton et al. 2011). In addition, the mainstem downstream from Iron Gate Dam would reflect natural temperature regimes (Hamilton et al. 2011). The conversion of an additional 22 miles of reservoir habitat to riverine and riparian habitat would improve water quality by restoring the nutrient cycling and aeration processes provided by a natural channel. These improvements resulting from the Proposed Action would likely moderate the anticipated stream temperature increases resulting from climate change.

Lower Klamath River: Downstream from Iron Gate Dam The thermal lag formerly caused by water storage in reservoirs and the associated increased thermal mass would be eliminated in the Lower Klamath River (subsection of Section 3.2.4.3.2). This elimination would cause water temperatures to become more in sync with historical migration and spawning periods for the Klamath River, warming earlier in the spring, and cooling earlier in the fall compared to existing conditions (Hamilton et al. 2011).

Under the Proposed Action, warmer springtime temperatures would result in fry emerging earlier (Sykes et al. 2009), encountering favorable temperatures for growth sooner than under existing conditions (Figure 3.3-18), which could support higher growth rates and encourage earlier emigration downstream, thereby reducing stress and disease (Bartholow et al. 2005; FERC 2007). A predicted earlier outmigration in response to elevated water temperatures in the spring is also supported by a vast body of literature relating to increased growth rates and thermal response of outmigrating salmonids (Hoar 1988). In addition, fall-run Chinook salmon spawning in the mainstem during fall would no longer be delayed (reducing prespawn mortality) (Figure 3.3-19), and adult migration would occur in more favorable water temperatures than under existing conditions (Figure 3.3-19). Overall, these changes would result in water temperatures more favorable for salmonids in the mainstem Klamath River downstream from Iron Gate Dam.

The elimination of the thermal lag would also cause water temperatures to have natural diel variations (Figure 3.3-19) similar to what would have occurred historically in the Klamath River. This effect would be most pronounced downstream from Iron Gate Dam, would decline with distance downstream, and by the confluence of the Salmon River (RM 66) would exhibit no difference between the Proposed Action and existing conditions. The highest temperatures experienced by aquatic species would increase during summer (June through August), which could increase physiological stress, reduce growth rates, and increase susceptibility to disease during summer (Figure 3.3-19).

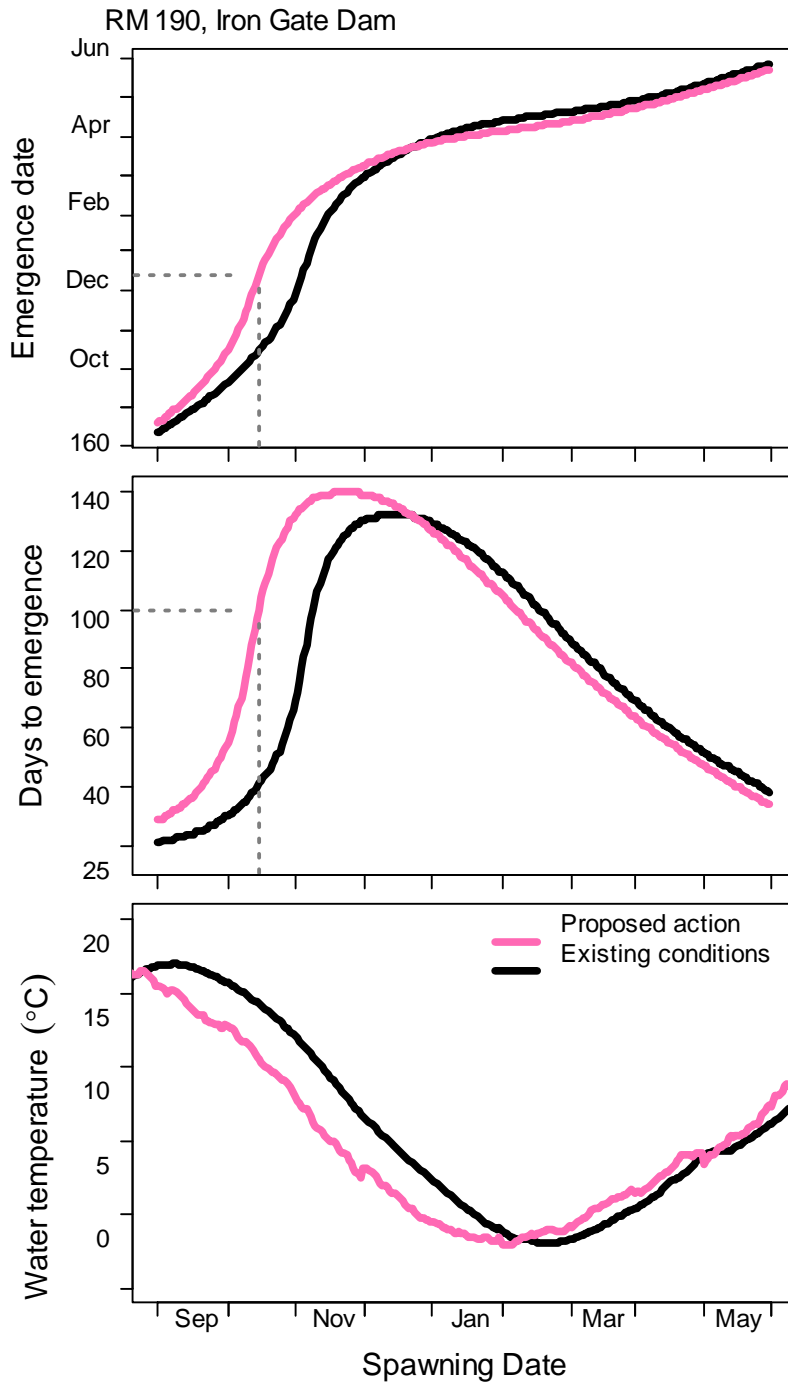

Figure 3.3-18. Time series of average daily mean water temperature (lower panel) forecasted at Iron Gate Dam (RM 190) for the Index Sequential climate scenario spanning years 2020 to 2061, for Proposed Action and Existing Conditions. Days to emergence (middle panel) and date of emergence (upper panel) for fall-run Chinook salmon was estimated as a function of spawning date assuming that emergence would occur at 889 degree days after spawning. (Perry et al. 2011)

Figure 3.3-19. PacifiCorp (2005) Simulated hourly water temperatures below Iron Gate Dam based on a dry water year (WY 2002) for existing conditions compared to the Proposed Action (without Project dams), and USEPA (2003) water temperature criteria for salmonid growth and migration.

However, the FERC (2007) states that the increase in average and maximum daily temperatures may be compensated for by lower temperatures at night, which NRC (2004) concludes may allow rearing fish to move out of temperature refugia to forage at night, allowing growth to occur even when ambient day time temperatures are above optimal. Foott et al. (2012) observed positive growth and no overt effect of elevated temperature on immune function or fitness in Klamath River juvenile Chinook salmon held over a 23 day period under conditions in the laboratory that simulated fluctuating water temperature profiles similar to what would be observed in the Klamath River under the Proposed Action. Salmonids in the Klamath River have been observed to use cooler hours to migrate between thermal refugia (Belchik 2003), and the decrease in minimum temperatures during the spring, summer, and fall under the Proposed Action would be a benefit for fish (Figure 3.3-19). Increased nighttime cooling of water temperatures is important to salmonids in warm systems, providing regular thermal relief, time for repair of proteins damaged by thermal stress, and significant bioenergetic benefits that help fish persist under marginal conditions (Schrank et al. 2003, NRC 2004). In addition, Dunsmoor and Huntington (2006) suggest that lower nighttime temperatures with dam removal would allow fish to leave thermal refugia in the Klamath River to forage and thereby allow more effective use of the available refugia habitat. Overall, the Proposed Action reductions in minimum daily temperatures below those under existing conditions would benefit salmonids in the Klamath River mainstem, helping them to tolerate the

warmer periods of the year when dwelling in the mainstem, but also allowing feeding excursions when confined to refugia during the warmer times of the day.

Simulations of water temperatures without the reservoirs (as discussed in Hamilton et al. 2011) show that the temperature difference with and without dams would be greatest downstream from Iron Gate Dam, but could extend an additional 120 to 130 miles downstream. Estimated decreases in stream temperature with dam removal relative to current conditions are likely to be smaller with continued climate change; however, temperature conditions would be much improved under the Proposed Action as compared to the No Action/No Project Alternative (See subsection of Section 3.2.4.3.2., Water Quality).

Klamath River Estuary and Pacific Ocean Nearshore Environment The influence of the Proposed Action would likely decrease with distance downstream from Iron Gate Dam (PacifiCorp 2004b), and it is unlikely that facility removal would have detectable effects on temperatures in the Klamath River Estuary and Pacific Ocean nearshore environment.

Fish Disease and Parasites

The Proposed Action would be expected to reduce impacts on salmon from fish disease. The greatest disease related mortality is due to *C. shasta* and *P. minibicornis* in the Lower Klamath River downstream from Iron Gate Dam. Among all of the salmon lifestages, juvenile salmon tend to be most susceptible to *P. minibicornis* and *C. shasta*, particularly during their outmigration in the spring months (Beeman et al. 2008). The main factors contributing to risk of infection by *C. shasta* and *P. minibicornis* include availability of habitat (pools, eddies, and sediment) for the polychaete intermediate host; microhabitat characteristics (static flows and low velocities); polychaete proximity to spawning areas; increased planktonic food sources from Project reservoirs; and water temperatures greater than 15°C (Bartholomew and Foott 2010).

The removal of Iron Gate Dam would reduce the concentration of adults and carcasses that presently occurs downstream. Greater dispersal of spawning adult salmon would reduce their proximity to dense populations of polychaetes. FERC's analysis (FERC 2007) concluded that restoring access to reaches above Iron Gate Dam for anadromous fish would allow adult fall-run Chinook salmon to distribute over a greater length of the river, reducing crowding and the concentration of disease pathogens that currently occur in the reach between Iron Gate Dam and the Shasta River. In addition, Bartholomew and Foott (2010) suggested that with dam removal it is likely that a greater diversity of salmon life histories will evolve, with some of those types more likely to avoid parasite exposure by migrating earlier or over wintering in tributaries and migrating in the fall. FERC (FERC 2007) concluded that restoring natural sediment transport processes would likely contribute to the scour of periphyton (attached algae) downstream from the current site of Iron Gate Dam, and deposited gravel and sand would provide a less favorable substrate for periphyton because of its greater mobility during high flow events than the existing armored substrate (see also the subsection of Section 3.4.4.3.2, Periphyton). The reduction in periphyton would provide less favorable habitat for the polychaete

intermediate host of *C. shasta* and *P. minibicornis*, which should reduce the infection rate of juvenile salmonids downstream from Iron Gate Dam (FERC 2007).

Under the Proposed Action, sediment bedload transport rates would increase downstream from the current location of Iron Gate Dam which includes habitats with large populations of polychaetes. Actinospores released from this portion of the Klamath River pass downstream and infect juvenile salmon in the current infectious zone downstream from the Shasta River to Seiad (RM 130) (Bartholomew and Foott 2010). In addition, while the area of significant bedload deposition under the Proposed Action is located upstream of Cottonwood Creek, sediment transport rates will also increase downstream from Cottonwood Creek (Appendix F). This increased movement and transport of sediment (sand, silt, and clay) is anticipated to disrupt polychaete habitat from the current location of Iron Gate Dam to downstream from Shasta River.

The net result of these effects would also depend on temperature. Dam removal would mean cooler temperatures in the late summer and fall, but slightly warmer temperatures during spring and early summer. FERC (2007) concluded that dam removal would enhance water quality and reduce the cumulative water quality and habitat effects that contribute to disease-induced salmon die-offs in the Klamath River downstream from Iron Gate Dam. In turn, this would benefit salmon outmigrants from tributaries downstream from Iron Gate Dam, such as the Shasta and Scott rivers. While Bartholomew and Foott (2010) stated that the effect of cooler temperatures in the early fall on the intermediate host or *C. shasta* is unknown, they also stated that a reduction in temperature could have the result of reducing polychaete reproductive rates (Bartholomew and Foott 2010). Reduced disease in the mainstem is anticipated to increase the likelihood that benefits to outmigrating smolts from restoration in the Shasta and Scott rivers are realized. In addition, with dam removal it is likely that a greater diversity of salmon life histories will evolve, with some of those types more likely to avoid parasite exposure by migrating earlier or over wintering in tributaries and migrating in the fall (Bartholomew and Foott 2010).

The net result of these effects would also depend on smolt behavior. FERC (2007) concluded that more rapid cooling of river temperatures in the fall with the project dams removed may also allow for fall Chinook salmon spawning to occur earlier in the fall. Bartholow et al. (2005) and FERC (2007) also both suggest that earlier warming of the river system could trigger juvenile salmonids to out migrate earlier, This is consistent with findings that accumulated temperature units are more important predictors of migration of juvenile Chinook salmon than flow or photoperiod (Sykes et al. 2009). A predicted earlier outmigration in response to elevated water temperatures in the spring is also supported by a vast body of literature relating to increased growth rates and thermal response of emigrating salmonids (Hoar 1988). This, in turn, would likely result in earlier emergence and growth, and encourage earlier emigration. In addition, a slight increase in the rate at which water temperatures increase in the spring would be likely to improve the growth rates of newly emerged fall Chinook salmon fry (FERC 2007). Earlier emigration and improved growth would likely mean most outmigrants would avoid periods of high disease infection of juvenile salmon.

Flows also play an important role in the regulation of disease in the Klamath River. If flows increase during spring, juvenile migration time could be decreased, potentially resulting in reduced disease exposure, especially for fish originating from Lower Klamath River tributaries. The Proposed Action would create a flow regime that more closely mimics natural conditions in the Lower Klamath River by increasing spring flow and by incorporating more variability in daily flows (Hetrick et al. 2009). Implementation of the KBRA will provide flexibility to manage flows that respond to real-time climatic and biological conditions. This would allow for management of out migration flows, as well as enhancing the diversity in flow and water temperature. Because polychaete populations are located outside of the main flow along the margins of the riverbanks (Bartholomew and Foott 2010), variable flows disrupt this habitat. Restoring these dynamic conditions in the Klamath River will create instability and disturbance in microhabitat conditions that are expected to reduce polychaete populations (Stocking and Bartholomew 2007; Bartholomew and Foott 2010) and presumably, reduce infection rates within polychaete populations (Hetrick et al. 2009). The removal of the Four Facilities would also be likely to reduce habitat quality for the polychaete host by reducing reservoir water quality effects and reducing planktonic food sources (Hetrick et al. 2009; Hamilton et al. 2011).

Periphytic algae would also play a role in disease in the Klamath River. Under the Proposed Action additional periphytic growth including *Cladophora* is anticipated within the Hydroelectric Reach, following the initial drawdown period, which could provide habitat for the intermediate host of *C. shasta*. Additional periphytic growth would be a direct result of the conversion of the lacustrine environment in the reservoirs, which fosters growth of phytoplankton algae, to a flowing, riverine habitat that fosters growth of attached aquatic vegetation (including both periphyton and macrophytes), in combination with already ample nutrient concentrations. In the absence of other factors, this could possibly increase the prevalence of the intermediate host for *C. shasta*. However, dam removal would also create other conditions that tend to offset the growth of aquatic vegetation. These conditions include a restoration of bedload sediment transport, a more mobile river bed, increased high flows during spring, more variable flows, and a more normal (and variable) temperature regime with substantially cooler fall water temperatures. FERC (2007) concluded that restoring natural sediment transport processes would likely contribute to the scour of attached vegetation in the Klamath River. Finally, under KBRA, progress toward achievement of TMDL targets, including the reduction of nutrients, would be accelerated compared to existing conditions and would eventually help control growth of periphyton or macrophytes.

There remains some uncertainty of the contribution of nutrients in increasing habitat for the intermediate host for *C. shasta*, the conditions that would offset the growth of aquatic vegetation, and the longitudinal gradations of these conditions. Given the already high concentrations of nutrients, increases in biomass of attached aquatic vegetation would be more attributable to the new habitat area than changes in nutrient concentrations. However, the net long-term effect of the Proposed Action is anticipated to be a slight- to moderate decrease in *Cladophora* and aquatic vegetation as a result of disruption by the flow and bedload conditions listed above and, ultimately, reductions in nutrients resulting

from the TMDLs or other nutrient management techniques in the Upper Klamath Basin. A decrease in Cladophora and aquatic vegetation would likely decrease habitat for the intermediate host which would reduce the incidence of *C. shasta*. This effect is likely to be reach dependent, with in aquatic vegetation possible in the Hydroelectric Reach. Nevertheless, increased dispersal of spawners and carcasses, transport of bedload, and establishment of variable flows, would likely reduce the severity of exposure to the infection to levels below critical thresholds (Bartholomew and Foott 2010), even if infection itself is not eliminated.

Removal of the Four Facilities would allow anadromous to move upstream in the mainstem Klamath River and tributaries. However, available information indicates that fish passage would not increase the risk of disease for resident species that occur upstream of Iron Gate Dam (Administrative Law Judge 2006). *C. shasta* and *P. minibicornis* exist throughout the Klamath River System in both the Upper and Lower Basins, so migration of wild anadromous fish upstream of downstream from Iron Gate Dam would not increase the risk of introducing pathogens to resident trout residing above Iron Gate Dam (Administrative Law Judge 2006). In addition, native Klamath River trout are generally resistant to *C. shasta*. The remaining known pathogens do not impact non-salmonids, with the exception of *F. columnaris* and *Ich*.

Recently several new *C. shasta* genotypes have been discovered in the Klamath River. In this regard, risk is related to host specificity, which appears to exist at least to some degree (Atkinson and Bartholomew 2010). As an example, redband trout are thought to be susceptible to Type 0, which already occurs in the upstream Basin and Chinook salmon are susceptible to Type I, which occurs in the Lower Klamath Basin. Type 0 genotype occurs in low densities and it is not very virulent (infection results in low or no mortality); if Type I genotype were to be reintroduced above Iron Gate Dam, it would affect only Chinook salmon. It is not expected that introduction of *C. shasta* genotypes upstream would be deleterious because fish in the upstream Basin have shown resistance to the downstream genotypes. Redband trout would presumably have been exposed to genotypes of *C. shasta* during the pre-dam period, and their populations were abundant. Because the salmonid species in the Klamath Basin already co-occur with the genotype of *C. shasta* to which they are susceptible, and the salmonid species are less susceptible to other genotypes of *C. shasta*, expanding the distribution of the different genotypes of *C. shasta* would be unlikely to be deleterious to salmonids. Recently discovered *C. shasta* genotypes and research findings in the past several years do not appear to contradict the finding that movement of anadromous salmonids into the Upper Klamath Basin presents a relatively low risk of introducing pathogens to resident fish (Administrative Law Judge 2006, USFWS/NOAA Fisheries Service Issue 2(B)).

Available information also indicates that risks associated with dam removal to anadromous fish upstream of Iron Gate Dam are minimal. For example, steelhead within the Klamath River system are generally resistant to *C. shasta*, (Administrative Law Judge 2006). Since salmon and associated disease pathogens were present historically above Iron Gate Dam, *C. shasta* genotype movement would be a reintroduction of associated risk to these anadromous species.

While it is possible that the current infectious nidus (reach with highest infectivity) for *C. shasta* and *P. minibicornis* may be recreated upstream where salmon spawning congregations occur, and there is associated uncertainty (Foott et al. 2011), the likelihood of this happening appears to be remote for the following reasons. Any creation of an infectious zone (or zones) would be the result of the synergistic effect of numerous factors, such as those that occur within the current disease zone in the Klamath River in the reach from the Shasta River downstream to Seiad Valley (FERC (2007; Bartholomew and Foott 2010). Here, flows in that reach that mimic natural conditions, combined with reestablishment of natural sediment transport rates, would restore natural geomorphic channel forming processes (Hetrick et al. 2009) necessary to create diverse habitat and reduce the influence of those synergistic factors that currently create conditions favorable for disease. Under a dams out alternative, those conditions that are believed to result in development of an infectious nidus below Iron Gate Dam, or a could result in development of a potential infectious nidus above Iron Gate Dam, are unlikely to occur.

Further, the likelihood of those synergistic factors in the Williamson River would be reduced as carcasses would likely be more dispersed in the watershed (Foott et al. 2011), and flow variability will act to reduce polychaete habitat stability above the Williamson River mouth. *C. shasta* in the Williamson River is currently maintained by planting of susceptible rainbow trout that become infected, likely produce myxospores, and die within a restricted reach in the lower Williamson River.

In addition, under a scenario of potential dam removal, it is likely that a greater diversity of salmon life histories will evolve, with some of those types more likely to avoid parasite exposure by migrating earlier or over wintering in tributaries and migrating in the fall (Bartholomew and Foott 2010; p. 40), thus missing the time of year when water temperatures in the Williamson River might possibly be conducive to disease. In some years, maximum temperatures in the Williamson River do not exceed the disease threshold of 15 C (Bartholomew and Foott 2010; Hamilton et al. 2010). The risk of a juvenile salmon disease response here would be lower than the current zone but not negligible in all water years (Scott Foott, USFWS, 2012, pers. comm.).

Historically, it appears spawning concentrations of upper basin Chinook salmon took place primarily in the Sprague River (Lane and Lane Associates 1981). There is no information indicating that high densities of polychaetes occur in the Sprague River (Foott et al. 2011). Thus, the synergistic factors that contribute to an infectious nidus for emigrants below Iron Gate Dam and near the Iron Gate Hatchery are unlikely to occur here either. There is some concern regarding a disease zone in the lower Williamson River downstream from the confluence with the Sprague River (Hurst et al. 2012). However, some Chinook emigrants from both these tributaries may very well emerge from groundwater areas early, then rear in Upper Klamath Lake, with growth opportunities that allow them to migrate when they can minimize exposure to *C. shasta*.

The Chinook Salmon Expert Panel convened to attempt to answer specific questions formulated by the project stakeholders to assist with assessing the effects of the Proposed Action compared with existing conditions (Goodman et al. 2011), concluded that the

Proposed Action offers greater potential than the current conditions in reducing disease-related mortality in Klamath River Chinook salmon.

Algal Toxins

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir This region is upstream of any proposed dam removal; therefore, removal of the reservoirs at the Four Facilities under the Proposed Action would not affect fish health as related to algal toxins. Any changes in algal toxin production in this region would be a result of other factors, including TMDL implementation. The effects in this area would be similar to those described for the No Action/No Project Alternative.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Removal of the reservoirs at the Four Facilities under the Proposed Action would eliminate growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa* in the Hydroelectric Reach, alleviating high seasonal concentrations of algal toxins and associated bioaccumulation of microcystin in fish tissue for species in this reach. While some microcystin may be transported downstream from large blooms occurring in Upper Klamath Lake, the levels would not be as high as those currently experienced due to the prevalence of seasonal in-reservoir blooms. Overall, bioaccumulation of algal toxins in fish tissue would be expected to decrease in the Hydroelectric Reach and would be beneficial.

Lower Klamath River: Downstream from Iron Gate Dam Removal of the reservoirs at the Four Facilities under the Proposed Action would eliminate growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa*, alleviating the transport of high seasonal concentrations of algal toxins to the Klamath River downstream from Iron Gate Dam. This would also decrease the associated bioaccumulation of microcystin in fish tissue for species downstream from the dam. While some microcystin may be transported downstream from large blooms occurring in Upper Klamath Lake, the levels would not be as high as those currently experienced due to the prevalence of seasonal in-reservoir blooms. Overall, bioaccumulation of algal toxins in fish tissue would be expected to decrease in the Klamath River downstream from Iron Gate Dam and would be beneficial.

Aquatic Habitat

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Under the Proposed Action access would be restored to an estimated 360 miles of potential anadromous fish habitat upstream of Upper Klamath Lake and Keno Impoundment/Lake Ewauna (Huntington 2006; DOI 2007; NOAA 2007). However, in their analysis the FERC (2007) excluded this 360 miles of anadromous fish habitat based upon poor water quality conditions in these water bodies during summer months. The Chinook Expert Panel (Goodman et al. 2011) also concluded that substantial gains in Chinook salmon abundance for areas upstream Keno Impoundment/ Lake Ewauna would be contingent upon successfully resolving limitations associated with poor water quality problems in Upper Klamath Lake and Keno Impoundment/ Lake Ewauna. The Coho Steelhead Expert Panel (Dunne et al. 2011) stated that poor water quality in Keno

Impoundment/ Lake Ewauna and in Upper Klamath Lake, and the possibility of difficult passage at Keno Dam, could impede steelhead from reaching improved habitat upstream of the Project Reach.

These concerns for Chinook salmon and steelhead migration and spawning overstate the seasonal habitat limitations of Keno Impoundment/ Lake Ewauna and Upper Klamath Lake for two main reasons. First, a recent study examined the response of salmon to Upper Klamath Lake under existing conditions. Iron Gate Hatchery Chinook salmon were tested in the lake and the lower Williamson River to assess whether current conditions would physiologically impair salmon reintroduced into the Upper Klamath Basin. Juvenile Chinook salmon were tested in cages in 2005 and 2006. These juveniles showed normal development as smolts in Upper Klamath Lake and survived well in both locations (Maule et al. 2009). This study strongly suggests that Upper Klamath Lake habitat is suitable to support salmonids for at least the October through May period. Maule et al. (2009) concluded that there was little evidence of physiological impairment or significant vulnerability to *C. shasta* that would preclude this stock from being reintroduced into the Upper Klamath Basin. In addition, the life history of type I fall-run Chinook salmon generally does not include a freshwater phase from June through September. Thus, conditions for juvenile fall-run Chinook emigration through Upper Klamath Lake appear favorable. Due to the timing of the migration period for spring-run Chinook salmon and steelhead, these runs would generally avoid the period of poor water quality in Upper Klamath Lake. Cool groundwater spring inputs in the Williamson River and on the west side of Upper Klamath Lake would likely provide thermal refugia for the year-round life-histories of spring-run Chinook salmon and steelhead. Under a scenario of potential dam removal, Bartholomew and Foott (2010) noted that it is likely that a greater diversity of salmon life histories will evolve, with some of those types more likely to avoid parasite exposure by migrating earlier or over wintering in tributaries and migrating in the fall. These life histories would also likely be able to avoid periods of poor water quality.

Second, water quality issues in Keno Impoundment/Lake Ewauna and Upper Klamath Lake are not year round. Both DOI and NOAA Fisheries Service have long recognized the issue of seasonally poor water quality in Keno Impoundment/ Lake Ewauna. When water quality is poor, which occurs seasonally between June 15 and November 15, both DOI and NOAA Fisheries Service prescribed the transfer of primarily adult Chinook salmon upstream of the Keno between June 15 and November 15 for the purposes of restoration and the safe, effective, and timely passage (DOI 2007; NOAA 2007). In the Klamath Facilities Removal Draft EIS/EIR, accommodation for related short distance, seasonal trap and haul facilities is made under all of the action alternatives other than the No Action/No Project Alternative analyzed below. Migrants of other species, if present, would be transported as well. Thus, under the action alternatives other than No Action/No Project Alternative, all anadromous species and life histories would be able to migrate to and from habitat upstream of Upper Klamath Lake, realize associated benefits provided by these habitats, and complete their life cycles.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Under the Proposed Action, short-term effects would include the release of water stored in the Four Facilities. Based on modeling results, this release is expected to last about 4 months, from January 1 into April 2020, but could vary depending on hydrologic conditions (Reclamation 2012), increasing flows downstream from the dams during the drawdown period. River flows would be expected to remain below the 10-year flood event of 11,000 cfs. Flows would increase not only in the bypass reaches, but also all other mainstem reaches due to changes in operations and the absence of reservoir evaporation. Hydrology in the J.C. Boyle Peaking Reach would follow the natural hydrograph more closely, including increased duration and magnitude of high flows, and cessation of daily extreme flow fluctuations (characteristic of hydroelectric peaking operations). Seasonal high flows will contribute to improving the quality of riparian habitat in the J.C. Boyle Bypass Reach by increasing the sediment deposit within the channel and decreasing reed canary grass (Administrative Law Judge 2006). The more normative flow regime associated with this alternative would provide these seasonal high flows.

These flow increases would provide more habitat than under existing conditions for redband/rainbow trout and other resident riverine species, as well as anadromous fish or lamprey that reestablish in this area. These flows are expected to meet channel maintenance needs to route coarse sediments, build bars, erode banks, flush fine sediments, scour vegetation and undercut and topple large woody riparian vegetation (NRC 2008). The removal of project dams would reestablish geomorphic and vegetative processes that form channels that provide fish habitat and spawning gravels in this reach, especially in the former bypassed reaches (FERC 2007). In addition, the impacts associated with daily extreme flow fluctuations resulting from peaking operations, such as stranding, displacement, reduced food production, and increased stress, would no longer occur. The removal of the Four Facilities would eliminate existing habitat for adult shortnose and Lost River suckers, as well as nonnative species occupying the reservoirs. The few shortnose and Lost River suckers that have been observed in these reservoirs are believed to be fish that have moved down from the upstream areas, but are not thought to represent a viable, self-supporting population (Buettner et al. 2006). The Proposed Action would restore 22 miles of riverine habitat (Cunanan 2009) for resident and anadromous fish through removal of reservoirs. The current reservoirs inundate sections of the river that had high sinuosity and complex channels that historically provided excellent salmonid spawning and rearing habitats (Hetrick et al. 2009).

Overall, because the Proposed Action would result in flows more favorable to all life stages, eliminate peaking operations, and remove barriers that have isolated populations; the Proposed Action would result in benefits to salmonid populations and their habitat.

Following drawdown of the reservoirs, revegetation efforts would be initiated to support establishment of native wetland and riparian species on newly exposed reservoir sediment. No short-term effects are anticipated from these reservoir restoration efforts, and in the long-term aquatic habitat may be improved from restored riparian vegetation.

Lower Klamath River: Downstream from Iron Gate Dam As described above, the Proposed Action would result in elevated flows for about 4 months once drawdown begins, but the flows would be expected to remain below the 5-year flood event. These elevated flow rates could have the beneficial effect of maintaining unsuitable habitat conditions for introduced species in the river downstream from Iron Gate Dam. These increased flows could result in faster transport of outmigrant fish and slower upstream migration of adult fish in the Klamath River during this time.

Over the long term, the Proposed Action would alter the hydrograph so that the duration, timing, and magnitude of flows would be more similar to the unregulated conditions under which the native fish community evolved (Hetrick et al. 2009). While mean annual flows would not substantially change from existing flows due to the lack of active reservoir storage (Stillwater Sciences 2009b; Reclamation 2012), flow variability would increase.

Restoration of the hydrologic function of the river system is paramount to creating habitat diversity and maintaining biophysical attributes of a river system (Stanford et al. 1996; Poff et al. 1997). Although implementation of Alternative 2 or 3 will not fully restore the natural hydrologic regime of the Klamath River, it would result in a flow pattern that mimics pre dam conditions, having greater intra- and inter-annual variability than exists today with the Klamath Dams in place (Hetrick et al. 2009). Implementation of the KBRA will provide flexibility to manage flows that respond to real-time climatic and biological conditions, thereby enhancing the diversity in flow and water temperature. Restoring these dynamic conditions in the Klamath River will create instability and disturbance in microhabitat conditions that we expect will reduce polychaete populations (Stocking and Bartholomew 2007) and presumably, reduce infection rates within polychaete populations (Hetrick et al. 2009).

The Proposed Action would substantially decrease the transit time of water in the Hydroelectric Reach, because it would no longer be detained by the reservoirs, resulting in a shift in the timing of the minimum flows (Balance Hydrologics Inc. 1996; NRC 2004, Fig. 4-2, p. 148, http://www.nap.edu/openbook.php?record_id=10838&page=144). These hydrologic effects would likely be more important in upstream areas (directly downstream from Iron Gate Dam) than downstream areas (downstream from the confluence of the Scott River) due to the substantial flow contribution of tributaries to the Klamath River (Reclamation 2012, Hydrologic modeling, Appendix E). In addition, these hydraulic changes would result in changes to water quality, water temperatures, sediment transport, and riparian habitat, as described in subsequent sections.

Klamath River Estuary and Pacific Ocean Nearshore Environment Modeling results indicate that because of the influence of the tributaries entering the Klamath River downstream from Iron Gate Dam, the flow changes for the Proposed Action would not substantially affect the flows entering the estuary. Section 3.6, Flood Hydrology, provides further information on this effect. Therefore, the Proposed Action would not affect flow-related fisheries habitat in the estuary or the Pacific Ocean.

Aquatic Resources Effects

Critical Habitat

As described below, reservoir drawdown associated with dam removal under the Proposed Action could alter the quality of critical habitat. In addition, the removal of dams and reservoirs could alter the availability and quality of critical habitat.

Coho Salmon Elevated levels of SSCs occurring during 3 to 4 months of drawdown would degrade critical habitat for coho salmon. Bedload movement following dam removal would increase supply of gravel downstream from the dam as far downstream as Cottonwood Creek. This effect would potentially improve critical habitat for coho salmon by reducing median substrate to a size more favorable for spawning (Reclamation 2012).

The Proposed Action would increase the amount of habitat available to coho salmon upstream of currently designated critical habitat and improve water quality in the mainstem Klamath River within current critical habitat. NOAA Fisheries Service may consider whether to designate the newly available habitat as critical habitat as part of its 5-year status review or as a separate reconsideration of the critical habitat designation for the species (J. Simondet, NOAA Fisheries Service, pers. comm., 2011). The Proposed Action would restore access for upper Klamath River Population coho salmon to the Hydroelectric Reach, expanding their distribution to include historical habitat along the mainstem Klamath River and all tributaries upstream at least as far as Spencer Creek; including in Jenny, Shovel, and Fall Creeks (Hamilton et al. 2005), including around 76 miles of potential habitat within the Hydroelectric Reach. In addition, coho salmon could find suitable temperatures for holding in pockets within the J.C. Boyle Bypass Reach, although the average and maximum temperatures in this reach are expected to exceed optimal temperatures for coho salmon. Access to this habitat would increase the availability of spawning sites, result in additional food resources, and provide access to areas of better water quality. Water quality conditions would also improve within the mainstem downstream from the J.C. Boyle Powerhouse. As discussed in detail above, the thermal lag formerly caused by water storage in reservoirs and the associated increased thermal mass would be eliminated in the Lower Klamath River. This elimination would cause water temperatures to have more natural diel variation, and would become more in sync with historical migration and spawning periods for Klamath River. Overall, these changes would result in water temperature more favorable for salmonids in the mainstem. Removal of the Four Facilities would also increase dissolved oxygen concentrations, and eliminate reservoir habitat that creates the conditions necessary for the growth of blue green algae and other phytoplankton. These changes would be beneficial for coho salmon critical habitat. **Based on reductions in habitat quality during reservoir drawdowns that would be detrimental to PCEs, the Proposed Action would have a significant effect on coho salmon critical habitat in the short term. Based on benefits to the PCEs, the Proposed Action would have a beneficial effect on critical habitat for coho salmon in the long term.**

Bull Trout Based on the restricted distribution of bull trout, implementation of the Proposed Action would not affect the physical or chemical components of critical habitat. However, the Proposed Action would allow Chinook salmon and steelhead to access

areas they have not been able to access since the completion of the Copco 1 Development in 1918. These species would potentially compete with and prey upon bull trout fry and juveniles; however, bull trout would also be expected to consume the eggs and fry of Chinook salmon and steelhead. These species co-evolved in the watershed together, and it is anticipated that they would be able to co-exist in the future. **The Proposed Action would have a less-than-significant impact on critical habitat for bull trout in the short and long term.**

Southern Resident Killer Whale The Klamath River contributes to critical habitat for Southern Resident Killer Whales through its contribution of Chinook salmon to their food supply. The Proposed Action would not affect the geographic extent of critical habitat for this species, as it is located in the State of Washington. The Proposed Action is expected to increase wild populations of anadromous salmonids, which could increase food supply for Southern Resident Killer Whales. In a compilation of potential adult production from habitats upstream of Iron Gate Dam, estimates ranged from 9,180 to 21,245 (Hamilton et al. 2011). Klamath River salmon are anticipated to provide less than 1 percent of the diet of Southern Resident Killer Whales in most months. The Proposed Action would not be likely to materially affect the food supply of Southern Resident Killer Whales. **Based on small influence of the Klamath River on PCEs of Southern Resident Killer Whale, the Proposed Action would have a less-than-significant impact on critical habitat for Southern Resident Killer Whales in the short and long term.**

Eulachon Under the Proposed Action, PCEs of critical habitat supporting eulachon would be degraded in the short term, including short-term adverse effects of suspended sediment on spawning and egg incubation habitat, and adult and larval migration habitat for southern DPS eulachon. Under the Proposed Action it is anticipated that water quality will improve throughout the Klamath River, including the estuary (WQST 2011) and that habitat restoration effort under KBRA will improve estuary habitat. Critical habitat for the Southern DPS eulachon includes approximately 539 miles of riverine and estuarine habitat in California, Oregon, and Washington, of which the Klamath River Estuary is a small proportion (<2%). **Although the Proposed Action would result in short-term reductions in habitat quality detrimental to PCEs, a very small proportion (< 2%) of eulachon critical habitat would be effected for a short duration, and the Proposed Action would have a less-than significant effect on eulachon critical habitat in the short term. Based on benefits to the PCEs, the Proposed Action would have a beneficial effect on critical habitat for eulachon in the long term.**

Essential Fish Habitat

As described below, reservoir drawdown associated with dam removal under the Proposed Action could alter the quality of EFH. In addition, the removal of dams and reservoirs could alter the availability and quality of EFH.

Chinook and Coho Salmon EFH The short-term release of sediment from the dams under the Proposed Action would be detrimental to Chinook and coho salmon EFH

during the months when SSC concentrations are elevated. In the long term, the Proposed Action would increase habitat for Chinook and coho salmon (upstream of currently designated EFH) by providing access to habitats upstream of Iron Gate Dam. EFH quality would be affected by improved water quality, and decreased prevalence of disease, as described above for coho salmon critical habitat. Improved access to habitats (upstream of designated EFH), improved water quality, increased sediment transport, and decreased prevalence of disease, would provide a benefit to EFH for Chinook and coho salmon. **Based on a substantial reduction in EFH quality during reservoir drawdown, the Proposed Action would have a significant effect on EFH for Chinook and coho salmon in the short term. Based on benefits to quality, the Proposed Action would have a beneficial effect on EFH for Chinook and coho salmon in the long term.**

Groundfish EFH EFH for Pacific Coast groundfish includes all waters and substrate within areas with a depth less than or equal to 3,500 m (1,914 fm) shoreward to the mean higher high water level or the upriver extent of saltwater intrusion. Under the Proposed Action, impacts to the nearshore environment are not anticipated to be distinguishable from existing conditions, based on a relatively small magnitude of SSCs released to the nearshore environment, an anticipated rapid dilution of the sediment plume as it expands in the ocean, and a relatively low rate of deposition of sediments to the marine nearshore bottom substrates (subsection of Section 3.3.4.3.2). EFH in the Klamath River Estuary could be affected by elevated suspended sediment from sediment releases during dam removal for about 3 months. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see subsection of Section 3.3.4.3.2). However, the area of EFH for groundfish affected by the Proposed Action within the Klamath River Estuary is a very small proportion (<1%) of the total EFH designated for groundfish along the Pacific Coast.

In the long term, SSCs would be similar to that under existing conditions. Natural bedload transport processes would resume, as the dams would no longer trap sediments upstream of Iron Gate Dam. Bedload in the estuary and ocean would not be appreciably affected, because of the small contribution of the area above Iron Gate Dam to the total bedload in the system. With the exception of algal toxins, water quality benefits resulting from dam removal would largely have dissipated upstream of the estuary, and therefore, water quality in the estuary would be expected to remain similar to existing conditions. **Based on small proportion of groundfish EFH affected, and short duration of poor water quality during reservoir drawdown in the near-shore environment and estuary, the Proposed Action would have a less-than-significant effect on EFH for groundfish in the short and long term.**

Pelagic Fish EFH EFH for coastal pelagic species occurs from the shorelines of California, Oregon, and Washington westward to the exclusive economic zone and above the thermocline where sea surface temperatures range from 10 to 26 °C. The effects of

the Proposed Action on pelagic fish EFH would be the same as those described for groundfish EFH in the estuary and near-shore environment. As described for groundfish, the area for EFH for pelagic fish affected by the Proposed Action within the Klamath River Estuary and near-shore environment is a very small proportion (<1%) of the total EFH designated for pelagic species along the Pacific Coast. **Based on small proportion of Pelagic fish EFH affected, and short duration of poor water quality during reservoir drawdown in the near-shore environment and estuary, the Proposed Action would have a less-than-significant effect on EFH for pelagic fish EFH in the short and long term.**

Species-Specific Impacts

As described below, reservoir drawdown associated with dam removal under the Proposed Action could affect aquatic species. In addition, the removal of dams and reservoirs could alter the availability and quality of habitat, resulting in effects on aquatic species.

Species-specific impacts are based upon effects on key ecological attributes summarized above.

Fall-Run Chinook Salmon Quantitative modeling of fall-run Chinook salmon populations suggests that the Proposed Action would increase population abundance. Modeling of dam removal and existing conditions by Oosterhout (2005) suggests that dam removal would substantially increase numbers of spawners over a 50-year period relative to other management scenarios. Additional population capacity and modeling efforts support this conclusion (Huntington 2006, Dunsmoor and Huntington 2006, Hendrix 2011, Lindley and Davis 2011). Of these, the Hendrix (2011) approach is considered the most intensive and robust conducted to date, because it addressed the Proposed Action, used stock-recruitment data from the Klamath River; explicitly incorporated variability in watershed, and ocean conditions; and presented variance estimates of uncertainty. Hendrix (2011) applied a life-cycle model (EDRRA) to forecast the abundance of Chinook salmon (Type I and Type II life history strategies) for both the Proposed Action and continuation of existing conditions (No Action/No Project Alternative) for the years 2012 to 2061. The EDRRA model includes hatchery releases of Chinook salmon from both Iron Gate and Trinity River hatcheries. All returning hatchery origin Chinook salmon are assumed to return to the hatchery and therefore, do not contribute to naturally spawning populations. Production benefits of Chinook salmon releases from Iron Gate hatchery are assumed to end in 2032, four years following the anticipated end of current mitigation releases (Trinity River Hatchery releases will continue). In addition, the model assumes reintroduction efforts described in the KBRA would fully seed available fry habitats upstream of Iron Gate Dam, including the Upper Klamath Basin upstream of Upper Klamath Lake prior to dam removal. The EDRRA model was not developed to be tributary specific; thus Chinook salmon populations originating from tributary streams cannot be separated from the mainstem, the Upper Klamath Basin or other tributaries. Neither implementation of total maximum daily loads (TMDLs) nor climate change was incorporated into the existing models, including the Chinook salmon life cycle model (EDRRA) developed by Hendrix (2011).

The EDRRA Chinook salmon life cycle model developed by Hendrix (2011) addressed fisheries management of Klamath River Chinook salmon. The Pacific Fishery Management Council (PFMC) was established by the Magnuson Fishery Conservation

and Management Act of 1976 and has regulatory jurisdiction over salmon fishing within the 317,690 square mile exclusive economic zone from 3 miles to 200 miles off the coast of Washington, Oregon and California. Jurisdiction over commercial and recreational salmon fishing regulations in nearshore areas, within 3 miles of shore, lies with the respective States. However, the States generally adopt regulations consistent with those established by the PFMC. The Salmon Fishery Management Plan developed by the PFMC describes the goals and methods for salmon management. Management tools such as season length, quotas, and bag limits vary depending on how many salmon are present. There are two central parts of the Plan: Conservation objectives, which are annual goals for the number of spawners of the major salmon stocks (“spawner escapement goals”), and allocation provisions of the harvest among different groups of fishers (commercial, recreational, tribal, various ports, ocean, and inland). The PFMC must also comply with laws such as the ESA. Since the management of salmon considers many factors that can fluctuate greatly from year to year (population abundance and environmental conditions) it is impossible to predict how future management decisions regarding the specific harvest of Klamath Basin salmon might change as a result of the Proposed Action.

Given these uncertainties in management, the EDRRA Chinook salmon life cycle model assumes that current management rules (fishery control rule) established by the PFMC for management of Klamath River Chinook salmon would remain in place throughout the fifty year period of analysis. As stated in Hendrix (2011) “this rule is based on an optimal (i.e., escapement that produces maximum sustainable yield) escapement target after harvest of 40,700 (PFMC 2005).” The analysis uses the same escapement target for both alternatives (40,700) despite the fact that Basin spawning distribution will be extended by hundreds of miles under the Proposed Action (as described below). Therefore, in the EDRRA model, the population is being managed optimally under the No Action/No Project Alternative, whereas it is being managed sub-optimally under the Proposed Action. The management of natural production could be improved by using a Fishery Control Rule that was tailored to the production potential available under the Proposed Action. Such a management change would likely increase EDRRA model predictions of catches and escapement under the Proposed Action.

Hendrix (2011) results indicated substantial uncertainty in Chinook salmon stock recruitment dynamics, resulting in uncertain escapement and harvest abundance forecasts. Despite the uncertainty, modeling results indicate that the Proposed Action would result in higher relative abundance of Chinook salmon. Median escapements to the Klamath Basin are predicted to be higher with the Proposed Action than under existing conditions. The median values were used because the distributions that describe the uncertainty were not symmetric. As a result, the median was a better metric for describing the central portion of the distribution than the mean value. Harvest is also predicted to be greater with the Proposed Action, and the probability of low escapement leading to fishery closures was less under the Proposed Action. Finally, simulations predicted that there is an approximately 75 percent probability that there would be higher escapement with the Proposed Action, and an approximately 70 percent probability of higher annual harvest.

The high degree of overlap in the 95 percent intervals indicate that the statistical properties of the distributions are similar; that is, the range of predicted values are similar due to the large range of uncertainty in stock production values. Conditions that caused model runs to be lower in the Proposed Action relative to the No Action/No Project Alternative are related to fisheries management and the stock production curves used in Lower and Upper Basins. Due to the Fishery Control Rule, productivity of the stock is optimal in almost all years. This occurs because the fishery management ensures that the spawning stock that produces maximum sustainable yield returns to spawn whenever the escapement in the absence of fishing is greater than maximum sustainable yield. This statement of optimal productivity is not true for the Proposed Action for two reasons: 1) Maximum sustainable yield is greater for the Proposed Action due to additional habitat, which is not incorporated into fishery management; and 2) the target escapement by the fishery is combined for the Lower and Upper Klamath Basin; the escapement is too low for the Lower Klamath Basin and too high for the Upper Basin (or vice versa). Thus there are some years and some model iterations when the combined (suboptimal) production from the Lower Klamath Basin and Upper Klamath Basin is less than the optimal production under the No Action/No Project Alternative. In addition to the quantitative modeling results, FERC (2007) and Hamilton et al. (2011) in synthesizing all available information both concluded that increased habitat access following dam removal would result in an increase in the abundance of fall-run Chinook salmon population in the Klamath River Watershed.

To help determine if the Proposed Action will advance restoration of the salmonid fisheries of the Klamath Basin, a Chinook Salmon Expert Panel was convened to attempt to answer specific questions that had been formulated by the project stakeholders to assist with assessing the effects of the Proposed Action compared with existing conditions (Goodman et al. 2011). The Panel concluded that the Proposed Action appears to be a major step forward in conserving target fish populations in the Klamath Basin. The Panel predicted that, based on the information provided to them, it was possible that the Proposed Action would provide a substantial increase in the abundance of naturally spawned Klamath River Chinook salmon above that expected under existing conditions in the reach between Iron Gate Dam and Keno Dam. In addition, the Panel concluded that the Proposed Action offers greater potential than the current conditions for Chinook salmon to tolerate climate change and changes in marine survival (Goodman et al. 2011). While the Panel agreed that there was also evidence for dramatic increases in abundance associated with the Proposed Action upstream of Keno Dam, they cautioned that achieving substantial gains in Chinook salmon abundance and distribution in the Klamath Basin is contingent upon successfully resolving key factors (discussed in this report in detail) that will continue to affect population, such as water quality, disease, and instream flows. In addition, they stated the concern that successful implementation of KBRA would be required, and would need appropriate scientific leadership.

The influence of the Proposed Action within specific reaches is described below.

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the Proposed Action, removal of the Four Facilities would allow fall-run Chinook salmon to

regain access to the upper Klamath River upstream of J.C. Boyle Reservoir. The access would expand the Chinook salmon's current habitat to include historical habitat along the mainstem Klamath River, upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds of miles of additional potentially productive habitat upstream of Iron Gate Dam (DOI 2007), including access to groundwater areas resistant to climate change (Hamilton et al. 2011).

Poor water quality (e.g., severe hypoxia, temperatures exceeding 25°C, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009; USGS 2010; both as cited in Hamilton et al. 2011). However, available information indicates that Upper Klamath Lake habitat is presently suitable to support Chinook salmon for at least the October through May period (Maule et al. 2009). Summer poor water quality conditions, may necessitate seasonal trap and haul around Keno Impoundment/Lake Ewauna for some life stages of primarily fall-run Chinook salmon until KBRA and TMDL implementation improve water quality. This is consistent with the fishway prescriptions of DOI and U.S. Department of Commerce (DOC) (DOI 2007; NOAA Fisheries Service 2007). For adult fall-run Chinook salmon, seasonal collection and transport mortality when water quality is poor is likely to be minor compared to mortality associated with unaided passage through areas of poor water quality at this time of year. Overall, dam removal and associated KBRA actions would accelerate water quality improvements (Dunne et al. 2011) related to implementation of TMDLs and that would help meet beneficial uses such as anadromous fish (WQST 2011).

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam The Proposed Action would restore fall-run Chinook salmon access to the Hydroelectric Reach), including around 76 miles of potential habitat within the Hydroelectric Reach, as described in the No Action/No Project Alternative analysis above. Historically Chinook salmon (both fall- and spring-run) spawned and were abundant in tributaries within the Hydroelectric Reach, including Jenny, Fall, and Shovel Creeks (Administrative Law Judge 2006).

Adults could first access this reach in fall 2020 after dam removal. Because of this they would not be exposed to the elevated SSCs that would occur during dam removal. By fall 2020, elevated SSCs from dam removal would have subsided. Most of the sediment stored within the removed reservoirs would likely be eroded within the first six months after dam removal, and, at most, cause minor (less than 0.5 foot) deposition in river reaches between reservoirs, settling into pool and other low-velocity habitats as water velocities decrease.

River channel habitat within the reservoir reaches would be low gradient habitat of critical importance for spawning and rearing for salmon, steelhead, redband trout, and Pacific lamprey. The upstream half of the J.C. Boyle Reservoir is shallow and considered low gradient (FERC 2007, p 3-185). FERC also considered the Copco No. 2 bypassed reach and reaches inundated by Iron Gate and Copco reservoirs to be low gradient. For these reaches, they estimated that the density of Chinook salmon spawners

per mile for mainstem habitat was twice that of high gradient habitat (FERC 2007). These river channels would likely excavate to their pre-dam elevations within six months, and revert to and maintain pool-riffle morphology due to restoration of riverine processes, creating holding and rearing habitat for anadromous salmonids.

Modeling (Reclamation 2011) indicate that after dam removal, spawning gravel in all sections of the Hydroelectric Reach would be within the range usable for fall-run Chinook salmon, but the amount of sand within the bed within former reservoir sections could initially inhibit spawning success. The bed material within the reservoirs and between Iron Gate to Cottonwood Creek is expected to have a high content (30 to 50 percent) of sand immediately following reservoir drawdown until a flushing flow moves the sand sized material out of the reach (Reclamation 2012). The flushing flow is expected to be at least 6,000 cfs and of several days to weeks to return the bed to a bed dominated by cobble and gravel with a sand content less than 20 percent. After the flushing flow, the bed is expected to maintain fractions of sand, gravel, and cobble which would be expected under natural conditions. Based on the historical record a sufficient flushing flow would likely occur within 5 years following dam removal. Riverine sections between reservoirs would be expected to provide the preferred substrate size range for fall-run Chinook salmon, with very little sand, suggesting that high-quality spawning habitat would be created.

Habitat exposed following dam removal is anticipated to be used during the first spawning migration after dam removal (fall 2020). At two dam removal sites in southern Oregon on the Rogue River, fall-run Chinook salmon quickly used spawning habitat that was formerly inaccessible under reservoirs, benefiting from conversion to riverine habitat and associated bedload/gravel movement. At Savage Rapids in 2010 (the first full fall after dam removal), 91 redds from within the bounds of the former reservoir were documented where no redds had existed previously, and more the following year. At the Gold Ray impoundment in 2010 (the fall after dam removal), 37 redds were documented from within the bounds of the former reservoir, with over twice that many the following year (ODFW 2011).

The Proposed Action would establish a flow regime that more closely mimics natural conditions by increasing spring flow and by incorporating more variability in daily flows. The reservoir drawdowns would allow tributaries and springs such as Fall, Shovel, and Spencer Creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). As described in detail in the subsection of Section 3.3.4.3.2, risk of fish disease and parasites for fall-run Chinook salmon will decrease. These changes and removal of the reservoirs would result in more favorable water temperature for salmonids, as well as improve water quality and reduce the incidence of disease and algal toxins.

Lower Klamath River: Downstream from Iron Gate Dam

The Proposed Action would decrease dissolved oxygen and release dam-stored sediment downstream to the Lower Klamath River in the short term, and restore a flow regime that more closely mimics natural conditions the long term. Suspended sediment effects on fall-run Chinook salmon under the Proposed Action are described in detail in Appendix E, and summarized here.

Under the most-likely-to-occur scenario or worst-case scenario, no effect from suspended sediment relative to existing conditions is anticipated for all adult fall-run Chinook salmon migrating or spawning within tributaries to the Klamath River during fall 2019 (around 92 percent of the population), or for juveniles rearing within tributaries (Table 3.3-5). Suspended sediment is anticipated to have sublethal effects on Type I and Type II outmigrants (Table 3.3-5). Effects would be distributed over three year-classes, rather than a single year-class. Therefore, Type-II and Type-III progeny of adults that successfully spawn in tributaries during 2020 will produce smolts that outmigrate to the ocean a year after the spring pulse of suspended sediment in 2020 and should not be noticeably affected by the Proposed Action. Direct mortality from suspended sediment is anticipated to include the following:

- Under the most-likely-to-occur or worst-case scenario complete loss of eggs from the 2019 brood year deposited in the mainstem in fall 2019 is predicted. Based on redd surveys from 1999 through 2009 (Magneson and Wright 2010), an average of around 2,100 redds could be affected. Based on escapement estimates in the Klamath Basin from 2001 through 2009 (CDFG 2010, unpublished data) this would be around 8 percent of all anticipated redds in the Basin in 2019.
- Type III juvenile fall-run Chinook salmon from the 2019 cohort (hatched from eggs laid in 2018) outmigrating to the ocean during spring 2020 would be exposed to high SSCs. However, based on outmigrant trapping in the mainstem Klamath River at Big Bar (Scheiff et al. 2001), Type III age 1 spring outmigrants are very rare, and only 31 were observed at Big Bar in four years of trapping, or around 0.1 percent of trap captures. Under a most-likely-to-occur scenario 0 to 20 percent mortality is predicted, or around 0 to 189 smolts (around 0.02 percent

Table 3.3-5. Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Fall-run Chinook Salmon

Scenario	Life History Stage: Fall-run Chinook Salmon			
	Adult migration (July 15–Oct 31 2020)	Spawning through fry emergence (Oct 15 2019–Feb 28 2020)	Age 0+ rearing (March 1–March 31 2020)	Outmigration (Type I April 1–August 31 2020) (Type II Sept 1–Nov 30 2020) (Type III Feb 1–April 15 2020)
Most-likely	Normal Existing Conditions (50% exceedance probabilities)			
	No effects	No effects.	Moderate stress for age 0 in upper mainstem.	Type I: Major stress for Type I fry (about 60% of production) Type II: No effects Type III: Major stress for about 2 weeks for Type III outmigrants (<1% of production)
	Proposed Action			
	Same as existing conditions	Up to 100% mortality of the progeny of mainstem spawners (approximately 2,100 redds, or around 8% of production).	No juvenile progeny anticipated rearing in mainstem due to impacts during incubation. Most other juveniles assumed to rear in tributaries prior to outmigration.	Type I: Major stress and reduced growth Type II: Same as existing conditions Type III: Major stress, reduced growth, and up to 20% mortality (0 to 189 smolts, or less than 1% of production)
	Extreme Existing Conditions (10% exceedance probabilities)			
Worst-case	No effect	A few days of suspended sediment may reduce size at emergence for progeny from mainstem spawning (about 8% of escapement).	Major stress for age 0 in upper mainstem.	Type I: Major stress and reduced growth for the about 60% of fry entering mainstem in April–May Type II: Moderate stress for the about 40% of Type II juveniles entering mainstem in Sept–Nov Type III: Major stress for the less than 1% of juveniles entering mainstem in Feb–April
	Proposed Action			
	Major stress and impaired homing	Up to 100% mortality of the progeny of mainstem spawners (approximately 2,100 redds, or around 8% of production).	No juvenile progeny anticipated in mainstem due to impacts during incubation. Most other juveniles assumed to rear in tributaries prior to outmigration.	Type I: Same as existing conditions Type II: Moderate (1 day) to major (about 1 wk) stress Type III: Major stress, reduced growth, and up to 71% mortality (Up to 669 smolts, or less than 1% of production)

of the total fall-run Chinook salmon smolt production). Under a worst-case scenario mortality rates of up to 71 percent are predicted for the Proposed Action, equating to 669 smolts, or around 0.07 percent of the total fall-run Chinook salmon smolt production. Type I and Type II juvenile outmigrants are expected to experience sublethal effects.

As described in detail in Appendix F, the 2021 cohorts could also be affected by sediment deposits with high levels of sand that would likely remain through fall 2020. In the long term, increased supply of gravel from upstream sources is predicted to increase the amount of fall-run Chinook salmon spawning habitat by decreasing the median substrate size to 40 to 60 mm (Reclamation 2012), within the observed range for Chinook salmon spawning (16 to 70 mm [Kondolf and Wolman 1993]). However, in the short term, high sand composition, may reduce the quality of spawning habitat. These levels of sand may continue to affect the 2020 brood year (2021 cohort) as these levels of sand that could remain through fall 2020 unless it is flushed from the substrate during winter flows. Changes in bedload would be limited to the reach from Iron Gate Dam to Cottonwood Creek, a length of 8 miles, or 4 percent of the channel length of the mainstem Klamath River downstream from Iron Gate Dam. The most severe effects would also be limited to a small proportion of the total channel length (0.5 miles, or less than 1 percent of the channel downstream from Iron Gate Dam), as sediment deposition would lessen downstream from Bogus Creek to Cottonwood Creek. At most, around 8 percent of fall-run Chinook salmon in the Klamath Basin are expected to spawn in the mainstem, with an even smaller percentage expected to spawn within the 8-mile affected reach (Appendix E).

In the long term, decreased substrate size is anticipated to improve spawning gravel quality in the mainstem downstream from Iron Gate Dam. Bedload sediment movement and transport are vital to create and maintain functional aquatic habitat. The river would eventually exhibit enhanced habitat complexity due to a more natural flow and reconnected bedload transport regime that will mean the restoration of spawning gravels and early rearing habitat downstream from Iron Gate Dam. Pools would likely return to their pre-sediment release depth within one year (Reclamation 2012), and the river is predicted to revert to and maintain a pool-riffle morphology providing suitable habitat for fall-run Chinook salmon.

Short-term (< 2 months) reductions in dissolved oxygen are anticipated to occur as a result of high SSCs following dam removal, as described in detail in Section X.X. While predicted short-term increases in oxygen demand under the Proposed Action generally result in dissolved oxygen concentrations above the minimum acceptable level (5 mg/L) for salmonids, exceptions to this would occur four to eight weeks following drawdown of J.C. Boyle and Iron Gate reservoirs (i.e., in February 2020), when dissolved oxygen would remain below 5 mg/L from Iron Gate Dam to near the confluence with the Shasta River (RM 176.7), or for a distance approximately 20–25 km downstream from the dam. Any incubating fall-Chinook salmon eggs in the river during this time are assumed to be already suffering 100% mortality caused by increased SSC during this time, and thus the

decrease in dissolved oxygen is not anticipated to have an additional effect. No other life-stages are anticipated to occur in the mainstem Klamath River during this time, and thus will not be affected.

The Proposed Action would establish a flow regime that more closely mimics natural conditions in the Lower Klamath River. Flows under the Proposed Action are intended to benefit fall-run Chinook salmon, and are anticipated to have positive consequences for Chinook salmon given their life cycle in the Klamath River.

As discussed in detail above in the subsection of Section 3.3.4.3.2, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall, and have diurnal variations more synchronized with historical migration and spawning periods (Hamilton et al. 2011). Under the Proposed Action, warmer springtime temperatures would result in fall-run Chinook salmon fry emerging earlier (Sykes et al. 2009), encountering favorable temperatures for growth sooner than under existing conditions (Figure 3.3-19), which could support higher growth rates and encourage earlier emigration downstream, thereby reducing stress and disease (Bartholow et al. 2005; FERC 2007). A predicted earlier outmigration in response to elevated water temperatures in the spring is also supported by a vast body of literature relating to increased growth rates and thermal response of outmigrating salmonids (Hoar 1988). In addition, fall-run Chinook salmon spawning in the mainstem during fall would no longer be delayed (reducing prespaw mortality) (Figure 3.3-18), and adult migration would occur in more favorable water temperatures than under existing conditions (Figure 3.3-19). Overall, these changes would result in water temperatures more favorable for fall-run Chinook salmon in the mainstem Klamath River downstream from Iron Gate Dam.

Incidence of disease are expected to be reduced by enhancing the scour capabilities of flow by uninterrupted sediment transport, a flow regime that more closely mimics natural conditions, thereby disturbing the habitat of the polychaete worm that hosts *C. shasta* (FERC 2007). Reducing polychaete habitat will likely increase abundance of smolts by increasing outmigration survival, particularly for Type I and Type III life-histories (FERC 2007).

Estuary

Under the Proposed Action, habitat in the estuary could be affected by elevated turbidity from sediment releases during dam removal for about 3 months. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see the subsection of Section 3.2.4.3.2). However, the Proposed Action would not substantially change or affect estuarine habitat used by fall-run Chinook salmon. Short- and long-term improvements to water quality and reductions in algal toxins would be expected with the establishment of a flow regime that more closely

mimics natural conditions, and would benefit fall-run Chinook salmon. In addition, flow, and water temperature effects would likely not extend downstream to the estuary.

Summary: Fall-Run Chinook Salmon

Reservoir drawdown associated with dam removal under the Proposed Action could alter SSCs and bedload sediment transport and deposition and affect fall-run Chinook salmon. Fall-run Chinook salmon use the mainstem Klamath River for spawning, rearing, and as a migratory corridor. Direct mortality is predicted for fall-run Chinook salmon redds and some smolts. However, the effect of SSC from the Proposed Action on the fall-run Chinook salmon population, under both most-likely and worst-case scenarios, is expected to be relatively minor because of variable life histories, the large majority of age 0 juveniles that remain in tributaries until later in the spring and summer, and because many of the fry that outmigrate to the mainstem come from tributaries in the mid- or Lower Klamath River, where SSCs resulting from the Proposed Action are expected to be lower due to dilution from tributaries. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Proposed Action would be significant for fall-run Chinook salmon in the short term.**

Mitigation Measures AR-1 through AR-4 (see Section 3.3.4.4) could be implemented to reduce the short-term effects of SSCs on fall-run Chinook salmon incubating eggs and smolts. There would still be short-term effects for fall-run Chinook salmon, including some direct mortality, but no one year class would suffer a substantial decrease in abundance. **Based on minimal reduction in the abundance of a year class in the short term, the Proposed Action would be a less-than-significant effect on fall-run Chinook salmon after mitigation.**

Under the Proposed Action, removal of dams could alter habitat availability, flow regime, water quality, temperature variation, fish disease incidence, and algal toxins, all of which could affect fall-run Chinook salmon in the long term. As stated above, dam removal would also restore connectivity to hundreds of miles of potentially usable habitat in the Upper Klamath Basin and would create additional spawning and rearing habitat within the Hydroelectric Reach. By providing an unimpeded migration corridor, the Proposed Action would provide the greatest possible benefit related to fish passage, hence, the highest survival and reproductive success. It is anticipated that the Proposed Action would increase the abundance, productivity, population spatial structure, and genetic diversity of fall-run Chinook salmon in the Klamath River watershed. In general, free flowing conditions as per the Proposed Action, would likely provide optimal efficiency, decrease outmigrant delay, and increase concomitant adult escapement (Buchanan et al. 2011b). As discussed in detail above, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem. In addition, under the Proposed Action diminished disease conditions and improved water quality in the mainstem Klamath River will likely improve the survival of smolts outmigrating from tributaries downstream from Iron Gate Dam (e.g., Scott and Shasta rivers), thus

increasing the likelihood of successful restoration actions in those watersheds. **Based on increased habitat availability and improved habitat quality, the effect of the Proposed Action would be beneficial for fall-run Chinook salmon in the long term.**

Spring-Run Chinook Salmon As discussed above for fall-run Chinook salmon, a Chinook Salmon Expert Panel was convened to attempt to answer specific questions that had been formulated by the project stakeholders to assist with assessing the effects of the Proposed Action compared with existing conditions (Goodman et al. 2011). While noting uncertainties based on existing data, the panel concluded that the prospects for the Proposed Action to provide a substantial positive effect for spring Chinook salmon is more remote than for fall-run Chinook salmon. The primary concern of the panel was that low abundance and productivity (return per spawner) of spring Chinook salmon would limit recolonization of habitats upstream of Iron Gate Dam. However, as described below in this section, this concern would be addressed in that the KBRA includes a reintroduction component to establish populations in the new habitats. KBRA implementation would reintroduce spring-run Chinook salmon upstream of Upper Klamath Lake in Phase 1. The adaptive management approach to reintroduction will include spring-run and fall-run Chinook salmon (Hooton and Smith 2008). Even without supplementation, it is likely that spring-run Chinook salmon recolonization would occur as it did for Chinook salmon following barrier removal at Landsburg Dam in Washington (Kiffney et al. 2009). In addition, KBRA actions would be implemented that are anticipated to improve productivity of existing and potentially newly accessible habitats. The influence of the Proposed Action within specific reaches is described below.

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Under the Proposed Action, dam removal would allow spring-run Chinook salmon to regain access to the upper Klamath River upstream of J.C. Boyle Reservoir (FERC 2007). The access would expand the Chinook salmon's current habitat to include historical habitat along the mainstem Klamath River and upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds of miles of additional potentially productive habitat (DOI 2007), including access to important thermal refugia within areas influenced by groundwater exchange that are more resistant to climate change (Hamilton et al. 2011). Some of these areas, such as the lower Williamson River, have habitat that would provide substantial holding areas for spring-run Chinook salmon (Hamilton et al. 2010). Other holding areas with suitable temperatures upstream of J.C. Boyle Reservoir include groundwater influenced areas on the west side of Upper Klamath Lake, and the Wood River (Gannett et al. 2007). Warmer winter water temperatures associated with groundwater would also be conducive to the growth of salmonids (Hamilton et al. 2011).

The Proposed Action would not result in changes to suspended or bedload sediment, flow-related habitat, or algal toxins in this reach. Facilitating the movement of anadromous fish presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006).

Poor water quality (e.g., severe hypoxia, temperatures exceeding 25 °C, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009; USGS 2010; both as cited in Hamilton et al. 2011). However, available information indicates that Upper Klamath Lake habitat is presently suitable to support Chinook salmon for at least the October through May period (Maule et al. 2009). Historically, adult spring-run Chinook salmon migrated upstream of the current location of Iron Gate Dam perhaps as early as February and March (Fortune et al. 1966) and likely held over in large holding pools in the mainstem in tributaries fed by cool water, and in refugia habitat upstream of Upper Klamath Lake (CDFG 1990c; Moyle 2002; Snyder 1931). One benefit of such early migration would be the avoidance of periods of poor water quality. The restored water temperature regime under the Proposed Action may restore upstream migration timing of adult spring-run Chinook salmon because of the shift in water temperatures downstream from Iron Gate dam (Bartholow et al. 2005).

Summer poor water quality conditions, may necessitate seasonal trap and haul around Keno Impoundment/ Lake Ewauna for some life stages of Chinook salmon (primarily fall-run) until KBRA and TMDL implementation improve water quality. This is consistent with the fishway prescriptions of DOI and DOC (DOI 2007; NOAA Fisheries Service 2007). Overall, dam removal and associated KBRA actions would accelerate water quality improvements (Dunne et al. 2011) and TMDL water quality benefits to anadromous fish (WQST 2011).

Huntington (2006) reasoned that spring-run Chinook salmon likely accounted for the majority of the Upper Klamath Basin's actual salmon production under historical conditions. Huntington (2006) cautioned that while access to the Upper Klamath Basin provides considerable promise of increasing spring-run abundance, the existing potential for Chinook salmon production within the Basin upstream of Upper Klamath Lake is clearly much lower than his estimate of historical potential. However, Huntington (2006) did not fully account for the historical (and unknown) production potential of Upper Klamath Lake itself, which could have been considerable, as suggested by a recent experimental reintroduction into Upper Klamath Lake (Maule et al. 2009).

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

The Proposed Action would restore spring-run Chinook salmon access to the Hydroelectric Reach), including around 76 miles of potential habitat within the Hydroelectric Reach, as described in the No Action/No Project Alternative analysis above. Chinook salmon (both fall- and spring-run) historically spawned and were abundant in tributaries within the Hydroelectric Reach, including Jenny, Fall, and Shovel creeks (Administrative Law Judge 2006). Adults could first access this reach in spring 2021 after dam removal; thus, short-term gains in flow-related habitat or habitat expansion would be limited to later cohorts. Elevated SSCs and bedload movement from dam removal would have dissipated by this time (see Figure 3.3-5, Figure 3.3-6, and Figure 3.3-7), returning to background levels similar to those under existing conditions and would not be expected to affect spring-run Chinook salmon using this area.

The Proposed Action would eliminate the Four Facilities and would establish a flow regime that more closely mimics natural conditions by increasing spring flow and by incorporating more variability in daily flows. The removal of the reservoirs would allow Fall, Shovel, and Spencer Creeks to flow directly into the mainstem Klamath River, along with Big Springs in the J.C. Boyle Bypass Reach and additional springs, which would provide fish with patches of cooler water as refugia during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). As described in detail in the subsection of Section 3.3.4.3.1, risk of fish disease and parasites for spring-run Chinook salmon will decrease. These changes and removal of the reservoirs would result in more favorable water temperature for salmonids, as well as improve water quality and reduce the incidence of disease and algal toxins.

Lower Klamath River: Downstream from Iron Gate Dam

The Proposed Action would release dam-stored sediment downstream to the Lower Klamath River Reach in the short term, and would establish a flow regime that more closely mimics natural conditions in the long term. Adult spring-run Chinook salmon do not currently occur upstream of the Salmon River, and would not be expected to be able to use the mainstem Klamath River upstream of Iron Gate Dam until conditions in the Hydroelectric Reach are suitable.

Suspended sediment effects on spring-run Chinook salmon under the Proposed Action are described in detail in Appendix E, and summarized here. The distribution of spring-run Chinook salmon in the Salmon River and tributaries downstream limits their exposure to mostly lower concentrations of suspended sediment. Under the most-likely-to-occur scenario or worst-case scenario, no effect from suspended sediment relative to existing conditions is anticipated for all spring-run Chinook salmon spawning and rearing, which occurs primarily within tributaries (Table 3.3-6). Suspended sediment is anticipated to have sublethal effects on adult migration, primarily for those adult returning to the Salmon River (around 5 percent of all spring-run migrants), and sublethal effects on Type I and Type II outmigrants (Table 3.3-6). Direct mortality from suspended sediment is anticipated to include the following:

- Type III juvenile spring-run Chinook salmon from the 2019 cohort (hatched from eggs laid in 2018) outmigrating to the ocean from the Salmon River during spring 2020 would be exposed to high SSCs. However, based on outmigrant trapping in the Salmon River, Type III age 1 spring outmigrants are very rare, and only 30 were observed in five years of trapping. Assuming a larger number of Type III smolts outmigrate from the Salmon River and are undetected (assume an average of around 78 Type III smolts per year), under a most-likely-to-occur scenario 0 to 20 percent mortality is predicted or 16 smolts at most (less than 1 percent of the total spring-run Chinook salmon smolt production). Under a worst-case scenario mortality rates of 20 to 36 percent are predicted, or around 28 smolts at worst (<1 percent of all production). Type I and Type II juvenile outmigrants are expected to experience sublethal effects.

Table 3.3-6. Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario SSCs Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Spring-run Chinook Salmon

Scenario	Life History Stage: Spring-run Chinook Salmon			
	Adult migration (Apr 1–Jun 30, 2020)	Spawning through fry emergence (Sept 1 2019–Feb 28, 2020)	Fry and juvenile rearing (year-round)	Outmigration (Type I: April 1–August 31 2020) (Type II: Sept 1–Nov 30 2020) (Type III: Feb 1–April 15 2020)
Most likely	Existing Conditions (normal)			
	Spring Migration: Moderate stress and Impaired homing for adults returning to Salmon River (average 5% of total run, up to 35% of natural run) Summer Migration: No effects	Most spawning takes place in tributaries; no effects predicted	Juveniles primarily rear in tributaries; no effects predicted	Type I: Major stress for Type I fry from Salmon River (about 80% of Salmon River production)
				Type II: No effects (about 20% of Salmon R. production)
				Type III: Major stress for Type III juveniles from Salmon River (< 1% of Salmon River production)
	Proposed Action			
	Spring Migration: Major stress and impaired homing Summer Migration: Same as existing conditions	Same as existing conditions	Same as existing conditions	Type I: Same as existing conditions
Type II: Same as existing conditions				
Type III: Major stress, reduced growth, and up to 20% mortality. (around 16 smolts, less than 1% of the total smolt population from the Salmon River)				
Worst-case	Existing conditions (extreme)			
	Spring Migration: Major stress and impaired homing Summer Migration: Moderate stress	Most spawning takes place in tributaries; no effects predicted	Juveniles primarily rear in tributaries; no effects predicted	Type I: Major stress for Type I fry from Salmon River (about 80% of Salmon River production)
				Type II: Moderate stress for Type II juveniles from Salmon River (about 20% of Salmon River production)
				Type III: Major stress for Type III juveniles from Salmon River (<1% of Salmon River production)
	Proposed Action			
	Spring Migration: Same as existing conditions Summer Migration: Impaired homing	Same as existing conditions	Same as existing conditions	Type I: Same as existing conditions
Type II: Same as existing conditions				
Type III: Major stress, reduced or no growth, and up to 36% mortality (up to 28 smolts, less than 1% of the total smolt population from the Salmon River)				

Adults could first access the reach upstream of the Iron Gate Dam in Spring 2021 if dam removal is completed by April of that year. As described in detail in Appendix F, short- and long-term changes in bedload would be limited to the reach from Iron Gate Dam to Cottonwood Creek, a length of 8 miles, or 4 percent of the mainstem Klamath River channel downstream from Iron Gate Dam (Appendix F). The most severe effects would also be limited to a small proportion of the total channel length (0.5 miles, or less than 1 percent of the channel downstream from Iron Gate Dam), as sediment deposition would lessen downstream from Bogus Creek to Cottonwood Creek and, thus, would not affect the area currently used by spring-run Chinook salmon. Within one year (i.e., by spring 2021), SSCs would have returned to background levels and the channel would likely have reverted back to its previous pool-riffle morphology (Stillwater Sciences 2008).

The Proposed Action would create a flow regime that more closely mimics natural conditions in the Lower Klamath River by increasing spring flow and by incorporating more variability in daily flows. As discussed in detail above, dam removal would cause water temperatures to warm earlier in the spring and early summer and cool earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem. Migrating adults and juveniles rearing or migrating in the mainstem in spring 2020 would be exposed to poor water quality due to the Proposed Action. Because most spawning occurs in the Salmon and Trinity Rivers, magnitude of exposure would be limited by dilution from tributaries entering downstream from Iron Gate Dam.

Incidence of disease are expected to be reduced by enhancing the scour capabilities of flow by uninterrupted sediment transport, a flow regime that more closely mimics natural conditions, thereby disturbing the habitat of the polychaete worm that hosts *C. shasta*. Reducing polychaete habitat would likely increase abundance of smolts by increasing outmigration survival, particularly for Type I and Type III life-histories.

Estuary

Under the Proposed Action, habitat in the estuary could be affected by elevated turbidity from sediment releases during dam removal for about 3 months. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see the subsection of Section 3.2.4.3.2). However, the Proposed Action is not expected to substantially change or affect spring-run Chinook salmon estuarine habitat. Short- and long-term improvements to water quality and reductions in algal toxins would be expected with the establishment of a flow regime that more closely mimics natural conditions. This would benefit spring-run Chinook salmon. Flow and water temperature effects would likely not extend downstream to the estuary.

Summary: Spring-Run Chinook Salmon

Reservoir drawdown associated with dam removal under the Proposed Action could alter SSCs and bedload sediment transport and deposition and affect spring-run Chinook salmon. The overall effect of suspended sediment from the Proposed Action on the spring-run Chinook salmon population is not anticipated to differ much from existing conditions and the No Action/No Project Alternative. There is very little difference from existing conditions and the No Action/No Project Alternative for adult migrants, all of which is predicted to be sublethal, and no effects are anticipated for the spawning, incubation, and fry stages because they do not spawn in the mainstem. Type I and II outmigrants are expected to experience very similar conditions under the Proposed Action as under existing conditions and the No Action/No Project Alternative. However, direct mortality is predicted for some Type III smolts (< 1 percent of production). **Based on minimal reduction in the abundance of a year class in the short term, the effect of the Proposed Action would be less-than-significant for spring-run Chinook salmon in the short term.**

Implementation of Mitigation Measures AR-2 (see Section 3.3.4.4) could reduce the short-term effects of SSCs on spring-run Chinook salmon Type III smolts. With implementation of mitigation measures, there would still be short-term effects for spring-run Chinook salmon including some potential direct mortality, but there would not be a substantial reduction in the abundance of a year class. **Based on minimal reduction in the abundance of a year class in the short term, the Proposed Action would be a less-than-significant effect on spring-run Chinook salmon after mitigation.**

Under the Proposed Action, removal of dams could result in alterations in habitat availability, flow regime, water quality, temperature variation, fish disease incidence, and algal toxins which could affect spring-run Chinook salmon in the long term. Dam removal would restore connectivity to hundreds of miles of potentially usable habitat in the Upper Klamath Basin, including additional habitat within the Hydroelectric Reach. Access to additional habitat would provide a long-term benefit to spring-run Chinook salmon populations. The expansion of habitat opportunities would allow maximum expression of life-history variation and the restoration of an additional population of spring-run Chinook salmon population to strengthen resiliency in the Klamath Basin, particularly because passage upstream of Iron Gate Dam would provide access to groundwater thermal refugia during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). By providing an unimpeded migration corridor, the Proposed Action would provide the greatest possible benefit related to fish passage, hence, the highest survival and reproductive success (Buchanan et al. 2011b). As discussed in detail above, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem. In addition, with large scale hydraulic mining operations now outlawed, spring-run Chinook salmon would no longer be subject to one of their most significant threats in the Klamath River (as discussed above in the subsection of Section 3.3.3.1.1.).

Current improved fisheries management also minimizes overharvest. It is anticipated that as a result of the Proposed Action the spring-run Chinook salmon population within the Klamath River watershed would have an increase in abundance, productivity, population spatial structure, and genetic diversity. **Based on increased habitat availability and improved habitat quality, the effect of the Proposed Action would be beneficial for spring-run Chinook salmon in the long term.**

Coho Salmon A Coho Salmon and Steelhead Expert Panel was convened and charged with answering specific questions that had been formulated by the project stakeholders to assist with assessing the effects of the Proposed Action on coho salmon and steelhead (Dunne et al. 2011). While noting the constraints of the Panel to arrive at conclusions within a short time period and without adequate quantitative or synthesized information, the conclusion of the Panel was that: “Although Current Conditions will likely continue to be detrimental to coho, the difference between the Proposed Action and Current Conditions is expected to be small, especially in the short term (0-10 years after dam removal). Larger (moderate) responses are possible under the Proposed Action if the KBRA is fully and effectively implemented and mortality caused by the pathogen *C. shasta* is reduced. The more likely small response will result from modest increases in habitat area usable by coho with dam removal, small changes in conditions in the mainstem, positive but un-quantified changes in tributary habitats where most coho spawn and rear, and the potential risk for disease and low ocean survival to offset gains in production in the new habitat.”

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

There is no historical evidence that coho salmon occurred upstream of J.C. Boyle Reservoir. However, in historical interviews Snyder (1931) noted that while, “silver salmon are said to migrate to the headwaters of the Klamath to spawn, the interviews were not conclusive since most people at the time did not distinguish between the various anadromous salmonid species. Overall, historical evidence of coho salmon occurrence upstream of Spencer Creek and J.C. Boyle reservoir is uncertain.

Hydroelectric Reach: from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

The Proposed Action would restore access for upper Klamath River Population coho salmon to the Hydroelectric Reach, expanding their distribution to include historical habitat along the mainstem Klamath River and all tributaries upstream at least as far as Spencer Creek; including in Jenny, Shovel, and Fall Creeks (Hamilton et al. 2005), including around 76 miles of potential habitat within the Hydroelectric Reach, as described in the No Action/No Project Alternative analysis above. Coho salmon downstream from Iron Gate Dam belonging to the Upper Klamath River Population Unit would migrate above the dam if access was provided by fishways (Administrative Law Judge 2006). Over time, access to habitat above Iron Gate Dam would benefit the Upper Klamath River Population Unit by: a) extending the range and distribution of the species thereby increasing the coho salmon’s reproductive potential; b) increase genetic diversity in the coho stocks; c) reduce the species vulnerability to the impacts of degradation; and d) increase the abundance of the coho salmon population (Administrative Law Judge 2006). The NRC of the National Academy of Science reviewed causes of decline and

strategies for recovery of endangered and threatened fishes of the Klamath Basin. The NRC concluded that “removal of Iron Gate Dam... could open new habitat, especially by making available tributaries that are now completely blocked to coho” (NRC 2004). In a recent evaluation of recolonization after access was provided, juvenile coho salmon established a population and outnumbered resident salmonid species by 40 percent within 5 years of colonization (Pess et al. 2011).

Adults could first access this reach in fall 2020 after dam removal. By this time, elevated SSCs from dam removal would likely have dissipated, returning to background levels similar to those of existing conditions. Most sediment released from the reservoirs would likely be eroded within the first six months after dam removal (by May 2020), returning sections of river currently inundated by the Four Facilities and riverine sections between reservoirs to pool-riffle morphology. Within this reach, coho salmon generally spawn in tributaries and not within the mainstem Klamath River, but might rear and migrate through the Hydroelectric Reach. Dam removal would result in the provision of suitable rearing habitat for juveniles and spawning habitat for the few individuals that might spawn in the mainstem Klamath River. Access to the cooler waters associated with spring inputs in the Hydroelectric Reach would benefit coho salmon rearing in the mainstem (Hamilton et al. 2011).

The Proposed Action would also eliminate the Four Facilities and would establish a flow regime that more closely mimics natural conditions by increasing spring flow and by incorporating more variability in daily flows. The reservoir drawdowns would allow tributaries and springs such as Fall, Shovel, and Spencer Creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). As described in detail in the subsection of Section 3.3.4.3.2, risk of fish disease and parasites for coho salmon will decrease. These changes and removal of the reservoirs would result in more favorable water temperature for salmonids, as well as improve water quality and reduce the incidence of disease and algal toxins. All of these changes would benefit coho salmon produced in the Hydroelectric Reach in 2020 and thereafter.

Lower Klamath River: Downstream from Iron Gate Dam

The Proposed Action would release dam-stored sediment downstream to the Lower Klamath River Reach in the short term and would establish a flow regime that more closely mimics natural conditions in the long term. Suspended sediment effects on coho salmon under the Proposed Action are described in detail in Appendix E, and summarized here. There are nine coho salmon population units in the Klamath River watershed (see the subsection of Section 3.3.3.1.4). Only negligible effects from suspended sediment would be expected on the three population units in the Trinity River, and on the Lower Klamath River Population Unit relative to existing conditions. Effects on the Salmon River Population Unit are anticipated to remain sublethal even under a worst-case scenario (Table 3.3-7). Effects on the upper Klamath River, mid-Klamath

Table 3.3-7. Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario SSCs Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Coho Salmon

Scenario	Life History Stage: Coho Salmon				
	Adult migration (Sept 1, 2019– Jan 1, 2020)	Spawning through fry emergence (Nov 1, 2019– Mar 14, 2020)	Age 0+ rearing during summer (Mar 15–Nov 14, 2020)	Age 1+ rearing during winter (Nov 15, 2019– Feb 14, 2020)	Outmigration Early spring outmigration: (Feb 15–March 31, 2020) Late spring outmigration: (April 1– June 30, 2020)
Most Likely	Existing Conditions (normal)				
	Stressful SSCs for about 5 days; deleterious effects on adults unlikely	Low survival (<20%)	Age 0+ summer: Major stress for age 0+ from 2020 cohort in mainstem (<50% of fry)	Age 1+ winter: Moderate stress for age 1+ juveniles from 2019 cohort in mainstem (assume <1% of juveniles)	Early spring outmigration: Major stress mortality for smolts coming from Upper Klamath, Mid-Klamath, Shasta River, and Scott River populations during early spring (approximately 44% of run outmigrate in early spring)
					Late spring outmigration: Major stress for smolts coming from Upper Klamath, Mid-Klamath, Shasta River, and Scott River populations during late spring (approximately 56% of run)
	Proposed Action				
Major stress and impaired homing	Up to 100% mortality of progeny of mainstem spawners (about 13 redds, or 0.7–26% of Upper Klamath River Population Unit natural escapement)	Age 0+ summer: Reduced growth	Age 1+ winter: Major stress, reduced growth, and up to 20% mortality	Early spring outmigration: Major stress, reduced growth, and up to 20% mortality for smolts coming from Upper Klamath, Mid-Klamath, Shasta River, and Scott River populations during early spring (~44 percent of run outmigrate in early spring). (2,668 smolts, 3% of total production in basin)	
				Late spring outmigration: Major stress and reduced growth	

Table 3.3-7. Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario SSCs Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Coho Salmon

Scenario	Life History Stage: Coho Salmon				
	Adult migration (Sept 1, 2019– Jan 1, 2020)	Spawning through fry emergence (Nov 1, 2019– Mar 14, 2020)	Age 0+ rearing during summer (Mar 15–Nov 14, 2020)	Age 1+ rearing during winter (Nov 15, 2019– Feb 14, 2020)	Outmigration Early spring outmigration: (Feb 15–March 31, 2020) Late spring outmigration: (April 1– June 30, 2020)
Worst-case	Existing Conditions (extreme)				
	Major stress and impaired homing	Up to 100% mortality of progeny of mainstem spawners (about13 redds, or 0.7–26% of Upper Klamath River Population Unit natural escapement)	Age 0+ summer: Major stress and reduced growth for fish rearing in mainstem (< 50% of fry)	Age 1+ winter: Major stress and reduced growth for fish rearing in mainstem (assume <1% of juveniles)	Early spring outmigration: Major stress and reduced growth for smolts coming from Upper Klamath, Mid-Klamath, Shasta River, and Scott River populations during early spring (approximately 44% of run outmigrate in early spring)
					Late spring outmigration: Major stress for smolts coming from Upper Klamath, Mid-Klamath, Shasta River, and Scott River populations during late spring (approximately 56% of run)
	Proposed Action				
Same as existing conditions	Same as existing conditions	Age 0+ summer: No growth	Age 1+ winter: Major stress, reduced growth and up to 52% mortality	Early spring outmigration: Major stress, reduced growth, and up to 49% mortality for smolts coming from Upper Klamath, Mid-Klamath, Shasta River, and Scott River populations during early spring (approximately 44% of run outmigrate in early spring) (6,536 smolts, 8% of total production in basin)	
				Late spring outmigration: Major stress and reduced growth	

River, Shasta, and Scott population units under the most-likely-to-occur or worst-case scenario are anticipated to be sublethal on most life-stages (Table 3.3-7), with the following exceptions:

- Under the most-likely-to-occur or worst-case scenario, coho salmon from the Upper Klamath River Population Unit that spawn in the mainstem, as well as their progeny, would suffer up to 100 percent mortality; however, even under existing conditions and the No Action/No Project Alternative, 80–100 percent mortality is expected due to the effects of suspended sediment on these life stages (in addition to other sources of mortality). Based on spawning surveys conducted from 2001 to 2005 (Magneson and Gough 2006), from 6 to 13 redds could be affected in 2019 during the Proposed Action, many of which are thought to be hatchery returning fish (NOAA Fisheries Service 2010a). Based on the range of escapement estimates of Ackerman et al. (2006), 13 redds (the highest number observed) could represent anywhere from 0.7 to 26 percent of the naturally returning spawning in the Upper Klamath River Population Unit, and much less than 1 percent of the natural and hatchery returns combined.
- Coho salmon smolts outmigrating from tributaries in the Upper or Mid-Klamath River, Shasta, or Scott populations during early spring (around 46 percent of outmigrating smolts compared to those that outmigrate in late spring) are predicted to experience 20 percent mortality under a most-likely-to-occur scenario, or around 49 percent mortality under a worst-case scenario. Anticipated total mortality varies by population, and is detailed in Appendix E.

All population units would be expected to recover from these losses within one or two generations, given the benefits to the population. Although no single year-class is expected to be completely lost, mortality of a portion of the smolt outmigration from the upper Klamath River, mid-Klamath River, Shasta River, and Scott River population units may affect the strength of the 2018 year class, requiring two or three generations to recover from losses.

The Proposed Action would also result in the release of bedload sediment, as described in detail in Appendix F. Effects associated with release of coarse sediment are expected to affect the same individuals described for suspended sediment above. For example, bedload sediment is predicted to bury redds constructed in fall 2019, which are the same redds expected to suffer from suspended sediment (~13 redds, or 0.7–26 percent of Upper Klamath River Population unit natural escapement). In addition, bedload sediment could result in the deposition that could aggrade pools or overwhelm other habitat features that coho salmon use for adult holding or juvenile rearing. However, the effect on habitat is anticipated to be short term, and pools would likely return to their pre-sediment release depth within one year (Reclamation 2012). If the magnitude and duration of flows in spring 2020 are sufficiently high to effectively mobilize the bed, coho salmon spawning

habitat in the mainstem downstream from Iron Gate Dam could improve over existing conditions. Within six months the river is predicted to revert to and maintain a pool-riffle morphology, providing a benefit to coho salmon.

As discussed in detail above in the subsection of Section 3.3.4.3.2, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem. Cooler water temperatures during fall would benefit upstream migrant adults and juveniles during fall upstream migration and juvenile redistribution to overwintering habitats by providing a broader window of suitable habitat. Spring outmigrants may also move out earlier, potentially reducing their susceptibility to parasites. As with SSCs, migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to poor water quality due to the Proposed Action, but these effects would be short term.

Incidence of disease are expected to be reduced by enhancing the scour capabilities of flow by uninterrupted sediment transport, a flow regime that more closely mimics natural conditions, thereby disturbing the habitat of the polychaete worm that hosts *C. shasta*. Reducing polychaete habitat would likely increase abundance of smolts by increasing outmigration survival.

Estuary

Under the Proposed Action, habitat in the estuary could be affected by elevated turbidity from sediment releases during dam removal for about 3 months. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see the subsection of Section 3.2.4.3.2). However, the Proposed Action is not expected to substantially change or affect coho salmon estuarine habitat. Flow and water temperature effects would likely not extend downstream to the estuary.

Summary: Coho Salmon

Reservoir drawdown associated with dam removal under the Proposed Action could alter SSCs and bedload sediment transport and deposition and affect coho salmon. In general, the wide distribution and use of tributaries by both juvenile and adult coho salmon will likely protect the population from the worst effects of the Proposed Action. However, direct mortality is anticipated for redds and smolts from the upper Klamath River, mid-Klamath River, Shasta River, and Scott River population units. No mortality is anticipated for the Salmon River, Trinity River, and Lower Klamath River populations under the most likely or worst-case scenarios. All population units would be expected to recover from these losses within one or two generations, given the benefits described below. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Proposed Action would be significant for the coho salmon**

from the Upper Klamath River, Mid-Klamath River, Shasta River, and Scott River population units in the short term. Based on no reduction in the abundance of a year class, the effect of the Proposed Action would be less-than-significant for the coho salmon from the three Trinity River population units, Salmon River and the Lower Klamath River Population Unit in the short term.

Implementation of Mitigation Measures AR-1 through AR-4 (see Section 3.3.4.4) could reduce the short-term effects of SSCs on coho salmon adults, incubating eggs, and smolts. With implementation of mitigation measures there would still be short term effects for coho salmon including direct mortality to as high as 18 percent of the smolts from some population units under a worst-case scenario (see Section 3.3.4.4). **Based on substantial reduction in the abundance of a year class in the short term, the Proposed Action would have a significant effect on coho salmon from the Upper Klamath River, Mid-Klamath River, Shasta River, and Scott River population units after mitigation in the short term.**

Under the Proposed Action, removal of dams could result in alterations in habitat availability, flow regime, water quality, temperature variation, fish disease incidence, and algal toxins which could affect coho salmon in the long term. Substantial declines in abundance resulting from effects of the Proposed Action are not anticipated for more than one year class (i.e. one generation), although complete recovery of that year class may require two to three generations. Dam removal would restore connectivity to habitat on the mainstem Klamath River up to and including Spencer Creek and would create additional habitat within the Hydroelectric Reach. As discussed in detail above, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem. It is anticipated that as a result of the Proposed Action, the Upper Klamath River, Mid-Klamath River, Shasta River, Scott River, Salmon River, and Lower Klamath River coho salmon population units would have an increase in abundance, productivity, population spatial structure, and genetic diversity. In general, free flowing conditions as per the Proposed Action, would likely provide optimal efficiency, decrease outmigrant delay, and increase concomitant adult escapement (Buchanan et al. 2011b). It is anticipated that as a result of the Proposed Action, the three Trinity River population units would have increased productivity. **Based on increased habitat availability and improved habitat quality, the effect of the Proposed Action would be beneficial for the coho salmon from the Upper Klamath River, Mid-Klamath River, Lower Klamath River, Shasta River, Scott River, and Salmon River population units in the long term. Based on improved habitat quality, the effect of the Proposed Action on coho salmon from the three Trinity River population units would be less-than-significant for the long term.**

Steelhead A Coho Salmon and Steelhead Expert Panel was convened and charged with answering specific questions that had been formulated by the project stakeholders to assist with assessing the effects of the Proposed Action on coho salmon and steelhead

(Dunne et al. 2011). The conclusion of the Panel was that the Proposed Action could result in increased spatial distribution and abundance of steelhead. This assessment is based on the observations that steelhead would be able to access a substantial extent of new habitat, steelhead are relatively tolerant to warmer water (compared to coho salmon), they are similar to other species (resident redband/rainbow trout) that are currently thriving in upstream habitats, and that while steelhead are currently at lower abundances than historical values, they are not yet rare. The influence of the Proposed Action within specific reaches is described below.

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Under the Proposed Action, dam removal would allow steelhead to regain access to the upper Klamath River upstream of J.C. Boyle Reservoir. This would expand the population's distribution to include historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising 360 miles of additional potentially productive habitat (Huntington 2006; DOI 2007; NOAA Fisheries Service 2007).

The Proposed Action would not result in changes to suspended or bedload sediment, flow-related habitat, or algal toxins and disease in the Upper Klamath River. Facilitating the movement of anadromous fish presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006).

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

The Proposed Action would restore steelhead access to the Hydroelectric Reach, including an estimated 80 miles of habitat within the Hydroelectric Reach, as described in the No Action/No Project Alternative analysis above. Adults could first access this reach in fall 2020 (winter steelhead) or winter 2021 (summer steelhead) after dam removal (summer steelhead spawning typically does not begin until December). Elevated SSCs resulting from dam removal would likely have returned to background levels similar to existing conditions. Steelhead could use this reach as a migration corridor, as most sediment released from the reservoirs would likely be eroded within the first 6 months after dam removal (by May 2020) and would not impede upstream movement. Reaches currently inundated by reservoirs and reaches between reservoirs would likely return to a pool-riffle morphology, which would benefit rearing steelhead.

The Proposed Action would also eliminate the reservoirs and establish a flow regime that more closely mimics natural conditions by increasing spring flow and by incorporating more variability in daily flows. The reservoir drawdowns would allow tributaries and springs such as Fall, Shovel, and Spencer Creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). The action would also be likely to nearly eliminate blue-green algae blooms and their associated toxins, improving water quality. These changes would benefit steelhead.

Lower Klamath River: Downstream from Iron Gate Dam

The Proposed Action would release dam-stored sediment downstream to the Lower Klamath River in the short term, and restore a flow regime that more closely mimics natural conditions in the long term. Suspended sediment effects on steelhead under the Proposed Action are described in detail in Appendix E, and summarized here.

Under the most-likely-to-occur scenario or worst-case scenario, no effect from suspended sediment relative to existing conditions is anticipated for the half-pounder life history, all spawning (which occurs primarily in tributaries), and age 0 rearing (Table 3.3-8). Sublethal effects are anticipated for all other life stages (Table 3.3-8), with the following exceptions:

- Under the most-likely-to-occur scenario, up to 36 percent mortality is predicted for the winter run steelhead (up to 1,008 adults, or up to 14 percent of the total winter run escapement). On average around 20 percent of winter steelhead migrate prior to initiation of reservoir drawdown on December 15th. In addition, steelhead are highly mobile species that have been known to stray to avoid habitat degradation (Bisson et al. 2005), and regularly occur in environments with high SSC, and therefore the predictions described here are likely more dire than would occur. It is likely that at least some would enter tributaries if conditions within the mainstem were adverse.
- Under the most-likely-to-occur scenario, up to 52 percent mortality is predicted for age 1 juveniles in the mainstem (up to 8,200 juveniles or around 14 percent of total basin-wide age 1 production).
- Under the most-likely-to-occur scenario, up to 52 percent mortality is predicted for age 2 juveniles in the mainstem (up to 6,893 juveniles or around 13 percent of total basin-wide age 2 production).
- Under the worst-case scenario, 0 to 20 percent mortality is predicted for the summer run steelhead (from 0 to 130 adults, or from 0 to 9 percent of the basin-wide escapement).
- Under the worst-case scenario, 71 percent mortality is predicted for the winter run steelhead (up to 1,988 adults, or up to 28 percent of the basin-wide escapement). On average around 20 percent of winter steelhead migrate prior to initiation of reservoir drawdown on December 15th. In addition, steelhead are highly migratory species that stray to avoid habitat degradation (Bisson et al. 2005), and regularly occur in environments with high SSC, and therefore the predictions described here are likely more dire than would occur.
- Under the worst-case scenario, up to 71 percent mortality is predicted for age 1 juveniles in the mainstem (up to 11,207 juveniles or around 19 percent of total basin-wide age 1 production).
- Under the worst-case scenario, up to 71 percent mortality is predicted for age 2 juveniles in the mainstem (up to 9,412 juveniles or around 18 percent of total basin-wide age 2 production).

Table 3.3-8. Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario SSCs Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Summer and Winter Steelhead

Scenario	Life History Stage: Summer and Winter Steelhead					
	Adult migration Summer run: (Mar 1–June 30, 2020) Winter run: (Aug 1 2019–Mar 31, 2020)	Adult runbacks: (Apr 1–May 30, 2020) Half-pounder residency (Aug 15, 2019–Mar 31, 2020)	Spawning through fry emergence (Dec 1, 2019– June 1, 2020)	Age 0+ rearing (Mar 15– Nov 14, 2020)	Juvenile rearing Age 1+: (year- round 2019 and 2020) Age 2+: (Nov 15, 2019–Mar 31, 2020)	Outmigration (Apr 1–Nov 14, 2020)
Most likely	Existing Conditions (normal)					
	<p>Summer run: Major stress, possibly impaired homing for fish spawning in mid- and upper-Klamath tributaries (about 45% of escapement)</p> <p>Winter run: Major stress, possibly impaired homing for fish spawning in mid- and upper-Klamath tributaries (about 80% of escapement)</p>	<p>Adult runbacks: Major stress depending on time spent in mainstem</p> <p>Half-pounder residency: Many will have returned to the ocean or estuary; those remaining may experience major stress in the mainstem, but may avoid suspended sediment by entering nearby tributaries</p>	Most spawning takes place in tributaries; no effects predicted	Major stress for age 0+ juveniles in mainstem (about 60% of juveniles)	<p>Age 1+ rearing: Major stress for juveniles in mainstem (about 60% of juveniles)</p> <p>Age 2+ rearing: Major stress for juveniles in mainstem (about 60% of juveniles)</p>	Major stress during outmigration, depending on time spent in mainstem; about 57% outmigrate from Trinity River and will have less exposure

Table 3.3-8. Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario SSCs Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Summer and Winter Steelhead

Scenario	Life History Stage: Summer and Winter Steelhead					
	Adult migration Summer run: (Mar 1–June 30, 2020) Winter run: (Aug 1 2019–Mar 31, 2020)	Adult runbacks: (Apr 1–May 30, 2020) Half-pounder residency (Aug 15, 2019–Mar 31, 2020)	Spawning through fry emergence (Dec 1, 2019– June 1, 2020)	Age 0+ rearing (Mar 15– Nov 14, 2020)	Juvenile rearing Age 1+: (year- round 2019 and 2020) Age 2+: (Nov 15, 2019–Mar 31, 2020)	Outmigration (Apr 1–Nov 14, 2020)
Most likely	Proposed Action					
	Summer run: Same as existing conditions Winter run: Major stress, impaired homing, and up to 36% mortality (Up to 1,008 adults, or up to 14% of the total escapement)	Adult runbacks: Same as existing conditions Half-pounder residency: Same as existing conditions	Same as existing conditions	Major stress resulting in reduced growth	Age 1+ rearing: Major stress, reduced growth, and up to 52% mortality. (Up to 8,200 juveniles or around 14% of total age 1 production) Age 2+ rearing: Reduced growth and up to 52% mortality (Up to 6,893 juveniles or around 13% of total age 2 production)	Major stress and reduced growth

As described in detail in Appendix F, dam-released sediment associated with the Proposed Action might aggrade pools or overwhelm other habitat features used for adult holding or juvenile rearing above Cottonwood Creek. The effect would be short term (< one years), as pools would likely return to their pre-sediment release depth (Reclamation 2012). Within six months the river would revert to and maintain a pool-riffle morphology. In the long term, under this alternative bedload sediment transport would restore vital aquatic habitat.

The Proposed Action would establish a flow regime that more closely mimics natural conditions in the Lower Klamath River. As discussed in detail above, dam removal would cause water temperatures to warm earlier in the spring and early summer and cool earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods. These changes would result in water temperature more favorable for salmonids occurring in the mainstem. Migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to low dissolved oxygen due to the Proposed Action, but these effects would be short term. All of these long-term changes would benefit steelhead using the Lower Klamath River Reach.

Estuary

Under the Proposed Action, habitat in the estuary could be affected by elevated turbidity from sediment releases during dam removal for about 3 months. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see the subsection of Section 3.2.4.3.2). However, the Proposed Action is not expected to substantially change or affect steelhead estuarine habitat. Flow and water temperature effects would likely not extend downstream to the estuary.

Summary: Steelhead

Reservoir drawdown associated with dam removal under the Proposed Action could alter SSCs and bedload sediment transport and deposition and affect steelhead. In general, the effects of suspended sediment resulting from the Proposed Action on steelhead are likely to be much higher than under existing conditions and the No Action/No Project Alternative, particularly for the portion of the population that spawns in tributaries upstream of the Trinity River. For that portion of the population, effects are anticipated on adults, run-backs, half-pounders, any juveniles rearing in the mainstem, and outmigrating smolts. However, the broad spatial distribution of steelhead in the Klamath Basin and their flexible life history suggests that some will avoid the most serious effects of the Proposed Action by (1) remaining in tributaries for extended rearing, (2) rearing farther downstream where SSC should be lower due to dilution (e.g., the progeny of the adults that spawn in the Trinity River Basin or tributaries downstream from the Trinity River), and/or (3) moving out of the mainstem into tributaries and off-channel habitats during winter. In addition, the life-history variability observed in steelhead means that, although numerous year classes will be affected, not all individuals in any given year

class will be exposed to the effects of the Proposed Action. In addition, some portion of the progeny of those adults that spawn successfully would rear in tributaries long enough to not only avoid the most serious impacts of the Proposed Action in 2020, but may also not return to spawn for up to two years, when any suspended sediment resulting from the Proposed Action should be greatly reduced. The high incidence of repeat spawning among summer-run steelhead (ranging from 40 to 64 percent, Hopelain 1998) should also increase that population's resilience (including all year classes) to effects of the Proposed Action. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Proposed Action would be significant for summer and winter steelhead in the short term.**

Implementation of Mitigation Measures AR-2 and AR-3 (see Section 3.3.4.4.2 and 3.3.4.4.3) could be implemented to reduce the short-term effects of SSCs on steelhead adults and outmigrating juveniles. With implementation of mitigation measures there would still be short-term effects on summer and winter steelhead, including sublethal and lethal effects. **Based on substantial reduction in the abundance of a year class in the short term, the Proposed Action would be a significant effect on summer and winter steelhead in the short term after mitigation.**

Under the Proposed Action, removal of dams could result in alterations in habitat availability, flow regime, water quality, temperature variation, and algal toxins which could affect steelhead in the long term. Dam removal would restore connectivity to hundreds of miles of historical habitat in the Upper Klamath Basin and would create additional habitat within the Hydroelectric Reach. FERC (FERC 2007) concluded that implementing fish passage would help to reduce adverse effects to steelhead associated with lost access to upstream spawning habitats. Hamilton et al. (2011) also concluded that access to additional habitat in the upper Klamath River watershed would benefit steelhead runs. In general, dam removal with KBRA would likely result in the restoration of more reproducing populations, increased abundance, higher genetic diversity, and the opportunity for variable life histories and use of new habitats (Hamilton et al. 2011). In general, free flowing conditions as per the Proposed Action, would likely provide optimal efficiency, decrease outmigrant delay, and increase concomitant adult escapement (Buchanan et al. 2011b). By providing an unimpeded migration corridor, the Proposed Action would provide the greatest possible benefit related to fish passage, hence, the highest survival and reproductive success (Buchanan et al. 2011b). As discussed in detail above, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem. **Based on increased habitat availability and improved habitat quality, the effect of the Proposed Action would be beneficial for summer and winter steelhead in the long term.**

Pacific Lamprey Access to habitat would benefit Pacific lamprey by increasing their viability through: a) extending the range and distribution of the species; b) providing additional spawning and rearing habitat; c) increasing the genetic diversity of the species;

and d) increasing the abundance of the Pacific lamprey population (Administrative Law Judge 2006). The FERC (2007) concluded that “Removal of Iron Gate dam provides the greatest potential to expand the range of Pacific lamprey, a species of cultural importance to the tribes, to potential habitat upstream of Iron Gate dam.” A Lamprey Expert Panel (Panel) was convened and charged with answering specific questions that had been formulated by the project stakeholders to assist with assessing the effects of the Proposed Action on lamprey (Close et al. 2010). The conclusion was that the Proposed Action could increase Pacific lamprey habitat by up to 14 percent. The increase could potentially be more if habitat in the Upper Klamath Basin is accessible and suitable. The panel also concluded there might be a total increase of production of outmigrant lamprey (and hence harvest potential) in the range of 1 to 10 percent relative to the No Action Alternative. The Panel expects that adult Pacific lamprey would recolonize newly accessible habitat after dam removal, but natural colonization of all habitat available to them may take decades. Larval rearing capacity downstream from Iron Gate Dam is expected to increase after dam removal because a large amount of fine sediment—a major component of larval rearing habitat—would be released through dam removal. The available burrowing habitat for larvae would subsequently decrease over time, but would likely remain higher than under current conditions because sediment input and transport processes would be restored and KBRA measures would increase sediment transport (Close et al. 2010). In addition, the return to a temperature regime and flows that more closely mimic natural patterns would likely benefit Pacific lamprey, which evolved under those conditions. The influence of the Proposed Action within specific reaches is described below.

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Pacific lamprey occurred historically at least to Spencer Creek (Hamilton et al. 2005), although there is some uncertainty in this regard (Administrative Law Judge (2006)). It is anticipated that Pacific lamprey below Iron Gate dam would migrate above the dam if access was provided (Administrative Law Judge (2006)).

Hydroelectric Reach: from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

The Proposed Action would provide Pacific lamprey with access to the Hydroelectric Reach and to the mainstem Klamath River and its tributaries upstream at least as far as Spencer Creek, including Jenny, Shovel, and Fall creeks (Hamilton et al. 2011). Most sediment released from the reservoirs would likely be eroded within the first six months after dam removal (by May 2020), returning sections of river currently inundated by reservoirs and riverine sections between reservoirs to a pool-riffle morphology. After erosion of dam-stored sediment, the Hydroelectric Reach would likely contain gravel suitable for lamprey spawning and rearing.

The Proposed Action would also eliminate the reservoirs and establish a flow regime that more closely mimics natural conditions. Drawing down the reservoirs would allow tributaries and springs such as Fall, Shovel, and Spencer Creeks and Big Springs to flow directly into the mainstem Klamath River. These changes would result in more favorable water temperatures for native fishes, and improved water quality. These changes would provide a long-term benefit to Pacific lamprey that occur within the Hydroelectric Reach.

Lower Klamath River: Downstream from Iron Gate Dam

The Proposed Action would release dam-stored sediment and reduce dissolved oxygen downstream to the Lower Klamath River in the short term, and restore a flow regime that more closely mimics natural conditions in the long term. Suspended sediment effects on Pacific lamprey under the Proposed Action are described in detail in Appendix E, and summarized here.

Under the most-likely-to-occur scenario or worst-case scenario, sublethal effects from suspended sediment relative to existing conditions is anticipated for outmigrants, and for Pacific lamprey migrating to or from the Trinity River or tributaries further downstream (Table 3.3-9). High rates of mortality are predicted for adults and ammocoetes in the mainstem Klamath River during winter and spring 2020. However, there is little to no literature on the effects of suspended sediment on lamprey. This analysis used the effects of suspended sediment on salmonids to predict effects on lamprey, with the assumption that effects on lamprey are equivalent or less severe than on salmonids. In general, most life stages of Pacific lamprey appear more resilient to poor water quality conditions (such as suspended sediment) than salmonids (Zaroban et al. 1999), so this is likely a conservative assessment of potential effects.

The Proposed Action would affect spawning and incubation in the area between Iron Gate Dam and Cottonwood Creek by burying gravel in dam-released sediment and increasing the proportion of sand in the bed, thereby decreasing ammocoete survival. The bed material within the reservoirs and between Iron Gate to Cottonwood Creek is expected to have a high content (30 to 50 percent) of sand immediately following reservoir drawdown until a flushing flow moves the sand sized material out of the reach (Reclamation 2012). The flushing flow is expected to be at least 6,000 cfs and of several days to weeks to return the bed to a bed dominated by cobble and gravel with a sand content less than 20 percent. After the flushing flow, the bed is expected to maintain fractions of sand, gravel, and cobble which would be expected under natural conditions, and suitable for Pacific lamprey. Based on the historical record a sufficient flushing flow would likely occur within 5 years following dam removal.

The Proposed Action would establish a flow regime that more closely mimics natural conditions in the Lower Klamath River Reach. Dam removal would cause water temperatures to have natural diurnal variations. These changes would result in water temperatures that are more similar to those that Pacific lamprey evolved with and would improve water quality. These long-term changes would likely provide a benefit to Pacific lamprey using the Lower Klamath River.

Estuary

Under the Proposed Action, habitat in the estuary could be affected by elevated turbidity from sediment releases during dam removal for about 3 months. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be

Table 3.3-9. Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Pacific Lamprey

Scenario	Life History Stage: Pacific Lamprey		
	Adult Migration and Spawning (all of 2020)	Ammocoete Rearing (all of 2020)	Outmigration Spring (May 1–June 30, 2020) Fall/winter (Sept 1–Dec 31, 2020)
Most Likely	Existing Conditions (normal)		
	Major stress and impaired homing; later-returning adults and those returning to lower tributaries would have less exposure	Ammocoete rearing: Major stress of ammocoetes in mainstem for multiple year classes of ammocoetes in mainstem; majority rear in tributaries and would have lower exposure	Spring outmigration: Major stress
			Fall and winter outmigration: Moderate stress and reduced feeding
	Proposed Action		
Major stress and up to 36% mortality; later-returning adults and those returning to lower tributaries would have less exposure	Ammocoete rearing: Major stress, reduced growth, and up to 52% mortality	Spring outmigration: Same as existing conditions	
		Fall and winter outmigration: Same as existing conditions	
Worst-case	Existing Conditions (extreme)		
	Major stress and impaired homing; later-returning adults and those returning to lower tributaries would have less exposure	Ammocoete rearing: Major stress and reduced growth	Spring outmigration: Moderate to major stress and reduced growth
			Fall and winter outmigration: Major stress
	Proposed Action		
Major stress, reduced growth, and up to 71% mortality	Ammocoete rearing: Major stress, reduced growth, and up to 71% mortality for multiple year classes of ammocoetes in mainstem; majority rear in tributaries and would not suffer mortality	Spring outmigration: Same as existing conditions	
		Fall and winter outmigration: Same as existing conditions	

higher than the extreme values estimated by the sediment transport model for existing conditions (see the subsection of Section 3.2.4.3.2). However, the Proposed Action is not expected to substantially change or affect Pacific lamprey estuarine habitat. Flow and water temperature effects would likely not extend downstream to the estuary.

Summary: Pacific Lamprey

Reservoir drawdown associated with dam removal under the Proposed Action could alter SSCs and bedload sediment transport and deposition and affect Pacific lamprey. The Proposed Action would have short-term effects related to SSCs, bedload sediment transport and deposition, and water quality (particularly dissolved oxygen). Overall, because multiple year classes of lamprey rear in the mainstem Klamath River at any given time, and since adults will migrate upstream over the entire year, including January 2020 when effects from the Proposed Action will be most pronounced, effects on Pacific lamprey adults and ammocoetes could be much higher in the mainstem Klamath River than under existing conditions and the No Action/No Project Alternative. However, because of their wide spatial distribution and varied life history, most of the population would likely avoid the most severe suspended sediment pulses resulting from the Proposed Action. In addition, Pacific lamprey are considered to have low fidelity to their natal streams (FERC 2006), and may not enter the mainstem Klamath River if environmental conditions are unfavorable in 2020. Migration into the Trinity River and other Lower Klamath River tributaries may also increase during 2020 because of poor water quality. Low fidelity also increases the potential that lamprey can recolonize mainstem habitat if ammocoetes rearing there suffer high mortality. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Proposed Action would be significant for Pacific lamprey in the short term.**

Implementation of Mitigation Measures AR-2 and AR-5 (see Sections 3.3.4.4.2 and 3.3.4.4.5) could be implemented to reduce the short-term effects of dissolved oxygen and SSCs on lamprey ammocoetes. With implementation of mitigation measures there could still be short-term effects for lamprey including sublethal and lethal effects. **Based on substantial reduction in the abundance of a year class in the short term, the Proposed Action would be a significant effect on Pacific lamprey in the short term after mitigation.**

Under the Proposed Action, removal of dams could result in alterations in habitat availability, flow regime, water quality, and temperature variation which could affect Pacific lamprey in the long term. The Proposed Action would provide access to habitat upstream of Iron Gate Dam at least as far as Spencer Creek. It is anticipated that as a result of the Proposed Action the Pacific lamprey population within the Klamath River watershed would have an increase in abundance, productivity, population spatial structure, and genetic diversity. **Based on increased habitat availability and improved habitat quality, the effect of the Proposed Action would be beneficial for Pacific lamprey in the long term.**

Green Sturgeon Listed Southern Green Sturgeon may enter the Klamath River estuary to forage during the summer months. They would not be present when the most severe

effects of dam removal are occurring, and are not expected to be affected by the Proposed Action. The remainder of this section focuses on the effects of the Proposed Action on the Northern Green Sturgeon DPS. Northern Green Sturgeon do not occur upstream of Ishi Pishi Falls and would not be affected by Proposed Action effects that do not extend downstream past these falls.

Lower Klamath River: Downstream from Iron Gate Dam

The Proposed Action would release dam-stored sediment downstream to the Lower Klamath River in the short term, and restore a flow regime that more closely mimics natural seasonal flow patterns in the long term. Suspended sediment effects on green sturgeon under the Proposed Action are described in detail in Appendix E, and summarized here.

Under the most-likely-to-occur scenario or worst-case scenario no effect relative to existing conditions is predicted for adults (Table 3.3-10), mostly because green sturgeon distribution within the mainstem Klamath River is primarily limited to areas downstream from Orleans, where the effects of SSC resulting from the Proposed Action are more diluted from tributary accretion. Up to 100 percent mortality is predicted for incubating eggs and larval life stages, and up to 20 percent mortality is predicted for rearing juveniles under a most-likely-to-occur scenario, or up to 40 percent mortality of juveniles under a worst-case scenario. However, around 30 percent of juveniles rear in the Trinity River and would not be exposed to SSC from the Proposed Action.

Bedload sediment effects related to dam-released sediment would not extend as far downstream to Ishi Pishi Falls and would not affect green sturgeon.

The Proposed Action would establish a flow regime that more closely mimics natural conditions in the Lower Klamath River and would improve water quality and reduce instances of algal toxins. These long-term effects would benefit green sturgeon using the Lower Klamath River reach.

Estuary

Under the Proposed Action, habitat in the estuary could be affected by elevated turbidity from sediment releases during dam removal for about 3 months. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see Section 3.2.4.3.2.2). However, the Proposed Action is not expected to substantially change or affect estuarine habitat. Flow and water temperature effects resulting from the Proposed Action would likely not extend downstream to the estuary.

Table 3.3-10. Proposed Action, Most-Likely Scenario SSCs Compared with Normal Existing Conditions (50% Exceedance Probabilities) and Proposed Action, Worst-Case Scenario Compared with Extreme Existing Conditions (10% Exceedance Probabilities) for Green Sturgeon. Based on salmonid literature; effects likely overestimated

Scenario	Life History Stage: Green Sturgeon			
	Adult migration	Post-spawning holding	Spawning through hatching/larvae	Juvenile Rearing (year-round) and Outmigration
Most Likely	Existing conditions (normal)			
	Moderate to major stress; 75% of adults not expected to migrate in 2020	No effects	Up to 68% mortality; about 30% that spawn in Trinity River would be unaffected (based on salmonid literature; effects likely overestimated)	Major stress; about 30% of juveniles rear in Trinity River and would be unaffected (based on salmonid literature; effects likely overestimated)
	Proposed Action			
	Major stress	Same as existing conditions	76% mortality for all mainstem production	Reduced growth and up to 20% mortality
Worst-case	Existing conditions (extreme)			
	Major stress	Short period (<1 week) of relatively low SSCs, not expected to result in deleterious effects	84% mortality for all mainstem production	Major stress and reduced or no growth (based on salmonid literature; effects likely overestimated)
	Proposed Action			
	Same as existing conditions; about 25% of adults expected to be exposed in 2020	Same as existing conditions; about 75% of adults hold in mainstem after spawning; remainder return to ocean	95% mortality for all mainstem production ; about 30% that spawn in Trinity River would be unaffected	Reduced growth and up to 36% mortality; about 30% of juveniles rear in Trinity River and would be unaffected

Summary: Green Sturgeon

Reservoir drawdown associated with dam removal under the Proposed Action could alter SSCs and affect green sturgeon. Overall the effects of the Proposed Action are most likely to include physiological stress, inhibited growth, and high mortality for some portion of the age-0 2020 cohort and age 1 2019 cohort. To summarize, green sturgeon in the Klamath Basin have the following traits likely to enhance the species' resilience to impacts of the Proposed Action:

- Most of the population (subadult and adult) would be in the ocean during the year of the Proposed Action (2020) and would be unaffected (Appendix E).
- The approximately 30 percent of the population that spawn and rear in the Trinity River would be unaffected.
- Much of the spawning and rearing of green sturgeon occurs downstream from the Trinity River, where sediment concentrations would be similar to existing conditions and the No Action/No Project Alternative.

Green sturgeon are long-lived (>40 years) and are able to spawn multiple times (~8 times) (Klimley et al. 2007), so effects on two year classes may have little influence on the population as a whole.

Based on substantial reduction in the abundance of a year class in the short term, the effect of the Proposed Action would be significant for green sturgeon in the short term.

Implementation of Mitigation Measure AR-3 (see Section 3.3.4.4.3) could be implemented to reduce the short-term effects of SSCs on green sturgeon adults post-spawning. With implementation of mitigation measures there would still be short-term effects for green sturgeon including sublethal and sublethal effects. **Based on substantial reduction in the abundance of a year class in the short term, the Proposed Action would be a significant effect on green sturgeon in the short term after mitigation.**

Under the Proposed Action, removal of dams could result in alterations in flow regime, water quality, temperature variation, and algal toxins which could affect green sturgeon in the long term. It is anticipated that as a result of the Proposed Action, the green sturgeon population within the Klamath River watershed would have an increased productivity. **Based on improvements in habitat quality within part of their range, the effect of the Proposed Action would be less-than-significant for green sturgeon in the long term.**

Lost River and Shortnose Sucker A Resident Fish Expert Panel (Panel) was convened to compare the potential effects of the Proposed Action and existing conditions on resident fish, including sucker populations (Buchanan et al. 2011a). The Panel concluded that under the Proposed Action, specifically with implementation of KBRA, restoration strategies used to recover suckers including lake level management, water quality improvement, and habitat restoration (wetlands and spawning and rearing habitat) are

expected to increase spawning success, and larval, juvenile, and adult survival leading to larger populations and more frequent recruitment.

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Under the Proposed Action, water elevations in Upper Klamath Lake would be higher, which would benefit Lost River and shortnose suckers, but the difference in habitat value would not be substantive. The KBRA is expected to provide benefits to sucker populations through the following measures: nutrient reduction, reconnecting former wetlands to Agency Lake, reconstructing quality rearing habitat for early life stages, and restoring shoreline spring spawning habitat restoration, among others.

Hydroelectric Reach: from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

Lost River and shortnose suckers are found within reservoirs in Hydroelectric Reach. The Proposed Action would eliminate reservoir habitat, and as dams within the Hydroelectric Reach were removed, sediment would move downstream. Under the Proposed Action adult Lost River and shortnose suckers in reservoirs downstream from Keno Dam would be captured and relocated to Upper Klamath Lake (Buchanan et al. 2011a). Those not relocated to the Upper Klamath Basin would likely be lost; however, since little or no reproduction occurs downstream from Keno Dam (Buettner et al. 2006), there is no potential for interaction with upstream populations, and they are not considered to substantially contribute to the achievement of conservation goals or recovery (Hamilton et al. 2011). Lost River and shortnose suckers are listed as fully protected species under California Fish and Game code; thus, any take of these species is prohibited. However, if there is an Affirmative Determination by the Secretary, and a concurrence by the State of California, CDFG will provide draft legislation to the other KHSA/KBRA parties which would authorize limited take of these fully protected species.

Facilitating the movement of anadromous fish via prescribed fishways presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006). Generally, with the exception of *F. columnaris* and Ich, pathogens associated with anadromous fish do not impact non-salmonids (e.g. suckers) (Administrative Law Judge 2006). In the most recent review of effects of interactions between reintroduced anadromous fish and federally listed suckers, the USFWS concludes that indirect effects of removal of the lower four dams is “not likely to adversely affect” listed fish because the effects are insignificant (Roninger 2012).

Summary: Lost River and Shortnose Suckers

*Reservoir removal associated with dam removal under the Proposed Action could alter habitat availability and affect Lost River and shortnose suckers. **Based on reduction in abundance within reservoirs, the effect of the Proposed Action would be significant for Lost River and shortnose sucker populations in the short term.***

Implementation of Mitigation Measure AR-6 (see Section 3.3.4.4.6) could be implemented to reduce the impact to individuals within reservoirs by rescuing fish prior to reservoir drawdown. **Based on small numbers of individuals affected after**

mitigation, and on anticipated legislation allowing take, the effect of the Proposed Action would be less-than-significant for Lost River and shortnose sucker populations in the short term after mitigation.

*Restoration action associated with KBRA implementation under the Proposed Action could alter habitat availability and suitability and affect Lost River and shortnose suckers. In the long term, restoration actions under KBRA are anticipated to improve conditions for sucker populations within Klamath Lake. **Based on improved habitat quality, the effect of the Proposed Action would be beneficial for Lost River and shortnose sucker populations in the long term.***

Redband Trout A Resident Fish Expert Panel (Panel) was convened to compare the potential effects of the Proposed Action and existing conditions on resident fish, including redband trout (Buchanan et al. 2011a). The Panel concluded that the habitat improvements associated with KBRA implementation, including water quality and quantity and riparian corridor improvements and protection, are anticipated to increase trout productivity in headwater and lower tributary areas of the Upper Klamath Lake Basin. The Panel predicted that following the Proposed Action, the abundance of redband trout in the free-flowing reach between Keno Dam and Iron Gate Dam could increase significantly. In addition, they expect the existing trout and colonizing anadromous steelhead to co-exist, as they do in other watersheds, although there may be shifts in abundance related to competition for space and food. The influence of the Proposed Action within specific reaches is described below.

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Under the Proposed Action, redband trout would be able to migrate more successfully from the Hydroelectric Reach to the Upper Klamath Basin (Hamilton et al. 2011) than

under existing conditions. Establishment of a flow regime that more closely mimics natural conditions downstream from Keno Dam would eliminate the stranding of redband trout caused by flow reductions at Klamath Hydroelectric Project facilities.

Redband trout could be affected by increased predation from reintroduced salmonids, but this loss might be offset by an increase in available food sources (e.g., eggs, fry, and juveniles of reintroduced salmonids) (Hamilton et al. 2011). Furthermore, anadromous steelhead trout and resident rainbow/redband trout co-existed and intermingled prior to the construction of Copco 1 Dam in 1917. There are many examples from nearby river systems in the Pacific Northwest showing that wild anadromous salmon and resident rainbow/redband trout can co-exist and maintain abundant populations without negative consequences. The Deschutes River in Oregon, the Yakima River in Washington, and the river systems in Idaho are examples (Administrative Law Judge 2006).

Facilitating the movement of anadromous fish presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006).

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

Under existing conditions, redband trout are found within the Hydroelectric Reach, but are impaired from migrating between tributaries and the reservoirs to complete their life cycle because of poorly functioning fishways at J.C. Boyle Dam (DOI 2007; NOAA Fisheries Service 2007). Under the Proposed Action, redband trout would be able to migrate more successfully than under existing conditions (Hamilton et al. 2011). In addition, approximately 4 mi (6.4 km) of habitat has been adversely affected by the dewatered (100 cfs) flows in the bypass reach, and 17 mi (27.4 km) of habitat has been adversely affected by the daily fluctuating flows in the peaking reach (Administrative Law Judge 2006). In addition, the Administrative Law Judge (2006) finding regarding project flow operations stated, “Current Project operations, particularly sediment blockage at the J.C. Boyle Dam, the flow regime, and peaking operations, negatively affect the redband trout fishery.”

Under this alternative, the establishment of a flow regime that more closely mimics natural conditions and eliminates peaking and associated negative aquatic impacts would benefit the redband trout populations downstream from J.C. Boyle. Redband trout throughout this reach of the mainstem, except upstream of J.C. Boyle Reservoir, would be affected by high SSCs for a period of three to four months during reservoir drawdown associated with the Proposed Action. Redband trout in riverine reaches between the reservoirs in the Hydroelectric Reach would be vulnerable to sublethal and lethal effects of sediment released during dam removal and bedload deposition (Newcombe and Jensen 1996, Buchanan et al. 2011a); however, a large proportion of the adult population should be already spawning in Spencer or Shovel creeks during the dam removal. Juvenile redband trout outmigrating from Spencer Creek would be expected to recolonize the mainstem by late spring or summer when water conditions become suitable. Those in the affected area could move to tributaries for refuge.

The Proposed Action would eliminate reservoir habitat, returning sections of river currently inundated by reservoirs and riverine sections between reservoirs to a pool-riffle morphology. Modeling data indicate that after dam removal, spawning gravel in all sections of the Hydroelectric Reach would be within the range usable for salmonids, but the amount of sand within the bed within former reservoir sections might inhibit spawning success. Riverine sections between reservoirs would be expected to provide the gravel with very little sand, suggesting high-quality spawning habitat. The initial movement of coarse and fine sediment after drawdown would likely create unfavorable conditions for redband trout within the mainstem Klamath River, but these conditions would be short term. Buchanan et al. (2011a) estimate that 43 miles of additional riverine habitat would be available to resident redband trout as a result of the Proposed Action. The adfluvial life-history strategy would no longer be possible within this reach. Migratory opportunities would increase for these fish, allowing them to access areas with suitable habitat when conditions become unfavorable in one area of their range. The Proposed Action would also increase the number of thermal refugia available to redband trout as they would have access to more tributaries, as well as to the cool areas near the mouths of tributaries and the many springs in this reach.

Summary: Redband Trout

*The Proposed Action would have short-term effects related to SSCs and bedload movement that could affect redband trout. **Based on a small proportion of the population with a potential to be exposed to short-term effects, the effect of the Proposed Action would be less-than-significant for redband trout in the short term.***

*Dam removal would restore connectivity among the Lower Klamath Basin, the Hydroelectric Reach and its tributaries, and the Upper Klamath Basin, and would rehabilitate and increase availability of riverine habitat within the Hydroelectric Reach. **Based on increased habitat availability and improved habitat quality, the effect of the Proposed Action would be beneficial for redband trout in the long term.***

Bull Trout

Upper Klamath River Upstream of the Influence of J.C. Boyle Reservoir

To evaluate the effects of the Proposed Action on bull trout, a four member expert panel (Buchanan et al. 2011a) was convened and tasked with reviewing all available information on bull trout in the upper Klamath River, and information on potential effects of the Proposed Action. The panel concluded that the Proposed Action provides promise for preventing extinction of bull trout and for increasing overall population abundance and distribution (Buchanan et al. 2011a).

Buchanan et al. (2011a) observed that the proposed KBRA actions would enhance resident populations of headwater bull trout, and implementation of KBRA could have a significant contribution toward recovery of these populations. Passage from Sun Creek to the Wood River may be improved by KBRA actions allowing for fluvial life history forms of bull trout in the Wood River system. The cold waters of the Wood River may successfully provide habitat for reintroductions of anadromous salmon and steelhead.

Rearing anadromous juveniles could provide an increased prey base for fluvial bull trout and produce predator/prey interactions ecologically similar to historical conditions (Buchanan et al. 1997).

Summary: Bull Trout

*Dam removal associated with the Proposed Action could alter habitat availability for anadromous fish, which could affect bull trout. **Based on the restricted distribution of bull trout, the Proposed Action would have a less-than-significant impact on bull trout in the short and long term.***

Eulachon

Lower Klamath River: Downstream from Iron Gate Dam and Estuary

The Proposed Action would release dam-stored sediment downstream to the Lower Klamath River and estuary. Adults entering the Klamath River in the winter and spring of 2020 may be exposed to high SSC for a portion of their migration period. Although no analysis of the effects of SCC on eulachon is available, based on application of the Newcombe and Jensen (1996) approach using studies of the effects on other estuary species, it is predicted that under a most-likely or worst-case scenario mortality would be

higher under the Proposed Action than under existing conditions. Mortality is also predicted to be higher for spawning, incubation, and larval life stages under the Proposed Action than under existing condition. However, there are two key factors that reduce the likelihood that substantial numbers of individuals would be exposed. First, eulachon are in very low abundance in the Klamath River, and thus there is a very low probability that many individuals will be in the Klamath River during implementation of the Proposed Action. Second, eulachon have a relatively long period of the year when they could potentially spawn in the Klamath River (January through April; Larson and Belchik 1998), and a relatively short duration of occurrence within freshwater (around one month), increasing the probability that most of the population would migrate and spawn either before or after the largest pulses of SCC (predicted to be over 1,000 mg/L for the month of January under a worst case scenario; Figure 3.3-10).

Summary: Eulachon

The Proposed Action would have short-term effects related to SSCs and bedload movement. Based on no substantial reduction in the abundance of a year class, the Proposed Action would be a less-than-significant effect on eulachon in the short term. Based on short duration of poor water quality in the estuary during reservoir drawdown in the estuary, the Proposed Action would have a less-than-significant effect on eulachon in the long term.

Longfin Smelt The Proposed Action would release dam-stored sediment downstream to the Klamath River Estuary. Longfin smelt entering the Klamath River in the winter and spring of 2020 may be exposed to high SSC for a portion of their migration period. Although no analysis of the effects of SCC on longfin smelt is available, based on application of the Newcombe and Jensen (1996) approach using studies of the effects on other estuary species, it is predicted that under a most-likely or worst-case scenario mortality would be higher under the Proposed Action than under existing conditions. However, as described for eulachon above, the protracted migration season for longfin smelt (throughout the year), and relatively short duration of occurrence in the estuary (<2 months), increase the probability that most of the population would migrate and spawn either before or after the largest pulses of SCC (predicted to be two weeks in duration or less).

The Proposed Action would have short-term effects related to SSCs and bedload movement. Based on no substantial reduction in the abundance of a year class, the Proposed Action would be a less-than-significant effect on longfin smelt in the short term. Based on short duration of poor water quality during reservoir drawdown, the Proposed Action would have a less-than-significant effect on longfin smelt in the long term.

Introduced Resident Species

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Introduced resident species occur in Lake Ewauna and Upper Klamath Lake, but the Proposed Action would not affect populations in this area.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

The Proposed Action would eliminate reservoir habitat upstream of Iron Gate Dam, and thus the abundance of these species would decline substantially or be reduced to nothing, as their preferred reservoir habitat would be eliminated (Buchanan et al. 2011a).

Lower Klamath River: Downstream from Iron Gate Dam

A few introduced resident species occur in the Lower Klamath River, but habitat conditions there are generally not suitable for these species. Under the Proposed Action, conditions would be expected to become less suitable.

Summary: Introduced Resident Species

*The Proposed Action would eliminate habitat for introduced resident species in the Hydroelectric Reach. **Because these species were introduced and they occur in other nearby water bodies, their loss would not be considered significant from a biological perspective, and would benefit native species. Their loss would, however, decrease opportunities for recreational fishing for these species, as discussed in Section 3.20, Recreation.***

Interactions Among Species The Proposed Action would restore access for anadromous salmon and steelhead to habitat upstream of Iron Gate Dam, as described in detail above. Restoration of access would result in anadromous salmon and steelhead potentially interacting with resident redband trout and bull trout. These species evolved together in the Upper Klamath Basin of the Klamath River, and co-existed prior to the construction of dams (Goodman et al. 2011).

Bull trout currently exist with redband trout in the upper basin and Proposed Action habitat benefits that would result in redband population increases would also benefit bull trout populations. In the 2007 USFWS Biological Opinion (USFWS 2007c) on relicensing of the Hydropower Project, the Service issued take for bull trout and determined that the level of anticipated take associated with reintroduction of anadromous salmonids is not likely to result in jeopardy to bull trout destruction or adverse modification of critical habitat for bull trout. In the most recent review of effects of interactions between reintroduced anadromous fish and federally listed bull trout, the USFWS concludes that indirect effects of removal of the lower four dams is “not likely to adversely affect” listed fish because the effects are insignificant (Roninger 2012).

Anadromous salmonids currently co-exist with resident rainbow trout and resident cutthroat trout downstream from Iron Gate Dam, without any obvious ecosystem detriment. While there is little information on the nature of any competitive interactions between steelhead and resident trout in the Klamath Basin, research does suggest that in some circumstances, resident trout may have a competitive edge over steelhead trout (Administrative Law Judge 2006). Conversely, a recent study showed that hatchery salmon supplementation negatively impacted resident trout abundance and salmonid biomass in a Washington watershed (Pearsons and Temple 2010). However, competition between steelhead and currently present indigenous species such as redband trout are not assumed to be a major limiting factor since these species historically co-evolved (Hooton

and Smith 2008). There are many examples from nearby river systems in the Pacific Northwest that show wild anadromous steelhead trout and resident rainbow/redband trout can co-exist and maintain abundant populations without adverse consequences. The Deschutes River in Oregon, the Yakima River in Washington, and the river systems in Idaho are examples (Administrative Law Judge 2006). As noted by Buchanan et al. (2011a), existing trout and colonizing anadromous steelhead are expected to co-exist, as they do in other watersheds, although there may be shifts in abundance related to competition for space and food.

Freshwater Mussels

Suspended Sediment Concentrations

Due to the limited data available regarding overall abundance, distribution, life history, and population recruitment of freshwater mussels within the mainstem Klamath River, the overall effects that would be associated with predicted short- and long-term exposure to elevated SSCs on freshwater mussel populations as a result of the Proposed Action are difficult to determine.

Under the Proposed Action, SSCs would be expected to be higher than under existing conditions and would likely exceed 600 mg/L, the minimum SSCs level that would be considered detrimental to freshwater mussels, for 2 to 4 months after facility removal, depending on hydrologic conditions and location on the river. The SSCs in excess of 600 mg/L for 2 to 3 months would occur as far downstream as Klamath Station (at RM 5.0; see Figure 3.3-14); however, the highest levels, well in excess of 1,000 mg/L, would occur between Seiad Valley and Iron Gate Dam. Over time, as sediment stored behind the dams was diminished, the expected increase in SSCs over background levels would also diminish. Under existing conditions, SSCs could spike to levels exceeding 600 mg/L upstream of Orleans, although these spikes generally occur for a few days as opposed to several months, which is what would be expected under the Proposed Action. SSCs in excess of 600 mg/L for more than 4- to 5-day periods within the mainstem Klamath River would cause major physiological stress to freshwater mussels and might result in substantial mortality. The most significant impacts would occur downstream from Iron Gate Reservoir, especially to those individual freshwater mussels or freshwater mussel beds upstream of Orleans and closest to Iron Gate Dam.

Because freshwater mussels found within the Klamath River are so long lived (from 10 to more than 100 years, depending on the species) and sexual maturity might not be reached until 4 years of age or more, even relatively short term (e.g., for more than 5 consecutive days) SSCs in excess of 600 mg/L, would be expected to be detrimental for freshwater mussel populations within the mainstem Klamath River. However, it is anticipated that mainstem Klamath freshwater mussel populations would rebound, recolonizing through the transport of larvae (glochidia) by host fish from downstream populations less affected by excessive SSCs or from populations within tributaries, such as the Salmon or Scott Rivers, or from populations on the Klamath River upstream of Iron Gate Reservoir. This process is expected to take many years, however.

Changes in Bed Elevation

Silt and fine material make up the largest proportion of the volume of sediment stored behind the dams and would be transported downstream primarily as suspended sediment. Coarser material (larger than 0.063 mm) would also be transported downstream and would likely be deposited in the river channel, changing riverbed elevations from the existing condition 8 miles between Iron Gate Dam and Cottonwood Creek. The 182 miles of mainstem downstream from Cottonwood Creek are not predicted to have any substantial aggradation.

Of the freshwater mussel species found on the mainstem Klamath River, the western ridged mussel (*G. angulata*) seems to be the most abundant and is widely distributed between Iron Gate Dam and the confluence of the Trinity River (Westover 2010). The Klamath River differs from other Pacific Northwest rivers in that this species dominates its mussel community (Westover 2010). *G. angulata* populations are currently sparsely distributed and it has been extirpated from a portion of its range; it is believed to have had a much wider distribution historically (Westover 2010). The floater species (*Anodonta spp.*) are less abundant, with the largest single bed found immediately downstream from Iron Gate Dam (Westover 2010). The western pearlshell (*Margaritifera falcata*) is the least abundant freshwater mussel found in the Klamath River and seems to be mostly found downstream from the confluence of the Salmon River (Westover 2010). It is not known how well any of these species could tolerate deposition of sediment and whether they could move upward through deposited material to the surface to breathe and feed. It seems reasonable to presume that some percentage of Klamath River freshwater mussels buried under 0.5 to 3.0 feet of new sediment would not survive. Because of the relatively small area affected, these changes in bed elevation are not expected to substantially affect the overall population of freshwater mussels. It is anticipated that Klamath freshwater mussel populations would rebound eventually, recolonizing through the transport of larvae (*glochidia*) by host fish from downstream populations less affected by bed elevation changes or from populations within tributaries, such as the Trinity, Salmon or Scott Rivers, or from populations on the Klamath River upstream of Iron Gate Reservoir. However, due to the extended time it takes for freshwater mussels to reach sexual maturity (4 years or more, depending on the species), the reestablishment of freshwater mussel populations within affected reaches might be slow and might not be readily noticeable for some time, possibly a decade or more. The seven to eight species of fingernail clams and peaclams, including the montane peaclam, found in the Hydroelectric Reach and from Iron Gate Dam to Shasta River, are expected to be similarly affected.

Changes in Bed Substrate

Draining the Four Facilities under the Proposed Action would result in the erosion of accumulated sediments, changing substrate characteristics within the Klamath River, especially within the current reservoir reaches. The reformation of river channels in the reservoir reaches is expected to occur within 6 months (see Figure 3.3-9). The reformation of river channels between Iron Gate Dam and the upstream reaches of J.C. Boyle Reservoir would benefit freshwater mussels by providing more suitable substrates (i.e., large gravel, cobble, and boulder) than currently exists, especially

within the current reservoir reaches. In addition, the Proposed Action would also open access to river reaches upstream of Iron Gate Dam to migratory fish species, which might serve as host fish for parasitic freshwater mussel larvae (glochidia). As a result, suitable habitats upstream of Iron Gate Dam might be colonized or recolonized by freshwater mussel species, transported as glochidia from downstream reaches by migratory fish species, which are currently blocked by Iron Gate Dam. An increased distribution of anadromous salmonids resulting from dam removal would be expected to benefit *M. falcata* by increasing its distribution as well. However, due to the long time it might take for freshwater mussels to reach sexual maturity, the recolonization and/or growth of existing freshwater mussel populations upstream of Iron Gate Dam might be slow and might not readily noticeable for some time.

Summary: Freshwater Mussels

The Proposed Action would have short-term effects related to SSCs and bedload movement. Based on substantial reduction in the abundance of multiple year classes in the short term and the slow recovery time of freshwater mussels, the effect of the Proposed Action would be significant for mussels in the short term.

Implementation of Mitigation Measure AR-7 (see Section 3.3.4.4.7) could be implemented to reduce the short- and long-term impacts of the Proposed Action on freshwater mussels. With implementation of mitigation measures there would still be impacts to a portion of the freshwater mussel population, and there could still be a substantial reduction in the abundance of at least one year class. **Based on substantial reduction in year classes, the Proposed Action would have a significant effect on freshwater mussels after mitigation in the short term.**

Dam removal would restore connectivity among the Lower Klamath Basin, the Hydroelectric Reach and its tributaries, and the Upper Klamath Basin, and would rehabilitate and increase availability of riverine habitat within the Hydroelectric Reach. Based on increased habitat availability and habitat quality in the long term, the effect of the Proposed Action would be beneficial for mussels in the long term.

Benthic Macroinvertebrates

Peaking Effects

Under the Proposed Action, Klamath Hydroelectric Project peaking operations would no longer kill, through stranding, large numbers of young fish and aquatic invertebrates that are the primary prey food for resident trout (Administrative Law Judge 2006).

Suspended Sediment Concentrations

Under the Proposed Action, increased SSCs would be expected to affect filter-feeding BMI populations in much the same fashion as described for freshwater mussels. Excessive levels of SSCs for durations longer than normally occur under existing conditions are expected to cause physiological stress, reduced growth, and potential mortality to filter-feeding BMIs. The scraper-grazers feeding guild among the BMIs are also expected to be deleteriously affected, but due to their increased mobility, would be affected less than the filter-feeders. This could affect BMI as far downstream as the

Orleans. The high concentrations of suspended sediment released during winter are not predicted to have a severe effect on macroinvertebrates during their winter dormancy period. During spring and summer SSC will be lower, but would be expected to impact macroinvertebrates during the peak of their feeding and reproductive period. Recolonization of affected BMI populations would occur relatively quickly due to the shortened life cycle of BMIs and rapid dispersal through drift and/or the flying stages of many BMI adults. In addition, recolonization is expected to occur rapidly through drift or dispersal of adult life stages from established BMI populations within the many tributary rivers and streams of the Klamath River.

Changes in Bed Elevation

Under the Proposed Action, changes in bed elevation would affect BMIs in much the same fashion as described for freshwater mussels. Higher levels of sediment deposition than would normally occur under existing conditions would be expected to cause physiological stress, reduced growth, and potentially mortality to BMIs. As with the freshwater mussels, the most substantial impacts on BMIs would occur between Cottonwood Creek and Iron Gate Dam (approximately 8 RMs), with the greatest impacts occurring between Willow Creek and Iron Gate Dam. Recolonization of affected BMI populations would occur relatively quickly due to the shortened life cycle and greater dispersal capabilities of BMIs compared to freshwater mussels.

Changes in Bed Substrate

The reformation of river channels in the reservoir reaches upstream of Iron Gate Dam under the Proposed Action would benefit BMIs by providing more suitable substrates than currently exist. As a result, suitable habitats formed upstream of Iron Gate Dam might be opened to additional colonization by BMIs through rapid dispersal by drift from upstream populations within current riverine reaches and/or dispersion of adult life stages. In addition, recolonization would occur rapidly from established BMI populations within the many tributary rivers and streams of the Klamath River.

Summary: Benthic Macroinvertebrates

*The Proposed Action would have short-term effects related to SSCs and bedload movement. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Proposed Action would be significant for macroinvertebrates downstream from Iron Gate Dam in the short term.***

While a large proportion of macroinvertebrate populations in the Hydroelectric Reach and in the mainstem Klamath River downstream from Iron Gate Dam would be affected in the short term by the Proposed Action, their populations would be expected to recover quickly because of the many sources for recolonization and their rapid dispersion through drift or aerial movement of adults. Habitat quality would also be improved in the Hydroelectric Reach by the ending of deleterious Klamath Hydroelectric Project peaking operations (Administrative Law Judge 2006).

Dam removal would restore connectivity among the Lower Klamath Basin, the Hydroelectric Reach and its tributaries, and the Upper Klamath Basin, and would

rehabilitate and increase availability of riverine habitat within the Hydroelectric Reach. Based on increased habitat availability and improved habitat quality, the effect of the Proposed Action on macroinvertebrates would be beneficial in the long term.

Deconstruction

As described below, disturbance to the river channel during construction could affect aquatic species.

The Proposed Action would require relocation of the City of Yreka's water supply pipeline in Iron Gate Reservoir, demolition of the dams and their associated structures, power generation facilities, transmission lines, installation of cofferdams, road upgrading, hauling, reservoir restoration, and other activities (as described in Section 2.4.3.1). These actions would include the use of heavy equipment, and blasting as necessary, and as such, have the potential to disturb aquatic species. Activities at the J.C. Boyle, Copco 1, and Copco 2 Dams would affect the riverine and introduced resident species in the Hydroelectric Reach.

At Iron Gate Dam, anadromous species could also be affected. These effects could include shockwaves associated with breaking down the dam structure using explosives or heavy equipment, potential crushing of aquatic species from operation of heavy equipment in the river, sedimentation, and release of oil, gasoline, or other toxic substances from construction sites. Demolition of the dams and their associated structures, power generation facilities, installation of cofferdams, and other activities are scheduled to occur at Iron Gate Dam between January 10 and June 26, with cofferdam installation scheduled to occur between 2 January 2020 and 6 February 2020. Therefore, this activity would occur during the first month of reservoir drawdown and the peak of SSC associated with reservoir drawdown. As discussed above, any aquatic species within the vicinity of Iron Gate Dam tailrace during this time would also be subject to SSC during the reservoir drawdown that are estimated to range from 80 to >10,000 mg/L during the January 10 through June 26, 2020, period. These SSCs corresponds to Newcombe and Jensen (1996) severity ratings of from 8 to 12, which equate to sub-lethal and lethal effects aquatic species. It is anticipated that this release of sediment would result in the displacement of any individuals that are rearing in the mainstem into tributaries or further downstream prior to deconstruction or cofferdam activities. Therefore, impacts associated with deconstruction would generally be of small magnitude, short duration, and low intensity when compared to those that would occur as a result of the changes in habitat structure and release of sediments stored behind the dams if they were removed.

To minimize these potential construction impacts, construction areas would be isolated from the active river where possible, and water would be routed around the construction area, allowing the flow to move down the other portion of the river, while the isolated portion of the dam is removed. After a work area is isolated, fish rescues to remove any native fish trapped in the work area would be conducted. Fish would be relocated to an area of suitable habitat within the Klamath River. Implementation of soil erosion and sedimentation control and stormwater pollution prevention would minimize soil erosion

and water quality effects on anadromous fish downstream from the work area, during and after construction. **Because best management practices for construction incorporated into the Proposed Action will prevent substantial effects, construction activities associated with the Proposed Action would be less-than-significant.**

Coastal Zone Consistency Determination

The following section provides an analysis of the effects of the Proposed Action on each of the relevant policies of the California Coastal Management Program as outlined in the California Coastal Act of 1976. The deconstruction activities of the Proposed Action would begin approximately 190 miles from the mouth of the Klamath River. Therefore, this analysis focuses on impacts that would be evident many RMs downstream in the estuary and near shore. The policies identified as applicable are Article 4 Marine Environment Section 30231 and Section 30236 (see *italicized* text below). Articles 2, Article 3, Article 5, Article 6, and Article 7 are not applicable due to the distance of deconstruction activities from the near shore environment and will not be further addressed in this analysis. Also this is a phased Coastal Zone Management Act (CZMA) analysis. Additional implementation specific analysis will be completed as needed if the Secretary makes an Affirmative Determination.

Section 30231 The biological productivity and the quality of coastal waters, streams, wetlands, estuaries and lakes appropriate to maintain optimum populations of marine organisms and for the protection of human health shall be maintained and, where feasible restored through, among other means, minimizing adverse effects of waste water discharges and entrainment, controlling runoff, preventing depletion of ground water supplies and substantial interference with surface water flow; encouraging waste water reclamation, maintaining natural vegetation buffer areas that protect riparian habitats, and minimizing alterations of natural streams.

As described above, the Proposed Action would result in substantial short-term increases in suspended sediment during 2020 while the reservoirs are drawdown in preparation for facility removal. The effect of these short-term increases would be significant for some species within the Klamath River. However, as described above, aquatic species within the river would benefit from increased habitat availability and improved habitat suitability in the long term. In addition, under a worst-case scenario, SSCs resulting from the Proposed Action would be elevated within the estuary and nearshore environment for approximately three months (January, February, and March) in 2020. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see the subsection of Section 3.2.4.3.2.). After this time, SSCs would return to levels similar to existing conditions. Based on the short duration of poor water quality during reservoir drawdown in the estuary and near-shore environment, the Proposed Action would not be deleterious in the short term, and would not likely affect the estuary and near-shore environment in the long term.

For all species analyzed, when the short-term deleterious effects occurring during reservoir drawdown in 2020 are weighed against the long-term benefits to the Klamath River, the systemic restoration espoused in the Proposed Action improves biological productivity and the quality of waters, streams, wetlands, estuaries, and lakes. Therefore the Proposed Action is consistent with the California Coast Act Policy 30231.

Section 30236 Channelizations, dams or other substantial alterations of rivers and streams shall incorporate the best mitigation measures feasible and be limited to (1) necessary water supply projects, (2) flood control projects where no other method for protecting existing structure in the flood plain is feasible and where such protections is necessary for public safety or to protect existing development, or (3) developments where the primary function is the improvement of fish and wildlife habitat.

The primary function of the Proposed Action is to improve fish and wildlife habitat and water quality. For this reason, the Proposed Action deconstruction schedule was crafted with careful attention to the timing necessary to limit the impact of sediment release on aquatic resources and water quality. The timing in the Proposed Action is designed to limit the effects on water quality to one single large increase in suspended sediment and one single reduced dissolved oxygen event occurring within the winter and early spring of 2020. By limiting the duration of elevated suspended sediment and reduced dissolved oxygen, the Proposed Action avoids multiple years of effects to aquatic species and minimizes impacts to the sensitive juvenile rearing and smolt life stages of migratory fish. In addition to this built-in avoidance and minimization measure, the Proposed Action includes several required best management practices for the deconstruction activities including erosion and stormwater management, dust abatement, and hazardous spill prevention and response measures. To further address the alteration of rivers and streams and the effects of returning some of the natural processes to the Klamath River system, mitigation measures are being considered including AR 1: Protection of Mainstem Spawning, AR2: Protection of Outmigrating Juveniles, AR3: Fall Pulse Flows, AR-4: Hatchery Management, and AR-5 Pacific Lamprey Capture and Relocation.

Given the careful crafting of the Proposed Action, the required Best Management Practices and mitigation measures, and the fact that the primary function of the project is improvement of fish and wildlife habitat, the Proposed Action is consistent with the California Coast Act Policy 30236.

Interim Measures

The Proposed Action includes IMs to be implemented prior to the initiation of dam removal in 2020 (as described in Section 2.4.3). These IM's will cease to be implemented if the Secretary makes a Negative Determination, and would therefore have no long-term effect on aquatic resources. As described below, two of these have the potential to affect aquatic resources, including:

- IM 7: J.C. Boyle Gravel Placement and/or Habitat Enhancement, and
- IM 16: Water Diversions.

Implementation of J.C. Boyle Gravel Placement and/or Habitat Enhancement could result in alterations to habitat availability and habitat quality, and affect aquatic species.

Currently trout spawning gravel in the J.C. Boyle bypass reach is embedded with fine silt. In July 2006, the spawning gravel in the bypass reach below the emergency spillway was fifty (“50”) percent embedded with silt and sand (ALJ Decision at 42 Finding of Fact number 14-7). Bedload mobilization is the natural geomorphic process whereby flow moves gravel for deposit on alluvial features and cleanses gravel of sediment. Diversion has reduced the capacity of flow to mobilize the bedload by an estimated eighty-three (“83”) percent to ninety-six (“96”) percent in the bypass reach (ALJ Decision at 40 Finding of Fact 11-2).

Under this IM, suitable spawning gravel would be placed in the J.C. Boyle Bypass and Peaking reaches following an Affirmative Determination and continuing through 2019. The first year would be before the Secretary makes a determination, and would therefore be included in the No Action/No Project Alternative. The following seven years would be part of the Proposed Action. This measure would use a passive approach to place gravel before high flow periods, or develop for other habitat enhancement that would provide equivalent fishery benefits in the Klamath River upstream of Copco Reservoir. These actions would provide improvements in habitat quality for resident fish prior to dam removal, and for resident and anadromous species following dam removal. The additional gravel could also improve bed mobility in this reach following dam removal. Seasonal high flows, in combination with a gravel augmentation program, will likely create a more dynamic channel with a wider range of sediment deposits. This sediment will be deposited higher on the channel margin which will serve as an ecological benefit (ALJ Decision at 38 Finding of Fact 10-5). Also additional gravel may contribute to increased periphyton scour and less favorable habitat for the polychaete intermediate host of *C. shasta* and *P. minibicornis*. This could reduce the potential for infection of juvenile salmonids in the Hydroelectric Reach following dam removal (see also the subsection of Section 3.4.4.3.2, Algae). **Based on anticipated improvements in habitat availability and habitat quality, implementation of J.C. Boyle Gravel Placement and/or Habitat Enhancement under the Proposed Action would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, redband trout, and benthic macroinvertebrates. These actions would also be beneficial for coho salmon from the Upper Klamath River Population Unit, and less-than-significant for all other population units in the Basin. Effects on bull trout, freshwater mussels, shortnose and Lost River suckers would be less-than-significant. Effects on green sturgeon, eulachon, and Southern Resident Killer Whales would not change from existing conditions.**

Implementation of IM 16 (Water Diversions) could result in alterations to habitat availability and habitat quality, and affect aquatic species. Under this IM, PacifiCorp would seek to eliminate three screened diversions (the Lower Shovel Creek Diversion [7.5 cfs], Upper Shovel Creek Diversion [2.5 cfs], and Negro Creek Diversion [5 cfs]) from Shovel and Negro Creeks and would seek to modify its water rights to move the

points of diversion from Shovel and Negro creeks to the mainstem Klamath River. Based upon available information, the upstream most diversion on Shovel Creek is approximately one mile upstream of the confluence with the Klamath River. If this were successful the screened diversions would be removed prior to dam removal in 2020. The intent of this measure is to provide additional water to Shovel and Negro creeks, thus increasing the quality and amount of suitable habitat for aquatic species within these tributaries, while not diminishing PacifiCorp's water rights. These actions would provide improvements in the quality and amount of suitable habitat for resident and anadromous aquatic species following dam removal. **Based on anticipated improvements in habitat availability and habitat quality with increased flow, implementation of IM 16 (Water Diversions) under the Proposed Action would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, redband trout, and benthic macroinvertebrates. These actions would also be beneficial for coho salmon from the Upper Klamath River Population Unit, and less-than-significant for all other population units in the Basin. Effects on bull trout, freshwater mussels, shortnose and Lost River suckers would be less-than-significant. Effects on green sturgeon, eulachon, and Southern Resident Killer Whales would not change from existing conditions.**

Keno Transfer

Implementation of the Keno Transfer could cause adverse aquatic resource effects. The Keno Transfer is a transfer of title for the Keno Facility from PacifiCorp to the DOI. This transfer would not result in the generation of new impacts on aquatic resources compared with existing facility operations. Following transfer of title, DOI would operate Keno in compliance with applicable law and would provide water levels upstream of Keno Dam for diversion and canal maintenance consistent with agreements and historic practice (KHSA Section 7.5.4). **Therefore, implementation of the Keno Transfer would result in no change from existing conditions.**

East and Westside Facilities – Programmatic Measure

Decommissioning the East and Westside Facilities could cause adverse aquatic resource effects. Decommissioning of the East and Westside canals and hydropower facilities of the Link River Dam by PacifiCorp as a part of the KHSA would no longer divert water flows at Link River Dam into the two canals. Risk of entrainment into these facilities would also be eliminated. Following decommissioning of the facilities, there would be no change in outflow from Upper Klamath Lake or inflow into Lake Ewauna. **Implementation of the East and Westside Facility Decommissioning action would be beneficial for suckers and redband, and no change from existing conditions for other aquatic species.**

City of Yreka Water Supply Pipeline Relocation – Programmatic Measure

The Proposed Action could require the relocation of the City of Yreka Water Supply Pipeline. The existing water supply pipeline for the City of Yreka passes under the Iron Gate Reservoir and would have to be relocated prior to the decommissioning of the dam to prevent damage from deconstruction activities or increased water velocities once the reservoir has been drawn down. The pipeline would be suspended from a pipe bridge

across the river near its current location. Standard construction Best Management Practices would reduce the likelihood and extent of aquatic impacts. **Therefore, the relocation of the City of Yreka Water Supply Pipeline would have less-than-significant impacts to aquatic resources.**

KBRA – Programmatic Measures

The KBRA, which is a connected action to the Proposed Action, encompasses several programs that could affect aquatic resources, including:

- Phases I and 2 Fisheries Restoration Plan
- Fisheries Monitoring Plan
- Fisheries Reintroduction and Management Plan - Phase I
- Water Diversion Limitations
- On-Project Plan
- Water Use Retirement Program
- Fish Entrainment Reduction
- Klamath Tribes Interim Fishing Site
- Upper Klamath Lake and Keno Nutrient Reduction

With implementation of the KBRA, ongoing habitat restoration would be better funded, better coordinated and monitored to ensure effective implementation. The actions that would be taken under the KBRA would generally benefit aquatic resources by reducing the impacts of past and ongoing disturbance on aquatic habitats. Any undesirable impacts associated with the actions would be short term in nature and could be largely avoided by employing Best Management Practices for construction activities in and near water. Individual components of the KBRA are described below.

Phases I and 2 Fisheries Restoration Plans and Fisheries Monitoring Plan

Implementation of Phases I and 2 Fisheries Restoration Plans and Fisheries Monitoring Plan could result in alterations to water quantity, water quality, habitat availability and habitat quality, and affect aquatic species. The Phases I and 2 Fisheries Restoration Plans and Fisheries Monitoring Plans are designed to improve habitat for aquatic species and measure the efficacy of restoration actions. These plans prioritize restoration needs within the Basin and establish a monitoring and adaptive management program to evaluate and optimize the success of restoration actions.

Measures that are ongoing in the Basin or that have been identified for inclusion in the plans include floodplain rehabilitation, large woody debris emplacement, fish passage improvement, livestock exclusion fencing, riparian vegetation management, purchase of conservation easements, road decommissioning, and treatment of fine sediment sources. Restoration actions will occur within the mainstem Klamath River, as well as within critical tributaries known to support salmonid rearing, such as Scott and Shasta rivers. These activities were chosen to benefit native fish populations as well as the health of the aquatic and riparian ecosystems of the Klamath Basin. Fish passage improvements would be designed to increase access to historical habitat. Many of these activities would

be constructed to reduce fine sediment supply to streams within the project area, improving spawning habitat and productive macroinvertebrate habitat.

Purchase of conservation easements or land could provide long-term protection to areas beneficial to the riverine ecosystem as a whole or specific areas of importance to fish species such as endangered suckers. It could also protect areas where restoration actions have been used to improve or restore habitats.

Some restoration activities under the Phases I and 2 Fisheries Restoration Plans and Fisheries Monitoring Plan could have short-term negative impacts, generally associated with construction and active management phases. Generally, these impacts would be localized and could be avoided through implementation of best management practices, such as control and containment of sediment and toxic discharge, isolation of work areas from the active channel of streams or rivers where possible, and rescuing fish where mortality may result from an action. The long-term water quality improvements generated by implementation of Phases I and 2 Fisheries Restoration Plans and Fisheries Monitoring Plan would contribute to the long-term improvements anticipated from hydroelectric facility removal. **Based on anticipated improvements in water quantity, water quality, habitat availability and habitat quality, implementation of Phases I and 2 Fisheries Restoration Plans and Fisheries Monitoring Plan under the Proposed Action would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, redband trout, benthic macroinvertebrates, and shortnose and Lost River suckers. These actions would also be beneficial for coho salmon, except those in the Trinity River population units, where they would be less-than-significant. Effects on green sturgeon, bull trout, eulachon, Southern Resident Killer Whales, and freshwater mussels would not change from existing conditions.**

Phase I Fisheries Reintroduction and Management Plan

Implementation of Phase I of the Fisheries Reintroduction and Management Plan could result in alterations to habitat availability (fish access), and could affect aquatic species. The Phase I Fisheries Reintroduction and Management Plan is intended to support the reintroduction and management of fish in the Upper Klamath Basin during and after implementation of the KHSA. As specified in the KHSA, the plan would include provisions for the continued operation of a fish hatchery at Fall Creek or in the Iron Gate Dam area and the construction of fish collection facilities to support primarily the transport of fall-run Chinook salmon around Keno Impoundment/ Lake Ewauna, when needed, on an interim seasonal basis.

The initial use of the hatchery facility at Iron Gate Dam or on Fall Creek would provide conservation of native salmon stocks during the impact period of dam removal. The development of guidelines for the use of the conservation hatchery at Iron Gate Dam or on Fall Creek outlined in the Phase I Fisheries Reintroduction and Management Plan would be to support the establishment of naturally producing populations in the Klamath Basin following implementation of the KHSA. Additionally, it is anticipated that a

smaller production facility would be constructed in the Upper Klamath Basin to provide necessary research stock and locally reared fish for the reintroduction.

As specified in the KHSA, volitional upstream and downstream passage facilities (screens and ladders) would be developed for passage around Keno Impoundment/ Lake Ewauna and will provide for volitional passage during the majority of the year. In addition, the development of fish collection facilities upstream and downstream from Keno Impoundment/Lake Ewauna would be required to provide effective migration for fall-run Chinook salmon when water quality is poor during the period from June 15 to November 15. During the limited period of use, fish collection and release facilities would be operated to minimize any delay and stress and provide for adequate acclimation. For adult fall-run Chinook salmon, fish transport would be an effective fish passage method because transport would be for a short distance on a seasonal, interim basis⁷. For adult fall-run Chinook salmon, seasonal collection and transport mortality when water quality is poor would be minor compared to mortality associated with unaided passage through areas of poor water quality at this time of year.

In some instances, the collection and transport of fall-run Chinook salmon around Keno Impoundment/Lake Ewauna could result in limited, seasonal mortality as follows:

1. Some juvenile federally listed suckers would likely be collected incidentally and may suffer related stress and mortality. However, regardless of any remediation at an upstream collection facility, nearly all these downstream migrant suckers would eventually die in the absence of lacustrine habitat below Keno Impoundment/Lake Ewauna. There is little to no evidence of recruitment of suckers in downstream reservoirs currently and this habitat does not contribute significantly to the recovery of the species. Suckers may be collected and returned to habitat above Keno Impoundment/Lake Ewauna.
2. Some redband trout may be collected incidentally resulting in displacement and incidental collection-related stress and mortality. Redband trout may be collected and returned to habitat above Keno Impoundment/Lake Ewauna.
3. For fall-run Chinook salmon emigrants, the seasonally poor quality conditions are not expected to overlap with the peak migration period, thus the majority of juvenile Chinook salmon would not be affected. For those fall-run Chinook salmon emigrants collected and transported during poor water quality conditions, transport related mortality would be minor compared to the mortality associated with unaided passage through areas of poor water quality at this time of year.

⁷ This seasonal, transport on an interim basis is not to be confused with permanent, year round trap and haul, which does not provide equal benefits for the Klamath River when compared with the Services' fishway prescriptions (U.S. Department of the Interior (2007) The Department of the Interior's Filing of Modified Terms, Conditions, and Prescriptions (Klamath Hydroelectric Project, No. 2082). Sacramento, California: 650 p.; NOAA Fisheries Service (2007). NOAA Fisheries Service Modified Prescriptions for Fishways and Alternatives Analysis for the Klamath Hydroelectric Project (FERC Project No. 2082): 151 p.).

4. For steelhead trout and spring-run Chinook salmon, migration would likely occur primarily when water quality was adequate, thus, collection and transport of these fish would not be necessary or minimal. However, all anadromous salmonids would be collected and transported when water quality is poor during the period from June 15 through November 15. Transport related mortality would be minor compared to the mortality associated with unaided passage through areas of poor water quality at this time of year.

Limited, seasonal transport of fall-run Chinook salmon would provide a net benefit by allowing them migration to and from additional (historical) spawning habitat, by providing more effective migration, and by reducing the density of spawners below Keno Dam in certain poor water quality situations. The majority of fish transported would likely be fall-run Chinook salmon. However, the Phase I Fisheries Reintroduction and Management Plan may include seasonal, interim transport for a minor component of the spring-run Chinook, and steelhead migrants. Thus, these fish would also receive benefits from this program. Increased anadromous fish abundance, especially Chinook salmon, would result in more prey availability for Southern Resident Killer Whales when the whales are near the Oregon and California coasts.

Other reintroduction activities under the Phase I Fisheries Reintroduction and Management Plan could have short-term impacts, generally associated with construction and active management phases. Generally, these impacts would be localized and could be avoided or minimized through implementation of best management practices, such as control and containment of sediment and toxic discharge, isolation of work areas from the active channel of streams or rivers where possible, and rescuing fish where mortality may result from an action. The habitat improvements generated by implementation of the Phase I Fisheries Reintroduction and Management Plan would contribute to the long-term improvements anticipated from hydroelectric facility removal. **Based on access to additional, historical habitat and the anticipated improvements in fish health, implementation of the Phase I Fisheries Reintroduction and Management Plan under the Proposed Action would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, Southern Resident Killer Whales, and benthic macroinvertebrates. These actions would also be beneficial for coho salmon, except those Trinity River population units, through continued support from the fish hatchery. The Trinity River population units, would experience no change from existing conditions in the long term. Effects on green sturgeon, bull trout, eulachon, and freshwater mussels would be no change from existing conditions. These actions would be less than significant for redband trout as well as for shortnose and Lost River suckers.**

Water Diversion Limitations Implementation of Water Diversion Limitations could result in reducing uncertainties associated with maintaining adequate ecological flows for aquatic species and their habitats, especially in low-flow years, and could alter water quality, and water temperatures in certain seasons and affect aquatic species. *This component of the KBRA would establish limits on specific diversions within*

Reclamation's Klamath Project to protect flows in the mainstem and ensure that adequate water supply is available for allocation to the wildlife refuges.

A plan would be developed for monitoring groundwater in order to restrict pumping to no more than 6 percent of the output of springs listed in the KBRA Section 15.2.4.A.i. This measure would protect an important resource that provides suitable habitat conditions that may be critical to the survival of some species. This reliable source of cool inflow from springs provides benefit to aquatic species by influencing temperature, dissolved oxygen, algal growth, and the dilution of contaminants or natural toxins, such as those produced by *M. aeruginosa*.

The long-term water quality and quantity improvements generated by implementation of diversion limitations would contribute to the long-term improvements anticipated from hydroelectric facility removal. **Based on anticipated improvements in water quantity and water quality, implementation of Water Diversion Limitations under the Proposed Action would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, redband trout, and shortnose and Lost River suckers. These actions would also be beneficial for coho salmon, except those in the Trinity River population units, where they would be no change from existing conditions. Effects on green sturgeon, bull trout, eulachon, Southern Resident Killer Whales, freshwater mussels, and BMIs would be no change from existing conditions.**

On-Project Plan Implementation of the On-Project Plan could result in alterations to water quantity and water quality and affect aquatic species. *The On-Project Plan would include a groundwater monitoring plan that limits pumping so that flows from springs in the watershed upstream of Copco 1 Dam would not be reduced by more than 6 percent, protecting these important habitats that provide suitable habitat conditions and often support rare or unique species. It would also provide a plan to implement the water diversion limitations described above. This measure would help protect flows in the mainstem with the benefits described above. The long-term water quality and quantity improvements generated by implementation of the On-Project Plan would contribute to the long-term improvements anticipated from hydroelectric facility removal. Based on anticipated improvements in water quantity and water quality, implementation of Water Diversion Limitations under the Proposed Action would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, redband trout, and shortnose and Lost River suckers. These actions would also be beneficial for coho salmon, except those in the Trinity River population units, where they would be no change from existing conditions. Effects on green sturgeon, bull trout, eulachon, Southern Resident Killer Whales, freshwater mussels, and BMIs would be no change from existing conditions.*

Water Use Retirement Program

The Water Use Retirement Program could alter water quantity and water quality, and affect aquatic species. This component of the KBRA would increase inflow to Upper Klamath Lake by 30,000 acre-feet per year on average. A variety of mechanisms may be used to achieve this objective, including acquisition of water rights, forbearance

agreements, water leasing, changes in agricultural cropping patterns, land fallowing, and juniper removal. The additional water provided would increase flows in tributaries to Upper Klamath Lake improving habitat for redband trout, shortnose and Lost River suckers, and bull trout. Anadromous salmon and steelhead that would have access to these tributaries as a result of the Proposed Action would also be expected to benefit.

This additional water could be used for a variety of purposes downstream from Upper Klamath Lake, including augmenting the base flow or high flow components of the annual hydrograph. Maintaining base flows, particularly during extreme droughts, is critical for fish spawning, rearing, passage, and preventing excessively warm water temperatures for all life stages. High flows are critical for shaping stream and river channels, creating diverse habitats, and connecting these habitats to riparian zones, terraces, and flood plains that provide nutrients to the riverine ecosystem and shelter for fish and other aquatic organisms when conditions in the river are unsuitable. Periodic springtime high flow events also have the potential of scouring the channel of fine-grained sediments and cladophora which harbor intermediate hosts for organisms that produce high mortality in juvenile salmon. High flows mobilize the streambed, which removes fine sediments and organic material that can reduce spawning success and macroinvertebrate production, as well as reduce interstitial habitat used as cover by small fish. They are also important drivers of riparian ecosystem functions, such as dispersing and germinating seeds of riparian plants, and creating new areas for vegetation colonization through erosion. Riparian ecosystems are important for filtering fine sediment from hillslope runoff, buffering streams from contaminants, providing shade and temperature regulation, bank stability, and nutrients to the stream. Augmenting low flows in some years may be critical due to temperature, water quality, or disease concerns.

The additional water flows generated by implementation of the Water Use Retirement Program would contribute to the long-term improvements anticipated from hydroelectric facility removal. **Based on anticipated improvements in water quantity, and water and stream channel quality, implementation of Water Use Retirement Program under the Proposed Action would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, redband trout, and shortnose and Lost River suckers. These actions would also be beneficial for coho salmon, except those in the Trinity River population units, where there would be no change from existing conditions. Effects on green sturgeon, bull trout, eulachon, Southern Resident Killer Whales, freshwater mussels, and BMIs would be no change from existing conditions.**

Fish Entrainment Reduction

Implementation of the Fish Entrainment Reduction could result in alterations to potential alterations to mortality risk and affect aquatic species. This KBRA action would involve designing and installing fish screens at Project Diversions, including the Lost River Diversion Channel and associated diversion points, North Canal, Ady Canal, and other Reclamation and Reclamation contractor diversions. This action would reduce mortality caused by entrainment of fish at these diversions, to the benefit of endangered shortnose

and Lost River suckers, as well as to redband trout. Steelhead and fall- and spring-run Chinook salmon would also benefit from this action once they recolonize areas upstream of Keno Dam. The reductions in entrainment mortality generated by implementation of the Water Use Retirement Program would contribute to the long-term improvements in anadromous species health anticipated from hydroelectric facility removal. **Based on anticipated reductions in entrainment mortality, implementation of Fish Entrainment Reduction under the Proposed Action would be beneficial for shortnose and Lost River suckers, redband trout, fall-run Chinook salmon, spring-run Chinook salmon, steelhead, and Pacific lamprey. These actions would also be beneficial for coho salmon from the Upper Klamath River population unit, and would be no change from existing conditions for all other coho salmon population units. Effects on green sturgeon, bull trout, eulachon, Southern Resident Killer Whales, freshwater mussels, and BMIs would be no change from existing conditions.**

Klamath Tribes Interim Fishing Site

*Implementation of the Klamath Tribes Interim Fishing Site could result in alterations to managed harvest mortality of fish species that are culturally important to the Klamath Tribes, including Chinook and coho salmon, steelhead, and Pacific lamprey. The harvest, which would take place between Iron Gate Dam and Interstate 5, would be coordinated with harvest by other tribes and the commercial fishery to remain within the predicted sustainable limits for the fishery. The coordinated harvest at the Klamath Tribes Interim Fishing Site would not be expected to contribute to any changes generated by the hydroelectric facility removal action. **Based on anticipated fisheries management coordination as part of the implementation of Klamath Tribes Interim Fishing Site under the Proposed Action, this action would result in no change from existing conditions for aquatic species.***

Upper Klamath Lake and Keno Nutrient Reduction Implementation of the Interim Flow and Lake Level Program could result in decreases in summer water temperature and nutrient inputs to Upper Klamath Lake. *KBRA (Appendix C-2, line 11) includes a program to study and reduce nutrient concentrations in the Keno Impoundment/Lake Ewauna and Upper Klamath Lake in order to reduce dissolved oxygen problems and algal problems in both water bodies. Restoration actions to control nutrients have not been developed, and there are many diverse possibilities that could require construction of treatment wetlands, construction of facilities, or chemical treatments of bottom sediment, among other possibilities. A nutrient reduction program in the Keno Impoundment/Lake Ewauna and Upper Klamath Lake would be designed to improve water quality (increasing dissolved oxygen and reducing algal concentration) and to provide fish passage through the Keno Impoundment/Lake Ewauna in summer and fall months; however, implementation of this nutrient reduction program will require future environmental compliance investigations and a determination on significance cannot be made at this time.*

The specific locations in which some of these KBRA actions would be undertaken are unknown at this time, but they would be implemented at different locations and times

than KHSA actions. Many of these actions would require additional environmental documentation and permitting before being implemented, and are covered programmatically in this document. Generally, the KBRA actions described above would be expected to result in a net benefit for fisheries resources and the aquatic environment. Any potential deleterious effects identified could be avoided or mitigated through careful planning and management.

3.3.4.3.3 Alternative 3: Partial Facilities Removal of Four Dams Alternative

The Partial Facilities Removal of Four Dams Alternative would include removal of enough of J.C. Boyle, Copco 1, Copco 2, and Iron Gate Dams to allow free-flowing river conditions and volitional fish passage at all times. Under this alternative, portions of each dam would remain in place along with ancillary buildings and structures such as powerhouses, foundations, tunnels, and pipes, all of which would be outside of the 100 year flood-prone width. Under this alternative, partial removal of the embankment/earth-filled dam and concrete dam structures would allow release of dam-stored sediment. The retention of these structures would not be expected to result in any difference in the physical or biological effects of dam removal from those described for the Proposed Action. This alternative would include the transfer of the Keno Facility to the DOI and implementation of the KBRA. Under this alternative, hatchery production would continue for eight years following the removal of Iron Gate Dam.

Key Ecological Attributes

Aquatic ecological attributes under the Partial Facilities Removal of Four Dams Alternative would have indistinguishable effects on aquatic species from the Proposed Action.

Species-Specific Impacts

Reservoir drawdown associated with dam removal under this alternative could affect aquatic species. In addition, the removal of dams and reservoirs could alter the availability and quality of habitat, resulting in effects on aquatic species. The impacts were considered for each of the following species and groups: fall-run Chinook salmon, spring-run Chinook salmon, coho salmon, steelhead, lamprey, green sturgeon, Lost River and shortnose suckers, redband trout, bull trout, eulachon, longfin smelt, introduced resident species, freshwater mussels and benthic macroinvertebrates. The effects of this Partial Facilities Removal of Four Dams Alternative on aquatic species would be indistinguishable from those described for the Proposed Action.

Interim Measures

Implementation of IMs 7 (J.C. Boyle Gravel Placement and/or Habitat Enhancement) and 16 (Water Diversions) could result in alterations to habitat availability and habitat quality, and affect aquatic species. These IM's will cease to be implemented if the Secretary makes a Negative Determination, and would therefore have no long-term effect on aquatic resources. These IMs would increase spawning gravel or habitat upstream of Copco Reservoir and would increase flows in Shovel and Negro Creeks. As described under the Proposed Action, these actions would provide improvements in habitat quality for resident fish prior to dam removal, and for resident and anadromous species following dam removal. **Based on anticipated improvements in habitat availability and habitat**

quality, implementation of IMs 7 and 16 under the Partial Facilities Removal would be beneficial for fall-run Chinook salmon, spring-run Chinook salmon, steelhead, Pacific lamprey, redband trout, and benthic macroinvertebrates. These actions would also be beneficial for coho salmon from the Upper Klamath River Population Unit, and less-than-significant for all other population units in the Basin. Effects on bull trout, freshwater mussels, shortnose and Lost River suckers would be less-than-significant. Effects on green sturgeon, eulachon, and Southern Resident Killer Whales would not change from existing conditions.

Keno Transfer

Implementation of the Keno Transfer could cause adverse aquatic resource effects. The Keno Transfer is a transfer of title for the Keno Facility from PacifiCorp to the DOI. This transfer would not result in the generation of new impacts on aquatic resources compared with existing facility operations. Following transfer of title, DOI would operate Keno in compliance with applicable law and would provide water levels upstream of Keno Dam for diversion and canal maintenance consistent with agreements and historic practice (KHSA Section 7.5.4). **Therefore, implementation of the Keno Transfer would result in no change from existing conditions.**

East and Westside Facilities – Programmatic Measure

Decommissioning the East and Westside Facilities could cause adverse aquatic resource effects. Decommissioning of the East and Westside canals and hydropower facilities of the Link River Dam by PacifiCorp as a part of the KHSA would no longer divert water flows at Link River Dam into the two canals. Risk of entrainment into these facilities would also be eliminated. Following decommissioning of the facilities, there would be no change in outflow from Upper Klamath Lake or inflow into Keno Impoundment/Lake Ewauna. **Implementation of the East and Westside Facility Decommissioning action would be beneficial for suckers and redband, and no change from existing conditions for other aquatic species.**

City of Yreka Water Supply Pipeline Relocation – Programmatic Measure

The Proposed Action would require the relocation of the City of Yreka Water Supply Pipeline. Under the Partial Facilities Removal Alternative, the relocation of the City of Yreka Water Supply Pipeline would have the same impacts as under the Proposed Action.

KBRA – Programmatic Measures

The KBRA would be implemented under the Partial Facilities Removal of Four Dams Alternative and would have indistinguishable effects on aquatic species from those of the Proposed Action.

3.3.4.3.4 Alternative 4: Fish Passage at Four Dams Alternative

The Fish Passage at Four Dams Alternative would provide upstream and downstream fish passage at the Four Facilities, but would not include implementation of the KBRA. The ongoing restoration actions, described in the No Action/No Project Alternative, would continue. The alternative would incorporate the prescriptions from the DOI and DOC imposed during the FERC relicensing process, including fishway installation for both

upstream and downstream migrations at all four facilities and barriers to prevent juvenile salmonid entrainment into turbines. In addition to the fishways, there are a series flow-related measures, including a condition that requires at least 40 percent of the inflow to the J.C. Boyle Reservoir to be released downstream. This alternative would limit generation of peaking power at J.C. Boyle Powerplant to one day per week as water supplies allow, and would include recreation flows one day a week.

Pursuant to FERC's Licensing Regulations, the Department of the Interior filed its comments regarding the impacts of facilities and operations of the Klamath Hydroelectric Project (FERC No. 2082) on public resources and recommended various terms and conditions to be incorporated into any new license to address these impacts. In addition, the Secretaries of Interior and Commerce filed fishway prescriptions under Section 18 of the Federal Power Act (FPA) to provide safe, timely, and effective fish passage, and, in doing so, specifically address the loss of fish habitat after the project was constructed.

Pursuant to the regulations of FERC (18 CFR 385.604), many of the Parties to the FERC licensing proceeding undertook confidential settlement discussions to resolve disputed issues in the licensing proceeding, resulting in the KHSA. Section 3.2.1 of the KHSA provides that the Secretary of the Interior is to undertake NEPA analysis and other appropriate actions to determine whether to proceed with Facilities Removal. Chapter 1 of this EIS/EIR states the purpose of the proposed Federal action "is to advance restoration of the salmonid fisheries in the Klamath Basin that is in the public interest, and is consistent with the KHSA and KBRA and their objectives." Consistency with the KHSA and KBRA and their objectives thus underlies the alternatives and analyses presented in this document. At time of document preparation, FERC has not taken final action on PacifiCorp's application for license. Therefore, the Department of the Interior's position in that proceeding has not changed, including the various impacts of PacifiCorp's dams on public resources and the need for and benefits of the fishways prescribed by the Secretaries. Fishways installed as part of fish passage alternatives in this EIS/EIR would need to comply with the Section 18 prescriptions for the construction, operation, and maintenance of upstream and downstream passage (DOI 2007). General prescriptions cover anadromous (fall- and spring-run Chinook salmon, coho salmon, steelhead, and Pacific lamprey) and resident (rainbow and redband trout, shortnose and Lost River suckers) fish passage at all Klamath Hydroelectric Project dams, and include implementing operation and maintenance plans and prescribing attraction flows for upstream migrants (DOI 2007). Specific provisions apply to individual dams and include performance standards for upstream and downstream passage facilities.

DOI and NOAA Fisheries Service passage prescriptions for Keno Dam include the collection of adult Chinook salmon for transport past Lake Ewauna during summer months when water quality is poor (DOI 2007). If dissolved oxygen concentrations are less than 6 mg/L and water temperatures are higher than 20°C, as measured at Miller Island (RM 246), trap and haul would occur from June 15 through November 15 until restoration efforts improve water quality to conditions suitable for anadromous fish (DOI 2007). Conditions in the reach from Keno Dam to Link River Dam are expected to

eventually improve through implementation of TMDL water quality measures and imposition of State water quality certification conditions to allow year-round volitional passage.

Under the Fish Passage at Four Dams Alternative, Iron Gate Hatchery will continue to operate to meet mitigation requirements.

Key Ecological Attributes

Suspended Sediment

Under the Fish Passage at Four Dams Alternative, SSCs would be the same as under existing conditions. Therefore, this alternative would have no effects associated with suspended sediment transport relative to existing conditions for any aquatic species.

Bedload Sediment

Under the Fish Passage at Four Dams Alternative, the dams would not be removed and sediment would continue to be stored behind Klamath Hydroelectric Project dams. As described for the No Action/No Project Alternative, the Klamath Hydroelectric Project dams would continue to trap fine and coarse sediment. These periodic inputs of bedload sediments are necessary for the long-term maintenance of aquatic habitats. As a result of the interception of sand, gravel and coarser sediment supply from sources upstream of Iron Gate Dam the channel downstream from Iron Gate Dam would continue to coarsen and decrease in mobility (Reclamation 2012), providing fewer components of habitat, in particular spawning habitat, and decreased quality habitat over time. This effect would gradually decrease in the downstream direction as coarse sediment is resupplied by tributary inputs (Hetrick et al. 2009), and would be substantially reduced at the Cottonwood Creek confluence (PacifiCorp 2004b). As occurs under existing conditions, the coarser bed material is mobilized at higher flows that occur less frequently, resulting in channel features that are unnaturally static and provide lower value aquatic habitat (Buer 1981).

Water Quality

Under the Fish Passage at Four Dams Alternative, water quality would be the same as under the No Action/No Project Alternative. Anadromous fish would be able to move through the Hydroelectric Reach and might be seasonally exposed to poor water quality during upstream and downstream migration. Dissolved oxygen concentrations within reservoirs can be seasonally stressful for anadromous fish from June to September (FERC 2007) and continued high rates of algal photosynthesis in the reservoirs would result in pH values that would not consistently meet applicable ODEQ and California Basin Plan water quality objectives (see Section 3.2.4.3). Implementation of water quality improvement measures under Oregon and California TMDLs (to address water quality impairments within the period of analysis) would improve conditions for migratory fish.

Water Temperature

Under the Fish Passage at Four Dams Alternative, the effects on water temperature are predicted to be similar to those that are predicted for the No Action/No Project Alternative. Under this Alternative, the expected overall higher flow releases would

result in more reservoir water entering the J.C. Boyle Bypass Reach and correspondingly warmer water temperatures during summer and early fall, and cooler water temperatures in late fall and winter. These effects would be similar to those under the Proposed Action and would move this short reach away from consistently cooler water temperatures during summer and early fall months; however, as with the Proposed Action, areas adjacent to the coldwater springs in the Bypass Reach would continue to serve as thermal refugia for aquatic species because the springs themselves would not be affected by the Fish Passage at Four Dams Alternative. Anadromous fish would be able to move through the Hydroelectric Reach and might be seasonally exposed to high temperatures during upstream and downstream migration. Water temperature in the reservoirs can be high from June to September (see Section 3.2.3.2) and surface layers may seasonally exceed thermal tolerances for salmonids or resident fish. However, these potential periods of high water temperature are outside of peak migration.

Since J.C. Boyle Reservoir, with its large thermal mass, would remain in place, effects on diel temperature variation in the Bypass Reach under the Fish Passage at Four Dams Alternative would be similar to those described for the No Action/No Project Alternative (i.e., reduced diel temperature variation). Maximum water temperatures in the Peaking Reach would be slightly cooler and temperatures would be less artificially variable compared to existing conditions, also due to higher overall flows and the lower frequency of peaking operations at the J.C. Boyle Powerhouse. Under existing conditions, there is a delay in the normal progression of water temperatures downstream from Iron Gate Dam (or Phase Shift from historical timing) (Bartholow et al. 2005). Under this alternative, the current phase shift and lack of temporal temperature diversity will persist, including current warm temperatures in late summer and fall (Hamilton et al. 2011). Juveniles and adults migrating later in the year would continue to experience warm temperatures in late summer and fall that could be deleterious to health and survival, including increased risk of disease, and high rates of delayed spawning and prespawn mortality (Hetrick et al. 2009).

Fish Disease and Parasites

The incidence of fish disease in salmon would be reduced under the Fish Passage at Four Dams Alternative relative to existing conditions. FERC's (2007) analysis concluded that restoring access to reaches above Iron Gate Dam for anadromous fish would allow adult fall-run Chinook salmon to distribute over a greater length of the river, reducing crowding and the concentration of disease pathogens that currently occur in the reach between Iron Gate Dam and the Shasta River. However, concentrations of post spawn salmon carcasses downstream from Iron Gate Dam may still be elevated associated with the continued operation of Iron Gate Hatchery. Provision of fish passage would allow anadromous salmonid migration to move upstream in the mainstem Klamath River and tributaries. Available information indicates that fish passage would not increase the risk of disease for resident species that occur upstream of Iron Gate Dam (Administrative Law Judge 2006). *C. shasta* and *P. minibicornis* exist throughout the Klamath River System in both the Upper and Lower Basins, so migration of wild anadromous fish upstream of downstream from Iron Gate Dam would not increase the risk of introducing pathogens to resident trout residing above Iron Gate Dam (Administrative Law Judge

2006). In addition, native Klamath River trout are generally resistant to *C. shasta*. The remaining known pathogens do not impact non-salmonids, with the exception of *F. columnaris* and *Ich*.

Recently several new *C. shasta* genotypes have been discovered in the Klamath River. In this regard, risk is related to host specificity, which appears to exist at least to some degree (Atkinson and Bartholomew 2010). As an example, redband trout are thought to be susceptible to Type 0, which already occurs in the upstream Basin and Chinook salmon are susceptible to Type I, which occurs in the Lower Klamath Basin. Type 0 genotype occurs in low densities and it is not very virulent (infection results in low or no mortality); if Type I genotype were to be reintroduced above Iron Gate Dam, it would affect only Chinook salmon. It is not expected that introduction of *C. shasta* genotypes upstream would be deleterious because fish in the upstream Basin have shown resistance to the downstream genotypes. Redband trout would presumably have been exposed to genotypes of *C. shasta* during the pre-dam period, and their populations were abundant. Because the salmonid species in the Klamath Basin already co-occur with the genotype of *C. shasta* to which they are susceptible, and the salmonid species are less susceptible to other genotypes of *C. shasta*, expanding the distribution of the different genotypes of *C. shasta* would be unlikely to be deleterious to salmonids. Recently discovered *C. shasta* genotypes and research findings in the past several years do not appear to contradict the finding that movement of anadromous salmonids into the Upper Klamath Basin presents a relatively low risk of introducing pathogens to resident fish (Administrative Law Judge 2006, USFWS/NOAA Fisheries Service Issue 2(B)).

Available information also indicates that risks associated with movement of anadromous fish upstream of Iron Gate Dam are minimal. For example, steelhead within the Klamath River system are generally resistant to *C. shasta*, (Administrative Law Judge 2006). Since salmon and associated disease pathogens were present historically above Iron Gate Dam, *C. shasta* genotype movement would be a reintroduction of associated risk to these anadromous species.

While it is possible that the current infections nidus (reach with highest infectivity) for *C. shasta* and *P. minibicornis* may be recreated upstream where salmon spawning congregations occur, and there is associated uncertainty (Foott et al. 2011), the likelihood of this happening appears to be remote for the following reasons. Any creation of an infectious zone (or zones) would be the result of the synergistic effect of numerous factors, such as those that occur within the current disease zone in the Klamath River in the reach from the Shasta River downstream to Seiad Valley (FERC (2007; Bartholomew and Foott 2010). Here, flows in that reach that mimic natural conditions, combined with reestablishment of natural sediment transport rates, would restore natural geomorphic channel forming processes (Hetrick et al. 2009) necessary to create diverse habitat and reduce the influence of those synergistic factors that currently create conditions favorable for disease. Under a dams out alternative, those conditions that are believed to result in development of an infectious nidus below Iron Gate Dam, or a could result in development of a potential infectious nidus above Iron Gate Dam, are unlikely to occur.

Further, the likelihood of those synergistic factors in the Williamson River would be reduced as carcasses would likely be more dispersed in the watershed (Foott et al. 2011), and flow variability will act to reduce polychaete habitat stability above the Williamson River mouth. *C. shasta* in the Williamson River is currently maintained by planting of susceptible rainbow trout that become infected, likely produce myxospores, and die within a restricted reach in the lower Williamson River.

In addition, under a scenario of dam removal, it is likely that a greater diversity of salmon life histories will evolve, with some of those types more likely to avoid parasite exposure by migrating earlier or over wintering in tributaries and migrating in the fall (Bartholomew and Foott 2010; p. 40), thus missing the time of year when water temperatures in the Williamson River might possibly be conducive to disease. Although their research was focused on dam removal, access to the habitat above Iron Gate Dam through other means, such as fishways under Alternative 4, would likely have a similar outcome. In some years, maximum temperatures in the Williamson River do not exceed the disease threshold of 15 C (Bartholomew and Foott 2010; Hamilton et al. 2010). The risk of a juvenile salmon disease response here would be lower than the current zone but not negligible in all water years (Foott 2012).

Historically, it appears spawning concentrations of upper basin Chinook salmon took place primarily in the Sprague River (Lane and Lane Associates 1981). There is no information indicating that high densities of polychaetes occur in the Sprague River (Foott et al. 2011). Thus, the synergistic factors that contribute to an infectious nidus for emigrants below Iron Gate Dam and near the Iron Gate Hatchery are unlikely to occur here either. There is some concern regarding a disease zone in the lower Williamson River downstream from the confluence with the Sprague River (Hurst et al. 2012). However, some Chinook emigrants from both these tributaries may very well emerge from groundwater areas early, then rear in Upper Klamath Lake, with growth opportunities that allow them to migrate when they can minimize exposure to *C. shasta*.

Algal Toxins

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the Fish Passage at Four Dams Alternative, high nutrient inputs supporting the growth of toxin-producing nuisance algal species such as *M. aeruginosa* in Upper Klamath Lake would remain similar to existing conditions for decades into the future. This would result in continued bioaccumulation of microcystin in suckers in Upper Klamath Lake and could be deleterious to fish health. For salmonids in Upper Klamath Lake, impacts would be similar to those currently observed downstream from Iron Gate Dam. Upon full attainment of the TMDLs (implementation mechanism and timing currently unknown), nutrients and toxin-producing nuisance algal species in Upper Klamath Lake would likely decrease (see the subsection of Section 3.2.4.3.1, Chlorophyll-a and Algal Toxins – Upper Klamath Basin, and Section 3.4.4.3.1, Alternative 1: No Action/No Project Alternative –Phytoplankton, for additional detail regarding TMDLs and algal growth in

Upper Klamath Lake). Accordingly, with full attainment of the TMDLs, improvements to microcystin tissue levels in suckers in Upper Klamath Lake would occur.

Hydroelectric Reach: from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Continued impoundment of water at the Four Facilities under the Fish Passage at Four Dams Alternative would support growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa* in Copco 1 and Iron Gate Reservoirs, resulting in high seasonal concentrations of algal toxins in the Hydroelectric Reach for decades into the future. This would result in continued bioaccumulation of microcystin in fish tissue for species in the Hydroelectric Reach and could be deleterious to fish health. For salmonids, impacts would be similar to those currently observed downstream from Iron Gate Dam. Upon full attainment of the TMDLs (implementation mechanism and timing currently unknown), nutrients and toxin-producing nuisance algal species would likely decrease in the Hydroelectric Reach (see the subsection of Section 3.2.4.3.1, Chlorophyll-a and Algal Toxins – Upper Klamath Basin, and Section 3.4.4.3.1, Alternative 1: No Action/No Project Alternative – Phytoplankton, for additional detail regarding TMDLs and algal growth in the Hydroelectric Reach). Accordingly, with full attainment of the TMDLs, improvements to microcystin tissue levels in fish in the Hydroelectric Reach would occur.

Lower Klamath River: Downstream from Iron Gate Dam Continued impoundment of water at the Four Facilities under the Fish Passage at Four Dams Alternative would support the seasonal transport of toxin-producing nuisance algae and microcystin to the Klamath River downstream from Iron Gate Dam. This would result in continued bioaccumulation of microcystin in fish and mussel tissue for species in the river and could be deleterious to fish health. For salmonids, impacts would be similar to those currently observed downstream from Iron Gate Dam. Upon full attainment of the TMDLs (implementation mechanism and timing currently unknown), nutrients and toxin-producing nuisance algal species would likely decrease in the Hydroelectric Reach (see the subsection of Section 3.2.4.3.1, Chlorophyll-a and Algal Toxins – Upper Klamath Basin, and Section 3.4.4.3.1, Alternative 1: No Action/No Project Alternative – Phytoplankton, for additional detail regarding TMDLs and algal growth in the Klamath River downstream from Iron Gate Dam). Accordingly, with full attainment of the TMDLs, improvements to microcystin tissue levels in fish and mussels in the Klamath River downstream from Iron Gate Dam would occur.

Aquatic Habitat

Under the Fish Passage at Four Dams Alternative access to historical anadromous fish habitat would be restored (with the exception of habitat under the four reservoirs) as discussed in the Aquatic Habitat section for Alternative 2 (subsection of Section 3.3.4.3.2). Hydrology of the Klamath River from Iron Gate Dam to the Klamath River Estuary would generally remain the same as under existing conditions, subject to the influence of climate change (discussed under Section 3.10, Greenhouse Gases/Global Climate Change). Activities currently underway to recover salmonid and sucker populations within the Klamath Basin would continue at their current levels. Fish would be able to migrate past the dams and would regain access to substantial areas of

additional habitat; however, access could be delayed at the ladders and seasonally may be impaired by water temperatures.

Fish migrating through reservoirs would be protected from entrainment at the hydroelectric intake by fish collection and routing facilities as required under the Section 18 prescriptions for FERC relicensing of the Klamath Hydroelectric Project (DOI 2007). Under this alternative, there would be substantial changes to hydroelectric operations. J.C. Boyle Powerhouse would no longer generate in peaking mode, and higher flow releases would be made through the J.C. Boyle Bypass Reach than under existing conditions. Higher base flows would also be provided in the Copco 2 Bypass Reach. Peaking operations would only occur one day a week to coincide with recreation flows, at least 40 percent of flow would go into the Bypass Reach (and not enter the powerhouse), and ramping rates would be slower than they are currently. Seasonal high flows will contribute to improving the quality of riparian habitat in the J.C. Boyle Bypass Reach by increasing the sediment deposit within the channel and decreasing reed canary grass (Administrative Law Judge 2006). The more normative flow regime associated with this alternative would provide these seasonal high flows. These modifications would benefit fish in this reach, including redband trout and anadromous fish.

Aquatic Resources Effects

Critical Habitat

As described below, continued impoundment of water within reservoirs and access to additional habitat under the Fish Passage at Four Dams Alternative could alter currently designated critical habitat.

Coho Salmon Under the Fish Passage at Four Dams Alternative, coho salmon would be able to access habitat in the Hydroelectric Reach by ascending the fishways associated with each of the dams. The upstream boundary of critical habitat for coho salmon in the Klamath Basin is Iron Gate Dam; any newly accessible areas would be outside of their currently designated critical habitat. NOAA Fisheries Service may want to consider including the newly accessible reaches as critical habitat as part of their 5-year status review or in a separate decision (J. Simondet, NOAA Fisheries Service, pers. comm., 2011). Under this alternative, the KBRA would not be implemented. However, ongoing restoration activities will continue. The areas inundated by the reservoirs would not provide suitable spawning or rearing habitat for coho salmon, but they would regain access to the riverine reaches on the mainstem and to the tributaries, although the downstream ends of most of the tributaries would be inundated by the reservoirs. Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through reduced (but not eliminated) peaking operations and increasing base flows.

Water temperatures would continue to be seasonally affected by the reservoirs. Similar to existing conditions, they would be warmer in the summer and fall when adults are migrating upstream and may pose a degree of seasonal risk to adult migrants downstream from Iron Gate Dam, upon entry into the reservoirs, and in bypass reaches. The incidence of fish disease in salmon would be reduced under the Fish Passage at Four

Dams Alternative relative to existing conditions. FERC's (2007) analysis concluded that restoring access to reaches above Iron Gate Dam for anadromous fish would allow salmon to distribute over a greater length of the river, reducing crowding and the concentration of disease pathogens that currently occur in the reach between Iron Gate Dam and the Shasta River. However, concentrations of post spawn salmon carcasses downstream from Iron Gate Dam may still be elevated associated with the continued operation of Iron Gate Hatchery.

In terms of PCEs of coho salmon critical habitat, this alternative would provide access to additional spawning habitat upstream of currently designated critical habitat, including in Fall, Jenny, Shovel and Spencer Creeks, although the downstream ends of these streams would continue to be inundated by the reservoirs and would not provide suitable spawning or rearing habitat. The food resources in these tributaries would also become available to fry and juvenile coho salmon rearing in those streams. Water quality conditions in the Hydroelectric Reach and downstream from Iron Gate Dam would be expected to improve over time with TMDL implementation, but would not improve as quickly or to the same extent as under the Proposed Action. **Based on the current designation of critical habitat, the effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for coho salmon critical habitat in the short and long term.**

Bull Trout Under the Fish Passage at Four Dams Alternative, the physical and chemical components of critical habitat for bull trout would be improved by the Oregon TMDL processes, but the KBRA would not be implemented. However, ongoing restoration activities will continue to occur. Actions taken as part of the Fish Passage at Four Dams Alternative would not affect the physical or chemical components of critical habitat, but would allow Chinook salmon and steelhead to access areas they have not been able to access since the completion of the Copco 1 Development in 1918. These species could compete with and prey upon bull trout fry and juveniles. However, bull trout would also be expected to consume the eggs and fry of Chinook salmon and steelhead. Because these species co-evolved in the watershed together, it is anticipated that they would be able to co-exist in the future. **Based on the restricted distribution of bull trout, the Fish Passage at Four Dams Alternative would result in no change from existing conditions.**

Southern Resident Killer Whale Klamath River contributes to critical habitat for Southern Resident Killer Whales through its contribution of Chinook salmon to their food supply. Fish Passage at Four Dams Alternative would not affect critical habitat for this species. Implementation of this alternative is expected to increase production of wild Chinook salmon by providing anadromous salmonids with access to habitat upstream of Iron Gate Dam. The Iron Gate Hatchery would continue to operate, ensuring ongoing production of hatchery Chinook salmon and contribution to ocean stocks. Klamath River Chinook salmon likely represent only a very small proportion of the diet of this killer whale population because most of their feeding is on Fraser River and Puget Sound stocks (Hanson et al. 2010); therefore, any increase in salmon production from this alternative would not substantially affect this species. **Based on small influence of the**

Klamath River on PCEs of Southern Resident Killer Whales, the Fish Passage at Four Dams Alternative would result in no change from existing conditions.

Essential Fish Habitat

As described below, continued impoundment of water within reservoirs and access to additional habitat under the Fish Passage at Four Dams Alternative could alter the availability and suitability of EFH.

Chinook and Coho Salmon EFH Implementation of the Fish Passage at Four Dams Alternative would increase habitat for Chinook and coho salmon (upstream of currently designated EFH) by providing access to habitat upstream of Iron Gate Dam. However, under this alternative, EFH for Chinook and coho salmon would be expected to remain similar to its current condition, as described for the No Action/No Project Alternative. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for Chinook and coho salmon EFH in the short and long term.**

Groundfish EFH Implementation of the Fish Passage at Four Dams Alternative would not affect groundfish EFH. SSCs and bedload would remain the same as under existing conditions, as would water quality. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for groundfish EFH in the short and long term.**

Pelagic Fish EFH Implementation of the Fish Passage at Four Dams Alternative would not affect pelagic fish EFH. SSCs and bedload would remain the same, as would water quality. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for pelagic fish EFH in the short and long term.**

Species-Specific Impacts

A described below, fishways at Four Dams could alter the availability of habitat resulting in effects on aquatic species.

Fall-Run Chinook Salmon

Upper Klamath Basin Upstream of J.C. Boyle Reservoir Under the Fish Passage at Four Dams Alternative, fish passage facilities installed at the four dams within the Hydroelectric Reach would allow fall-run Chinook salmon to regain access to the upper Klamath River upstream of J.C. Boyle Reservoir. The access would expand the Chinook salmon's current habitat to include historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds of miles of additional potentially productive habitat (DOI 2007), including access to groundwater discharge areas relatively resistant to effects of climate change (Hamilton et al. 2011). Implementation of the Fish Passage at Four Dams Alternative would not result in changes to the suspended sediments or bedload sediment, flow-related habitat, or algal toxins and disease. Facilitating the movement of anadromous fish via prescribed fishways presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006).

Poor water quality (e.g., severe hypoxia, temperatures exceeding 25°C, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009; USGS 2010; both as cited in Hamilton et al. 2011). However, evidence indicates that Upper Klamath Lake habitat is presently suitable to support Chinook salmon for at least the October through May period (Maule et al. 2009). Poor water quality conditions from Link Dam to Keno Dam during the late summer and fall could be detrimental to fish in this area, particularly anadromous salmonids (FERC 2007). Therefore, the Fish Passage at Four Dams Alternative would include an interim seasonal trap and haul operation that would involve capturing and trucking both upstream and downstream migrant fish (primarily adult fall-run Chinook salmon) around this area when water quality conditions would be prohibitively stressful. This is consistent with the fishway prescriptions of DOI and U.S. Department of Commerce (DOC) (DOI 2007; NOAA Fisheries Service 2007). As adult fall-run Chinook salmon in the Klamath River migrate upstream of August through October, and juveniles migrate to the ocean from spring to early fall, stress-related mortality associated with seasonal, interim trap and haul activities would affect this species to some degree (Buchanan et al. 2011b). The distance that fish would be transported under this alternative would be limited however, and trap and haul would only be used when fish would otherwise be exposed to stressful conditions.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Implementation of the Fish Passage at Four Dams Alternative would restore fall-run Chinook salmon access to the Hydroelectric Reach. Passage through the reach would provide approximately 54 miles of additional habitat along the mainstem and within accessible tributaries, based on access to 58 miles of anadromous fish (steelhead) habitat (Administrative Law Judge 2006)⁸, taking into account the restricted distribution of Chinook salmon (DOI 2007), habitat in the bypass reaches, and the continuation of around 22 miles of spawning and rearing habitat inundated by Klamath Hydroelectric Project reservoirs (Cunanan 2009). Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through reduced (but not eliminated) peaking operations and increasing base flows. Under this Alternative, the expected overall higher flow releases would result in more reservoir water entering the J. C. Boyle Bypass Reach and correspondingly warmer water temperatures during summer and early fall, and cooler temperatures in late fall and winter. These effects would be similar to those under the Proposed Action and would move this short reach away from consistently cooler water temperatures during summer and early fall months; however, passage structures would provide access to thermal refugia created by 200 to 250 cfs of spring flow accretion in the J.C. Boyle Bypass Reach (DOI 2007; FERC 2007). Under this alternative, suspended and bedload sediment, water quality, and algal toxins would be the same as under existing conditions.

Under this alternative fish migrating through reservoirs would be seasonally exposed to some degree to stressful water quality conditions including high temperatures in reservoir

⁸ This also takes into consideration slight differences in the Administrative Law Judge (2006) definition of the Project Reach from what is used in this report.

surface layers with low dissolved oxygen in reservoir surface layers in the summer and fall, changes in dissolved oxygen, pH, and ammonia associated with algal blooms, and exposure to microcystin from *M. aeruginosa* blooms (Dunsmoor and Huntington 2006; FERC 2007). These conditions can become stressful in June through September, contributing to lower resistance to disease seasonally. Based on the reservoir dynamics and the predator population that currently occurs, predation of outmigrating salmonids above Iron Gate Dam is anticipated to be low (Administrative Law Judge 2006). In restoration efforts elsewhere in the Pacific Northwest, anadromous juveniles successfully pass through reservoirs under similarly difficult circumstances (Administrative Law Judge 2006). The fact that anadromous fish currently complete life cycles through eight dams and reservoirs on the Columbia and Snake rivers, and historically completed life cycles through Upper Klamath Lake, provides strong evidence that anadromous salmonids could also migrate through the reservoirs created by Project facilities (Administrative Law Judge 2006).

Lower Klamath River: Downstream from Iron Gate Dam Under the Fish Passage at Four Dams Alternative, suspended sediment would be the same as under existing conditions, thus having no suspended sediment effects relative to existing conditions for any aquatic species. Klamath Hydroelectric Project dams would continue to trap fine and coarse sediment. The channel directly downstream from Iron Gate Dam would continue to be starved of fine sediment, but the effect would gradually decrease in the downstream direction as coarse sediment would be resupplied by tributary inputs (Hetrick et al. 2009; Stillwater Sciences 2010a). Coarsening of the bed could reduce spawning habitat for fall-run Chinook salmon downstream from the dam over time, but this impact would be limited to the area upstream of Cottonwood Creek. Rearing habitat would be expected to remain similar to existing conditions.

Under the Fish Passage at Four Dams Alternative, the Lower Klamath River downstream from Iron Gate Dam reach would continue to have seasonally poor water quality because of the continued presence of the reservoirs with their increased hydraulic residence time and thermal mass (Bartholow 2005). The continuation of warm water releases from Iron Gate Dam will contribute to the delay in adult upstream migration of fall-run Chinook salmon (Dunsmoor and Huntington 2006), and increase the risk of prespawn mortality (Hamilton et al. 2011).

As described above, the incidence of fish disease for fall-run Chinook salmon would be reduced under the Fish Passage at Four Dams Alternative relative to existing conditions. Dissolved oxygen concentrations during August-October immediately downstream from Iron Gate Dam would continue to be low (less than 85 percent saturation during August-September and 90 percent saturation from October-November (see subsection of Section 3.2.4.3.1, Lower Klamath River). In addition, the presence of microcystin, associated with the dense blooms of *M. aeruginosa* in Iron Gate and Copco Reservoirs, would continue to occur downstream from Iron Gate Dam.

Estuary

The Fish Passage at Four Dams Alternative is not expected to substantially change or affect fall-run Chinook salmon estuarine habitat relative to existing conditions.

Summary: Fall-Run Chinook Salmon

Under this alternative, fishways at Four Dams could result in alterations in habitat availability for fall-run Chinook salmon in the long term. Under the Fish Passage at Four Dams Alternative, fall-run Chinook salmon would regain access to mainstem and tributary habitat in the upper Klamath River and Hydroelectric Reach, and thermal refugia within the Hydroelectric Reach, which would benefit the population. Some degree of stress and mortality of adult and juvenile salmon may result from the interim seasonal trap and haul operations (Buchanan et al. 2011b), especially between Link Dam and Keno Dam, and during periods with high water temperatures or poor water quality. Poor water quality, high water temperature, low dissolved oxygen, algal blooms and toxins could reduce survival of fall-run Chinook salmon passing through the four reservoirs. The distance that fish would be transported under this alternative would be limited however, and trap and haul only used when fish would otherwise be exposed to stressful conditions.

This alternative would result in continuation of some of the stresses that currently affect Chinook salmon populations. The presence of dams under the Fish Passage at Four Dams Alternative would continue to cause seasonally poor water quality, and high late summer and early fall water temperatures, allowing some conditions favorable for the transmission of fish disease to persist. These conditions would continue to have negative short- and long-term impacts on fall-run Chinook salmon populations. Further, under the Fish Passage at Four Dams Alternative, the KBRA would not be implemented, so any potential habitat improvements from KBRA restoration projects would not be realized. However, ongoing restoration activities would continue to occur. Climate change could also increase the frequency and duration of stressful water temperatures for salmonids under the Fish Passage at Four Dams Alternative. It is anticipated that as a result of the Fish Passage at Four Dams Alternative the fall-run Chinook salmon population within the Klamath River watershed would have an increase in abundance, population spatial structure, and genetic diversity. However, smolts produced from tributaries downstream from Iron Gate Dam would experience a continuation of existing deleterious effects. **Based on increased habitat availability, the effect of the Fish Passage at Four Dams Alternative would be beneficial for fall-run Chinook salmon in the short and long term.**

Spring-Run Chinook Salmon

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the Fish Passage at Four Dams Alternative, fish passage facilities installed at the four dams within the Hydroelectric Reach would allow spring-run Chinook salmon to regain access to the upper Klamath River upstream of J.C. Boyle Reservoir. The access would expand the Chinook salmon's current habitat to include historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005, Butler et al. 2010). Huntington (2006) reasoned that spring-run Chinook salmon likely accounted for the majority of the Upper Klamath Basin's actual salmon production under historical conditions. Huntington (2006) cautioned that while access to the Upper Klamath Basin provides considerable promise of increasing spring-run abundance, the existing potential for Chinook salmon production within the Basin upstream of Upper

Klamath Lake is clearly much lower than his estimate of historical potential. However, Huntington (2006) did not fully account for the historical (and unknown) production potential of Upper Klamath Lake itself, which could have been considerable, as suggested by a recent experimental reintroduction into Upper Klamath Lake (Maule et al. 2009). Overall, the Fish Passage at Four Dams Alternative would provide access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds of miles of additional potentially productive anadromous fish habitat upstream of Iron Gate Dam (DOI 2007), including access to important thermal refugia within areas influenced by groundwater exchange that are more resistant to climate change (Hamilton et al. 2011). Some of these areas, such as the lower Williamson River, have habitat that would provide substantial holding areas for spring-run Chinook salmon (Hamilton et al. 2010). Other holding areas with suitable temperatures upstream of J.C. Boyle Reservoir include groundwater influenced areas on the west side of Upper Klamath Lake, and the Wood River (Gannett et al. 2007).

The Fish Passage at Four Dams Alternative is not expected to result in changes to suspended or bedload sediment, flow-related habitat, or algal toxins and disease. Facilitating the movement of anadromous fish via prescribed fishways presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006).

Poor water quality (e.g., severe hypoxia, temperatures exceeding 25 °C, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009; USGS 2010; both as cited in Hamilton et al. 2011). However, evidence indicates that Upper Klamath Lake habitat is presently suitable to support Chinook salmon for at least the October through May period (Maule et al. 2009). Poor water quality conditions, particularly in Lake Ewauna during the late summer and early fall, could be detrimental to fish in this area, particularly anadromous salmonids (FERC 2007). Therefore, an interim seasonal trap and haul operation would be implemented to capture and truck migrant fish around Lake Ewauna during stressful water quality conditions (from June 15 to November 15). As adult spring-run Chinook salmon in the Klamath River migrate upstream from April through June, and most juveniles migrate from April through May or October through November, trap and haul activities would be expected to have only minor effects on this run of Chinook salmon.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam The Fish Passage at Four Dams Alternative would include restoring spring-run Chinook salmon access to the Hydroelectric Reach. Passage through the reach would provide approximately 54 miles of additional habitat along the mainstem and within accessible tributaries, based on access to 58 miles of anadromous fish (steelhead) habitat (Administrative Law Judge 2006),⁹ taking into account the more limited distribution of Chinook salmon (DOI 2007), habitat in the bypass reaches, and the continuation of around 22 miles of spawning and rearing habitat inundated by Klamath Hydroelectric Project reservoirs (Cunanan 2009). Habitat in the J.C. Boyle

⁹ This also takes into consideration slight differences in the Administrative Law Judge (2006) definition of the Project Reach from what is used in this report.

Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through reduced (but not eliminated) peaking operations and increasing base flows. Under this Alternative, the expected overall higher flow releases than under current conditions would result in more reservoir water entering the J.C. Boyle Bypass Reach and correspondingly warmer water temperatures during summer and early fall, and cooler temperatures in late fall and winter. These effects would be similar to those under the Proposed Action and would move this short reach away from consistently cooler water temperatures during summer and early fall months; however, passage structures would provide fish with some refuge from high temperatures because of access to cooler water from tributaries, in addition to that provided by 200 to 250 cfs of accretion from springs in the J.C. Boyle Bypass Reach (DOI 2007; FERC 2007; Hamilton et al. 2011). Under this alternative, flows and access would also be restored to the 1.4 mile Copco 2 bypass reach. Under this alternative, suspended and bedload sediment, water quality, and the occurrence of fish disease and algal toxins would be the same as under existing conditions.

This alternative would result in continuation of some of the stresses that currently affect Chinook salmon populations. The presence of J. C. Boyle, Copco 1, Copco 2, and Iron Gate Dams under the Fish Passage at Four Dams Alternative would continue to cause seasonally poor water quality, and high late summer and early fall water temperatures, allowing some conditions favorable for the transmission of fish disease to persist. Adult spring-run Chinook salmon in the Klamath River migrate upstream from April through June (and possibly earlier, Fortune et al. 1966), and most juveniles migrate from April through May or in the fall, as flows increase. Therefore water quality in reservoirs is expected to have minor effects on this species.

Lower Klamath River: Downstream from Iron Gate Dam Under the Fish Passage at Four Dams Alternative, suspended sediment would be the same as under existing conditions, thus having no suspended sediment effects relative to existing conditions for any aquatic species. Klamath Hydroelectric Project dams would continue to trap fine and coarse sediment. The channel directly downstream from Iron Gate Dam would continue to be starved of fine sediment, but the effect would gradually decrease in the downstream direction as coarse sediment would be resupplied by tributary inputs (Hetrick et al. 2009; Stillwater Sciences 2010a).

Under the Fish Passage at Four Dams Alternative, the Lower Klamath River downstream from Iron Gate Dam would continue to have seasonally poor water quality because of the continued presence of the reservoirs, with their increased hydraulic residence time and thermal mass (Bartholow et al. 2005). Under this alternative, the current phase shift and lack of temporal temperature diversity will persist, including current warm temperatures in late summer and fall (Hamilton et al. 2011). Juveniles and adults migrating would continue to experience warm temperatures in late summer and fall that could be deleterious to health and survival, including increased risk of disease, and high rates of delayed spawning and prespawn mortality (Hetrick et al. 2009).

As described above, the incidence of fish disease for spring-run Chinook salmon would be reduced under the Fish Passage at Four Dams Alternative relative to existing conditions. Dissolved oxygen concentrations during August-October immediately downstream from Iron Gate Dam would continue to be low (less than 85 percent

saturation during August-September and 90 percent saturation from October-November (see Section 3.2.4.3.1.4 – Lower Klamath River). In addition, the presence of microcystin, associated with the dense blooms of *M. aeruginosa* in Iron Gate and Copco Reservoirs, would continue to occur downstream from Iron Gate Dam.

Estuary

The Fish Passage at Four Dams Alternative is not expected to substantially change or affect spring-run Chinook salmon estuarine habitat relative to existing conditions.

Summary: Spring-Run Chinook Salmon

Under this alternative, fishways at Four Dams could result in alterations in habitat availability which could affect spring-run Chinook salmon in the long term. Under the Fish Passage at Four Dams Alternative, spring-run Chinook salmon would regain access to mainstem and tributary habitat in the upper Klamath River and Hydroelectric Reach and thermal refugia within the Hydroelectric Reach. The expansion of habitat opportunities will allow maximum expression of life-history variation and the restoration of an additional population of spring-run Chinook salmon population to strengthen resiliency in the Klamath Basin, particularly because passage upstream of Iron Gate Dam will provide access to thermal refugia at groundwater areas (Hamilton et al. 2011). Stress to migrating adults and juveniles associated with potential interim seasonal trap and haul operation and poor reservoir water quality would likely be minor. As described below, predation could result in some mortality of spring-run Chinook salmon juveniles passing through the reservoirs. Based on the reservoir dynamics and the predator population that currently occurs, predation of outmigrating salmonids above Iron Gate Dam is anticipated to be low (Administrative Law Judge 2006). In restoration efforts elsewhere in the Pacific Northwest anadromous juveniles successfully pass through reservoirs under similarly difficult circumstances (Administrative Law Judge 2006). Cooler water temperatures (similar to existing conditions) during the spring would continue to benefit upstream migrating adult and downstream migrant juvenile spring-run Chinook salmon. Warmer water temperatures in the fall would continue to be detrimental to juveniles and adults migrating at that time. These effects would be most pronounced for fish migrating through areas upstream of the Scott River.

This alternative would result in continuation of some the stresses that currently affect Chinook salmon populations. The presence of J.C. Boyle, Copco 1, Copco 2, and Iron Gate Dams under the Fish Passage at Four Dams Alternative would continue to cause seasonally poor water quality, and high late summer and early fall water temperatures, allowing some conditions favorable for the transmission of disease for salmon to persist. These conditions would continue to have negative short- and long-term impacts on spring-run Chinook salmon populations. Further, under the Fish Passage at Four Dams Alternative, the KBRA would not be implemented, so any potential habitat improvements from KBRA restoration projects would not be realized. However, ongoing restoration activities will continue to occur. Climate change could also increase the frequency and duration of stressful water temperatures for salmonids under the Fish Passage at Four Dams Alternative. It is anticipated that as a result of the Fish Passage at Four Dams Alternative the spring-run Chinook salmon population within the Klamath River

watershed would have an increase in abundance, population spatial structure, and genetic diversity. In addition, with large scale hydraulic mining operations now outlawed, spring-run Chinook salmon would no longer be subject to one of their most significant threats in the Klamath River (as discussed above in the subsection of Section 3.3.3.1.1). Current improved fisheries management also minimizes overharvest. However, smolts produced from the Salmon River and tributaries downstream from Iron Gate Dam would experience a continuation of existing effects. **Based on increased habitat availability the effect of the Fish Passage at Four Dams Alternative would be beneficial for spring-run Chinook salmon in the short- and long term.**

Coho Salmon

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Hamilton et al. (2005) states that historically coho salmon occurred at least as far as Spencer Creek (J.C. Boyle Reservoir). The Fish Passage at Four Dams Alternative may not affect coho salmon in the Upper Klamath Basin upstream of J.C. Boyle Reservoir Reach.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Coho salmon downstream from Iron Gate Dam belonging to the Upper Klamath River Population Unit would migrate above the dam if access was provided by fishways (Administrative Law Judge 2006). Over time, access to habitat above Iron Gate Dam would benefit the Upper Klamath River Population Unit by: a) extending the range and distribution of the species thereby increasing the coho salmon's reproductive potential; b) increase genetic diversity in the coho stocks; c) reduce the species vulnerability to the impacts of degradation; and d) increase the abundance of the coho salmon population (Administrative Law Judge 2006). Implementation of the Fish Passage at Four Dams Alternative would restore Upper Klamath River Population Unit access to the Hydroelectric Reach, thereby expanding their distribution to include historical habitat along the mainstem Klamath River not inundated by reservoirs and all tributaries upstream at least as far as Spencer Creek, including Jenny, Shovel, and Fall creeks (Hamilton et al. 2005). Passage through the reach would provide approximately 54 miles of additional habitat along the mainstem and within accessible tributaries, based on access to 58 miles of anadromous fish (steelhead) habitat (Administrative Law Judge 2006),¹⁰ taking into account the restricted distribution of coho salmon (DOI 2007), habitat in the bypass reaches, and the continuation of around 22 miles of spawning and rearing habitat inundated by Klamath Hydroelectric Project reservoirs (Cunanan 2009). Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through reduced (but not eliminated) peaking operations and increasing base flows. Under this alternative, the expected overall higher flow releases would result in more reservoir water entering the J.C. Boyle Bypass Reach and correspondingly warmer water temperatures during summer and early fall, and cooler temperatures in late fall and winter. These effects would be similar to those under the Proposed Action and would move this short reach away from consistently cooler water temperatures during summer and early fall months; however, upstream passage would

¹⁰ This also takes into consideration slight differences in the Administrative Law Judge (2006) definition of the Project Reach from what is used in this report.

provide fish with some refuge from high temperatures because of access to cooler water from tributaries, in addition to the 200 to 250 cfs provided by coldwater springs in the J.C. Boyle Bypass Reach (DOI 2007; FERC 2007; Hamilton et al. 2011).

Under this alternative, suspended and bedload sediment, water quality, and the occurrence of algal toxins would be the same as under existing conditions.

This alternative would result in continuation of some of the stresses that currently affect coho salmon populations. The presence of J. C. Boyle, Copco 1, Copco 2, and Iron Gate Dams under the Fish Passage at Four Dams Alternative would continue to cause seasonally poor water quality, and high late summer and early fall water temperatures, allowing some conditions favorable for the transmission of fish disease to persist. Although water temperature in the summer above Iron Gate Dam is an issue, the available information shows that water temperature would not preclude coho salmon from successfully utilizing the habitat within the Project area (Administrative Law Judge 2006). Adult coho salmon enter the Klamath River between late September and mid-December, with peak upstream migration occurring between late October and mid-November, and fry outmigrate to the ocean beginning in late February, with most outmigration occurring in April and May, as such, poor water quality in reservoirs would have minor effect on this species.

Lower Klamath River: Downstream from Iron Gate Dam Under the Fish Passage at Four Dams Alternative, suspended sediment would be the same as under existing conditions, thus having no suspended sediment effects relative to existing conditions for any aquatic species. Klamath Hydroelectric Project dams would continue to trap fine and coarse sediment. The channel directly downstream from Iron Gate Dam would continue to be starved of fine sediment, but the effect would gradually decrease in the downstream direction as coarse sediment would be resupplied by tributary inputs (Hetrick et al. 2009; Stillwater Sciences 2010a). Most spawning and rearing takes place within tributaries. But for the few coho salmon from the Upper Klamath River Population Unit that spawn in the mainstem, coarsening of the bed could reduce spawning habitat for coho salmon between Iron Gate Dam and Cottonwood Creek over time. Rearing habitat would be expected to remain similar to existing conditions.

Under the Fish Passage at Four Dams Alternative, the Lower Klamath River downstream from Iron Gate Dam would continue to have seasonally poor water quality because of the continued presence of the reservoirs, with their increased hydraulic residence time and thermal mass (Bartholow et al. 2005).

As described above, the incidence of fish disease for coho salmon would be reduced under the Fish Passage at Four Dams Alternative relative to existing conditions. Dissolved oxygen concentrations during August-October immediately downstream from Iron Gate Dam would continue to be low (less than 85 percent saturation during August-September and 90 percent saturation from October-November (see the subsection of Section 3.2.4.3.1, Lower Klamath River). In addition, the presence of microcystin,

associated with the dense blooms of *M. aeruginosa* in Iron Gate and Copco Reservoirs, would continue to occur downstream from Iron Gate Dam.

Estuary

The Fish Passage at Four Dams Alternative is not expected to substantially change or affect coho salmon estuarine habitat relative to existing conditions.

Summary: Coho Salmon

Under this alternative, fishways at Four Dams could result in alterations in habitat availability which could affect coho salmon in the long term. Under the Fish Passage at Four Dams Alternative, coho salmon would regain access to mainstem and tributary habitat in the Hydroelectric Reach, and thermal refugia within the Hydroelectric Reach. Stress to migrating adults and juveniles associated with poor reservoir water quality and predation (as described below) would occur, but would likely be minor. Based on the reservoir dynamics and the predator population that currently occurs, predation of outmigrating salmonids above Iron Gate Dam is anticipated to be low (Administrative Law Judge 2006). In restoration efforts elsewhere in the Pacific Northwest, coho salmon and other anadromous juveniles successfully pass through reservoirs under similarly difficult circumstances (Administrative Law Judge 2006).

The presence of dams under the Fish Passage at Four Dams Alternative would continue to cause seasonally poor water quality, and high late summer and early fall water temperatures, allowing some conditions favorable for the transmission of fish disease to persist. These conditions would continue to have negative short- and long-term impacts on coho salmon populations. Further, under the Fish Passage at Four Dams Alternative, the KBRA would not be implemented, so any potential habitat improvements from KBRA restoration projects would not be realized. However, ongoing restoration activities will continue to occur. Climate change could also increase the frequency and duration of stressful water temperatures for salmonids under the Fish Passage at Four Dams Alternative. It is anticipated that as a result of the Fish Passage at Four Dams Alternative the Upper Klamath River Population Unit would have an increase in abundance, population spatial structure, and genetic diversity. It is also anticipated that as a result of the Fish Passage at Four Dams Alternative the Mid-Klamath River, Shasta River, Scott River, Salmon River population units would experience a continuation of existing effects, and the three Trinity River population units, and the Lower Klamath River population units would not be affected. **Based on increased habitat availability the effect of the Fish Passage at Four Dams Alternative would be beneficial for coho salmon from the Upper Klamath River population unit in the short- and long term. Based on the continuation of existing conditions for populations downstream from Iron Gate Dam, this alternative would be no change from existing conditions for the coho salmon from the Mid-Klamath River, Shasta River, Scott River, and Salmon River, three Trinity River population units, and the Lower Klamath River population units in the short- and long term.**

Steelhead

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the Fish Passage at Four Dams Alternative, steelhead would regain access to the Upper Klamath Basin upstream of J.C. Boyle Reservoir. This would expand the population's distribution to include historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005,). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising 360 miles of additional potentially productive habitat (Huntington 2006; DOI 2007; NOAA Fisheries Service 2007). This alternative would not result in changes to suspended or bedload sediment, flow-related habitat, or algal toxins. Facilitating the movement of anadromous fish via prescribed fishways presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006). Poor water quality (e.g., severe hypoxia, temperatures exceeding 25°C, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009; USGS 2010; both as cited in Hamilton et al. 2011).

Poor water quality conditions, particularly in Lake Ewauna during the late spring and early summer could be detrimental to fish in this area, particularly anadromous salmonids (FERC 2007). Therefore, the Fish Passage at Four Dams Alternative includes interim seasonal trap and haul to capture and transport migrant fish (primarily adult fall-run Chinook salmon) around the Keno Impoundment/Lake Ewauna when water quality conditions would be prohibitively stressful.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Fish Passage at Four Dams would provide steelhead with access to the Hydroelectric Reach, which would expand the population's distribution to include historical habitat in the mainstem Klamath River and its tributaries, including Jenny, Spencer, Shovel, and Fall creeks (Hamilton et al. 2005). Passage through the reach would provide approximately 59 miles of additional habitat along the mainstem and within accessible tributaries (Administrative Law Judge 2006), taking into account habitat in the bypass reaches, and the continuation of around 22 miles of spawning and rearing habitat inundated by Klamath Hydroelectric Project reservoirs (Cunanan 2009). Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through reduced (but not eliminated) peaking operations and increasing base flows, consistent with mandatory conditions (DOI 2007). Under this Alternative, the expected overall higher flow releases would result in more reservoir water entering the J. C. Boyle Bypass Reach and correspondingly warmer water temperatures during summer and early fall, and cooler water temperatures in late fall and winter. These effects would be similar to those under the Proposed Action and would move this short reach away from consistently cooler water temperatures during summer and early fall months.

Poor water quality conditions in reservoirs, such as high temperatures with low dissolved oxygen, fluctuations in dissolved oxygen, pH, ammonia associated with algal blooms, and microcystin from *M. aeruginosa* blooms would continue to be stressful to fish from

June through September (Dunsmoor and Huntington 2006; FERC 2007). Winter steelhead enter and migrate from August to March; thus, poor water quality could have an effect on these fish as they move through reservoirs. Steelhead spawn in tributaries, and juveniles typically outmigrate from April through November, but the peak occurs from April through June, so most individuals would be likely to avoid poor reservoir water quality.

Lower Klamath River: Downstream from Iron Gate Dam Under the Fish Passage at Four Dams Alternative, suspended sediment dynamics would be the same as under existing conditions, thus having no suspended sediment effects relative to existing conditions for any aquatic species. Klamath Hydroelectric Project dams would continue to trap fine and coarse sediment. The channel directly downstream from Iron Gate Dam would continue to be starved of fine sediment, but the effect would gradually decrease in the downstream direction as coarse sediment would be resupplied by tributary inputs (Hetrick et al. 2009; Stillwater Sciences 2010a). Current summer steelhead distribution extends from the mouth of the Klamath River upstream to Empire Creek, while winter steelhead are distributed throughout the Lower Klamath River up to Iron Gate Dam (Stillwater Sciences 2010b). Summer and winter steelhead do not spawn in the mainstem Klamath River, nor are they expected to in the future, so spawning habitat would not be affected by alterations to bedload composition downstream from Iron Gate Dam under the Fish Passage at Four Dams Alternative. Changes to bedload sediment would not be expected to affect juvenile rearing and migration.

Under the Fish Passage at Four Dams Alternative, the Lower Klamath River downstream from Iron Gate Dam Reach would continue to have seasonally poor water quality because of the continued presence of the reservoirs, with their increased hydraulic residence time and thermal mass (Bartholow et al. 2005). Dissolved oxygen concentrations during August-October immediately downstream from Iron Gate Dam would continue to be low (less than 85 percent saturation during August-September and 90 percent saturation from October-November (see the subsection of Section 3.2.4.3.1, Lower Klamath River). In addition, the presence of microcystin, associated with the dense blooms of *M. aeruginosa* in Iron Gate and Copco Reservoirs, would continue to occur downstream from Iron Gate Dam.

Estuary

The Fish Passage at Four Dams Alternative is not expected to substantially change or affect steelhead estuarine habitat relative to existing conditions.

Summary: Steelhead

Under this alternative, fishways at Four Dams could result in alterations in habitat availability which could affect steelhead in the long term. Under the Fish Passage at Four Dams Alternative, steelhead would regain access to mainstem and tributary habitat in the Hydroelectric Reach, and thermal refugia within the Hydroelectric Reach. Stress to migrating adults and juveniles associated with seasonally poor reservoir water quality would likely be minor. Survival during migration through reservoirs could be negatively affected at some level by predation.

This alternative would result in continuation of some the stresses that currently affect steelhead populations. The presence of dams under the Fish Passage at Four Dams Alternative would continue to cause seasonally poor water quality, and high late summer and early fall water temperatures. These conditions would continue to have negative short- and long-term impacts on steelhead populations. Further, under the Fish Passage at Four Dams Alternative, the KBRA would not be implemented, so any potential habitat improvements from KBRA restoration projects would not be realized. However, ongoing restoration activities will continue to occur. Climate change could also increase the frequency and duration of stressful water temperatures for salmonids under the Fish Passage at Four Dams Alternative. FERC (FERC 2007) concluded that implementing fish passage would help to reduce adverse effects to steelhead associated with lost access to upstream spawning habitats. Hamilton et al. (2011) also concluded that access to additional habitat in the Upper Klamath River watershed would benefit steelhead runs. It is anticipated that as a result of the Fish Passage at Four Dams Alternative the summer and winter steelhead within the Klamath River watershed would have an increase in abundance, population spatial structure, and genetic diversity. **Based on increased habitat availability, the Fish Passage at Four Dams Alternative would be beneficial for summer and winter steelhead in the short- and long term.**

Pacific Lamprey

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Pacific lamprey occurred historically at least to Spencer Creek (Hamilton et al. 2005) although there is some uncertainty in this regard (Administrative Law Judge 2006). Pacific lamprey below Iron Gate dam would migrate above the dam if access was provided through fishways (Administrative Law Judge (2006). They may not have historically occurred upstream of J.C. Boyle Reservoir (Administrative Law Judge 2006), and may not occupy this reach after implementation of this alternative.

Hydroelectric Reach: from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

The Fish Passage at Four Dams Alternative would provide Pacific lamprey with access to habitat upstream of Iron Gate Dam, which would benefit lamprey by providing them with additional spawning and rearing habitat (Administrative Law Judge 2006). Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through reduced (but not eliminated) peaking operations and increasing base flows. In addition, passage would provide fish with some refuge from high temperatures by allowing cooler tributaries to flow directly into the mainstem Klamath River, adding to the 200 to 250 cfs provided by coldwater springs in the J.C. Boyle Bypass Reach (DOI 2007; FERC 2007; Hamilton et al. 2011). Under this alternative, suspended and bedload sediment, water quality, water temperature, and the occurrence of algal toxins would continue to be the same as under existing conditions.

Poor water quality conditions in reservoirs, such as high temperatures with low dissolved oxygen, changes in dissolved oxygen, pH, and ammonia associated with algal blooms, and microcystin from *M. aeruginosa* blooms would continue to be stressful from June to September (Dunsmoor and Huntington 2006; FERC 2007). Pacific lamprey adults migrate from winter through spring, while juveniles (age 2 to age 10) outmigrate year-

round, with peaks during late spring and fall. Seasonally poor reservoir quality would likely not affect migrating adults, but could affect juveniles. Juveniles would be subject to some level of predation by introduced resident species including largemouth bass, catfish, and yellow perch (FERC 2007). Volitional passage for Pacific lamprey has been designed and is in place in other river systems (Administrative Law Judge 2006).

Lower Klamath River: Downstream from Iron Gate Dam Under the Fish Passage at Four Dams Alternative, Klamath Hydroelectric Project Dams would continue to trap fine and coarse sediment. Suspended sediment would be the same as under existing conditions, thus having no suspended sediment effects relative to existing conditions for any aquatic species. The channel directly downstream from Iron Gate Dam would continue to be starved of fine sediment. Coarsening of the bed could reduce spawning habitat for lamprey downstream from the dam over time, but this impact would be limited to the area upstream of Cottonwood Creek, as coarse sediment was resupplied by tributary inputs (Hetrick et al. 2009; Stillwater Sciences 2010a).

Under the Fish Passage at Four Dams Alternative, the Lower Klamath River downstream from Iron Gate Dam reach would continue to have seasonally poor water quality. Water quality would continue to be influenced by reservoirs, with increased hydraulic residence time and thermal mass (Bartholow et al. 2005). Finally, the KBRA would not be implemented, so any potential habitat improvements from KBRA restoration projects would not be realized. However, ongoing restoration activities will continue to occur.

Estuary

The Fish Passage at Four Dams Alternative is not expected to substantially change or affect Pacific Lamprey estuarine habitat relative to existing conditions.

Summary: Pacific Lamprey

Under this alternative, fishways could result in alterations in habitat availability which could affect Pacific lamprey in the long term. Under the Fish Passage at Four Dams Alternative, lamprey would regain access to mainstem and tributary habitat in the Hydroelectric Reach, and thermal refugia within the Hydroelectric Reach. Seasonally poor reservoir quality would likely not affect migrating adults, but could affect juveniles. Juveniles would also be exposed to predation from nonnative resident fish.

This alternative would result in continuation of some the stresses that currently affect lamprey populations. The presence of dams under the Fish Passage at Four Dams Alternative would continue to cause seasonally poor water quality and high late summer and early fall water temperatures. Climate change could also increase the frequency and duration of stressful water temperatures for lamprey under the Fish Passage at Four Dams Alternative. It is anticipated that as a result of the Fish Passage at Four Dams Alternative the Pacific lamprey population within the Klamath River watershed would have an increase in abundance, population spatial structure, and genetic diversity (Administrative Law Judge 2006). However, lamprey downstream from Iron Gate Dam would experience a continuation of existing effects. **Based**

on increased habitat availability, the Fish Passage at Four Dams Alternative would be beneficial for Pacific lamprey in the short- and long term.

Green Sturgeon

Under this alternative, fishways at Four Dams could result in alterations in habitat availability which could affect green sturgeon in the long term. Under the Fish Passage at Four Dams Alternative, conditions in the area occupied by green sturgeon are unlikely to change relative to existing conditions as green sturgeon occur downstream from Ishi Pishi Falls, and the effects of this alternative are not anticipated to extend that far downstream.

It is anticipated that as a result of the Fish Passage at Four Dams Alternative the green sturgeon population within the Klamath River watershed would experience a continuation of existing effects. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for green sturgeon in the short- and long term.**

Shortnose and Lost River Sucker

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir The KBRA would not be implemented under this alternative. However, ongoing restoration activities will continue to occur.

Hydroelectric Reach: from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

Construction of fishways could affect shortnose and Lost River Sucker populations by continuing poor water quality and high rates of predation. Shortnose and Lost River suckers would continue to be subject to seasonally poor water quality and high rates of predation within reservoirs. But with little or no successful reproduction (Buettner et al. 2006), populations downstream from Keno Dam contribute minimally to conservation goals and insignificantly to recovery (Hamilton et al. 2011). Fish passage was not prescribed for sucker species at Iron Gate, J.C. Boyle, Copco 1, or Copco 2 Dams.

Under the Fish Passage at Four Dams Alternative, existing efforts to restore habitat for shortnose and Lost River sucker and improve water quality conditions would continue. These actions would be expected to improve conditions for these species over time and their populations would be expected to increase. **The effect of the Fish Passage at Four Dams Alternative would be less-than-significant for Lost River and shortnose sucker populations in the short and long term.**

Redband Trout

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the Fish Passage at Four Dams Alternative, redband trout would be able to migrate more successfully from the Hydroelectric Reach to the Upper Klamath Basin (Hamilton et al. 2011) than under existing conditions. Fish passage facilities would improve connectivity to Spencer Creek, which provides important spawning habitat and temperature refugia for redband trout (DOI 2007; Buchanan et al. 2011a). Upstream fish passage would also restore connectivity of resident redband populations in the mainstem Klamath River to those in Lake Ewauna, the Link River, and Upper Klamath Lake (DOI 2007). The Fish

Passage at Four Dams Alternative is not expected to result in changes to suspended or bedload sediment, flow-related habitat, or algal toxins and disease.

Redband could be affected by the reintroduction of anadromous fish, including the potential for competition, predation, and exposure to disease, as described for the Proposed Action above.

Hydroelectric Reach: from Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

Fish passage resulting from the Fish Passage at Four Dams Alternative would allow redband trout to express the seasonal movements and migration patterns that were historically in place, restore population connectivity and genetic diversity, and allow greater utilization of existing habitat and refugia. Effective fishways at J.C. Boyle would greatly improve connectivity to Spencer Creek. Fish passage at Copco 1 and Copco 2 Dams would restore connectivity throughout the Hydroelectric Reach to Shovel Creek, which provides spawning habitat and temperature refugia (DOI 2007). Passage at Iron Gate Dam would restore connectivity between populations in the mainstem Klamath River and those in the Copco 2 bypass channel and in Slide, Scotch, Camp, Jenny, Salt, and Fall Creeks, which also provide spawning habitat and temperature refugia (DOI 2007). The current fish screen and ladder at the J.C. Boyle Dam do not meet current State and Federal fish passage criteria and the ladder impairs upstream migration (Administrative Law Judge 2006). Improvements in efficiency to the fishway at J.C. Boyle Dam would result in significant trout population migration above the dam over time (Administrative Law Judge 2006). Habitat in the J.C. Boyle bypass and peaking reaches and the Copco 2 Bypass Reach would be improved through reduced (but not eliminated) peaking operations and increasing base flows.

Populations of nonnative species within the reservoirs of the Hydroelectric Reach would continue to prey on smaller redband trout rearing in those reservoirs at some level. Water quality would continue to be seasonally poor, although TMDL implementation would improve water quality conditions from existing conditions throughout the Basin through time, benefiting this species. Climate change would result in warmer conditions, which would reduce the suitability of habitat.

Summary: Redband Trout

Under this alternative, fishways at Four Dams and changes in operations could result in alterations in habitat availability and suitability which could affect redband trout in the long term. The Fish Passage at Four Dams Alternative would improve habitat connectivity throughout the Hydroelectric Reach and to the upper Klamath River in the long term, increasing access to spawning habitat and temperature refugia. Redband trout would still be subject to seasonally poor water quality, and some level of predation within the reservoirs, but increases in connectivity and reduced effects of hydropower peaking operations would likely provide a benefit to redband trout populations. **Based on increased habitat connectivity, the effect of the Fish Passage at Four Dams Alternative would be beneficial for redband trout in the short- and long term.**

Bull Trout

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Effects to bull trout under this alternative are the same as those discussed in the subsection of Section 3.3.4.3.2, Alternative 2, Species Specific Impacts.

Fishways at Four Dams could alter habitat access for anadromous fish, which could affect bull trout. Based on the restricted distribution of bull trout, the Fish Passage at Four Dams Alternative would have a less-than-significant impact on bull trout in the short- and long term.

Eulachon Under the Fish Passage at Four Dams Alternative, the extent and quality of eulachon habitat would be expected to remain similar to that under existing conditions. Because eulachon occur far downstream in the river, mixing and inflows from intervening tributaries would reduce seasonally poor water quality conditions originating in the dams. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for eulachon in the short and long term.**

Longfin Smelt Under the Fish Passage at Four Dams Alternative, the extent and quality of longfin smelt habitat would be expected to remain similar to that under existing conditions. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for longfin smelt in the short and long term.**

Introduced Resident Species *The Fish Passage at Four Dams Alternative would not affect introduced resident species upstream of J.C. Boyle Reservoir.* Under the Fish Passage at Four Dams Alternative, dams in the Hydroelectric Reach would not be removed, allowing reservoir habitat to remain similar to existing conditions. Connectivity between the reservoirs could increase available habitat area for these species if they are able to migrate through passage facilities. Over time the total volume of habitat would diminish, as sediment accumulates in the reservoirs. TMDL implementation would be expected to improve water quality conditions over time, but climate change would cause temperatures to increase. These species are adapted to warm-water conditions, and are not expected to be affected by these changes. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for introduced resident species population.**

Interactions Among Species The Fish Passage at Four Dams Alternative would restore access for anadromous salmon, lamprey, and steelhead to habitat upstream of Iron Gate Dam, as described in detail above. Restoration of access will result in anadromous salmon and steelhead potentially interacting with resident redband trout and bull trout. Juvenile salmonids and lamprey traveling through the four hydroelectric reservoirs would be exposed to some level of predation by introduced resident fish including largemouth bass, catfish, and yellow perch, resulting in mortality rates that would depend largely on their size (larger migrants would do better) (Administrative Law Judge 2006). Based on the reservoir dynamics and the predator population that currently occurs, predation of outmigrating salmonids above Iron Gate Dam is anticipated to be low (Administrative Law Judge 2006). In restoration efforts elsewhere in the Pacific Northwest, anadromous

juveniles successfully pass through reservoirs under similarly difficult circumstances (Administrative Law Judge 2006). Other interactions among species under the Fish Passage at Four Dams Alternative would be the same as described for the Proposed Action.

Freshwater Mussels *Under the Fish Passage at Four Dams Alternative, suspended sediment would be the same as under existing conditions, thus having no suspended sediment effects relative to existing conditions for any aquatic species. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for mussels in the short and long term.***

Benthic Macroinvertebrates Under the Fish Passage at Four Dams Alternative, Klamath Hydroelectric Project peaking operations (although reduced in frequency) in the hydroelectric reach would continue (although less frequently) to kill, through stranding, large numbers of young fish and aquatic invertebrates that are the primary prey food for resident trout (Administrative Law Judge 2006). Suspended sediment would also be the same as under existing conditions, thus having no suspended sediment effects relative to existing conditions for benthic macroinvertebrates.

*Under the Fish Passage at Four Dams Alternative, habitat conditions would be the same as under existing conditions. **The effect of the Fish Passage at Four Dams Alternative would be no change from existing conditions for macroinvertebrates in the short and long term.***

Trap and Haul – Programmatic Measure

Implementation of trap and haul measures could affect aquatic species. Trap and haul measures would pass upstream and downstream migrating fish around Keno Impoundment and Link River during periods of seasonally poor water quality. The measures would provide effective migration for primarily fall-run Chinook salmon when water quality is poor during the period from June 15 to November 15. During the limited period of use, fish collection and release facilities would be operated to minimize any delay and stress and provide for adequate acclimation. For adult fall-run Chinook salmon, fish transport would be an effective fish passage method because transport would be for a short distance on a seasonal, interim basis.¹¹ For adult fall-run Chinook salmon, seasonal collection and transport mortality when water quality is poor is likely to be minor compared to mortality associated with unaided passage through areas of poor water quality at this time of year.

In some instances, the collection and transport of fall-run Chinook salmon around Keno Impoundment/Lake Ewauna could result in limited, seasonal mortality as follows:

¹¹ This seasonal, transport on an interim basis is not to be confused with permanent, year round trap and haul which does not provide equal benefits for the Klamath River when compared with the Services' fishway prescriptions (U.S. Department of the Interior (2007) The Department of the Interior's Filing of Modified Terms, Conditions, and Prescriptions (Klamath Hydroelectric Project, No. 2082). Sacramento, California: 650 p.; NOAA Fisheries Service (2007). NOAA Fisheries Service Modified Prescriptions for Fishways and Alternatives Analysis for the Klamath Hydroelectric Project (FERC Project No. 2082): 151 p.).

1. Some juvenile federally listed suckers would likely be collected incidentally and may suffer related stress and mortality. However, regardless of any remediation at an upstream collection facility, nearly all these downstream migrant suckers would eventually die in the absence of lacustrine habitat below Keno Impoundment/Lake Ewauna. There is little to no evidence of recruitment of suckers in downstream reservoirs currently and this habitat does not contribute significantly to the recovery of the species. Suckers may be collected and returned to habitat above Keno Impoundment/Lake Ewauna.
2. Some redband trout may be collected incidentally resulting in displacement and incidental collection-related stress and mortality. Redband trout may be collected and returned to habitat above Keno Impoundment/Lake Ewauna.
3. For fall-run Chinook salmon emigrants, the seasonally poor quality conditions are not expected to overlap with the peak migration period, thus the majority of juvenile Chinook salmon would not be affected. For those fall-run Chinook salmon emigrants collected and transported when water quality is poor, transport related mortality would be minor compared to the mortality associated with unaided passage through areas of poor water quality at this time of year.
4. For steelhead trout and spring-run Chinook salmon, migration would primarily be expected to occur when water quality was adequate, thus, collection and transport of these fish would not be necessary or minimal. However, all anadromous salmonids would be collected and transported when water quality is poor during the period from June 15 through November 15. Transport related mortality would be minor compared to the mortality associated with unaided passage through areas of poor water quality at this time of year.

Limited, seasonal transport of fall-run Chinook salmon would provide a net benefit by allowing them migration to and from additional (historical) spawning habitat, by providing more effective migration, and by reducing the density of spawners below Keno Dam in certain poor water quality situations.

In the short term, constructing fish handling facilities could have localized construction-related impacts; however, they could be avoided or minimized through implementation of best management practices, such as control and containment of sediment and toxic discharge, isolation of work areas from the active channel of streams or rivers where possible, and rescuing fish where mortality may result from an action. In the long term, trap and haul would benefit fish because of the access to additional habitat and avoidance of areas with seasonally poor water quality. **Based on access to additional, historical habitat and the anticipated improvements in fish health, implementation of trap and haul measures in the Fish Passage at Four Dams Alternative would be beneficial for fall-run Chinook salmon.**

3.3.4.3.5 Alternative 5: Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative proposes to remove the two largest dams in the Hydroelectric Reach (Copco 1 and Iron Gate Dams) and install fishways for volitional fish passage on the remaining installations (J.C. Boyle and Copco 2). The prescriptions and conditions would still apply to the remaining dams, including flow requirements, the specific provisions and performance standards for both upstream and downstream fish passage facilities at the remaining dams, and the interim seasonal trap and haul trap actions at Keno Dam as described above under the Fish Passage at Four Dams Alternative. Because the four dams would not be removed as required under the KHSRA, the KBRA would not be implemented. The ongoing restoration actions described in the No Action/No Project Alternative would continue. Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, peaking power would not be generated due to limits on flow regulation at J.C. Boyle and Copco 2 Reservoirs. Similar to the Fish Passage at Four Dams Alternative, 40 percent of the inflow to J.C. Boyle Reservoir would be passed through to the Bypass Reach, except in periods when inflow to J.C. Boyle Reservoir falls below 470 cfs, at which point outflow to the Bypass Reach is required to equal reservoir inflow.

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, Iron Gate Hatchery would be operated to meet existing mitigation requirements until Iron Gate Dam is removed, after which time the disposition of the hatchery would be determined by the DFG in consultation with NOAA Fisheries Service, the USFWS and other Klamath River fish managers, in response to fish population monitoring trends. Funding for continued hatchery operations would need to be identified.

Key Ecological Attributes

Suspended Sediment

Under this alternative, SSCs have not been modeled, but would be very similar to those described with the removal of all four facilities under the Proposed Action (see Section 3.3.4.3.2.1.1), because most stored sediment affecting downstream resources is stored in Copco 1 and Iron Gate Reservoirs. Therefore, this alternative would have very similar effects on aquatic species associated with suspended sediment transport as the Proposed Action.

Bedload Sediment

Under this alternative, J.C. Boyle Dam would continue to store sediment, but the storage capacity of Copco 2 Dam would likely be filled by the release of sediments during the Copco 1 Dam removal, and then bedload would likely pass through Copco 2. This scenario has not been modeled, but the effects of bedload sediment movement under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be similar to, but of slightly lesser magnitude, than under the Proposed Action.

Water Quality

Under this alternative, the effects on water quality would have results intermediate between the Proposed Action and Fish Passage at Four Dams Alternatives. As Copco 1 and Iron Gate Reservoirs are the largest of the four reservoirs, they have the greatest impact on water quality (FERC 2007), and their removal would result in water quality conditions similar to those of the Proposed Action. Because of their small size and short residence times, the retention of J.C. Boyle and Copco 2 Dams would not result in the same poor water quality conditions that occur under current conditions.

Since Alternative 5 would include no peaking power generation or release of flow for recreation at J.C. Boyle, water temperature effects in the J.C. Boyle Bypass Reach would be similar to those under the Fish Passage at Four Dams Alternative because the Fish Passage at Four Dams Alternative also keeps J.C. Boyle Reservoir in place and includes significantly increased flow releases over the No Action/No Project Alternative, approaching the flow conditions for this alternative (i.e., no peaking power generation or release of recreation flows). Thus, the effects would be continued low diel temperature variation and overall warmer water temperatures in the Bypass Reach during summer and early fall, and cooler temperatures in late fall and winter. In the Peaking Reach, water temperature effects would be the same as under the Proposed Action (i.e., slightly lower maximum water temperatures and less artificial diel temperature variation during summer and early fall) since no peaking flows would occur and the effect of J.C. Boyle thermal mass on water temperatures does not extend this far downstream.

In the Hydroelectric Reach, the effects of removing Iron Gate and Copco 1 Reservoirs and converting the reservoir areas to a free-flowing river under this alternative would be similar to effects for the lower Klamath River immediately downstream from Iron Gate Dam under the Proposed Action (i.e., long-term increases in spring water temperatures and decreases in late summer/fall water temperatures) (see Section 3.2.4.3.5).

Fish Disease and Parasites

Under this alternative, there would be fewer deleterious effects in terms of fish disease as compared to existing conditions. Although it would not result in the same level of reduction in fish disease as the Proposed Action, removal of Iron Gate and Copco 1 Dams would result in water quality improvements and would reduce favorable habitat for polychaete worms downstream from Iron Gate Dam. The removal of the two dams would likely increase the availability of nutrients and physical habitat (i.e., periphyton mats) favorable to the polychaete host for *C. shasta* and *P. minibicornis* in the Hydroelectric Reach and downstream from Iron Gate Dam, although to a slightly lesser extent than under the Proposed Action because J.C. Boyle Dam would not be removed. Flow variability and scouring in the Hydroelectric Reach and downstream from Iron Gate Dam will be increased as described for the Proposed Action, with the exception of downstream from J.C. Boyle Dam where peaking flows will be eliminated. Removal of the two dams would likely result in more favorable water temperature for salmonids than under existing conditions as well as improve water quality and reduce instances of algal toxins (see Section 3.2.4.3.5).

Under this alternative, spawning fish would be expected to disperse more fully throughout the watershed than under existing conditions. Fish passage upstream by anadromous salmonids would increase under this alternative, which could reduce the concentration of salmon using the area immediately downstream from Iron Gate Dam for spawning, potentially reducing the transfer of myxospores from fish to the polychaete hosts. FERC's analysis concluded that restoring access to reaches above Iron Gate Dam for anadromous fish would allow adult fall-run Chinook salmon to distribute over a greater length of the river, reducing crowding and the concentration of disease pathogens that currently occur in the reach between Iron Gate Dam and the Shasta River (FERC 2007).

Provision of fish passage would allow anadromous salmonid migration to move upstream in the mainstem Klamath River and tributaries. Available information indicates that fish passage would not increase the risk of disease for resident species that occur upstream of Iron Gate Dam (Administrative Law Judge 2006). *C. shasta* and *P. minibicornis* exist throughout the Klamath River System in both the Upper and Lower Basins, so migration of wild anadromous fish upstream of downstream from Iron Gate Dam would not increase the risk of introducing pathogens to resident trout residing above Iron Gate Dam (Administrative Law Judge 2006). In addition, native Klamath River trout are generally resistant to *C. shasta*. The remaining known pathogens do not impact non-salmonids, with the exception of *F. columnaris* and *Ich*.

Recently several new *C. shasta* genotypes have been discovered in the Klamath River. In this regard, risk is related to host specificity, which appears to exist at least to some degree (Atkinson and Bartholomew 2010). As an example, redband trout are thought to be susceptible to Type 0, which already occurs in the upstream Basin and Chinook salmon are susceptible to Type I, which occurs in the Lower Klamath Basin. Type 0 genotype occurs in low densities and it is not very virulent (infection results in low or no mortality); if Type I genotype were to be reintroduced above Iron Gate Dam, it would affect only Chinook salmon. It is not expected that introduction of *C. shasta* genotypes upstream would be deleterious because fish in the upstream Basin have shown resistance to the downstream genotypes. Redband trout would presumably have been exposed to genotypes of *C. shasta* during the pre-dam period, and their populations were abundant. Because the salmonid species in the Klamath Basin already co-occur with the genotype of *C. shasta* to which they are susceptible, and the salmonid species are less susceptible to other genotypes of *C. shasta*, expanding the distribution of the different genotypes of *C. shasta* would be unlikely to be deleterious to salmonids. Recently discovered *C. shasta* genotypes and research findings in the past several years do not appear to contradict the finding that movement of anadromous salmonids into the Upper Klamath Basin presents a relatively low risk of introducing pathogens to resident fish (Administrative Law Judge 2006, USFWS/NOAA Fisheries Service Issue 2(B)).

Available information also indicates that risks associated with movement of anadromous fish upstream of Iron Gate Dam are minimal. For example, steelhead within the Klamath River system are generally resistant to *C. shasta*, (Administrative Law Judge 2006).

Since salmon and associated disease pathogens were present historically above Iron Gate Dam, *C. shasta* genotype movement would be a reintroduction of associated risk to these anadromous species.

While it is possible that the current infections nidus (reach with highest infectivity) for *C. shasta* and *P. minibicornis* may be recreated upstream where salmon spawning congregations occur, and there is associated uncertainty (Foott et al. 2011), the likelihood of this happening appears to be remote for the following reasons. Any creation of an infectious zone (or zones) would be the result of the synergistic effect of numerous factors, such as those that occur within the current disease zone in the Klamath River in the reach from the Shasta River downstream to Seiad Valley (FERC (2007; Bartholomew and Foott 2010). Here, flows in that reach that mimic natural conditions, combined with reestablishment of natural sediment transport rates, would restore natural geomorphic channel forming processes (Hetrick et al. 2009) necessary to create diverse habitat and reduce the influence of those synergistic factors that currently create conditions favorable for disease. Under a dams out alternative, those conditions that are believed to result in development of an infectious nidus below Iron Gate Dam, or a could result in development of a potential infectious nidus above Iron Gate Dam, are unlikely to occur.

Further, the likelihood of those synergistic factors in the Williamson River would be reduced as carcasses would likely be more dispersed in the watershed (Foott et al. 2011), and flow variability will act to reduce polychaete habitat stability above the Williamson River mouth. *C. shasta* in the Williamson River is currently maintained by planting of susceptible rainbow trout that become infected, likely produce myxospores, and die within a restricted reach in the lower Williamson River.

In addition, under a scenario of potential dam removal, it is likely that a greater diversity of salmon life histories will evolve, with some of those types more likely to avoid parasite exposure by migrating earlier or over wintering in tributaries and migrating in the fall (Bartholomew and Foott 2010; p. 40), thus missing the time of year when water temperatures in the Williamson River might possibly be conducive to disease. Although their research was focused on dam removal, access to the habitat above Iron Gate Dam through other means, such as fishways under Alternative 4, would likely have a similar outcome. In some years, maximum temperatures in the Williamson River do not exceed the disease threshold of 15 C (Bartholomew and Foott 2010; Hamilton et al. 2010). The risk of a juvenile salmon disease response here would be lower than the current zone but not negligible in all water years (Foott 2012).

Historically, it appears spawning concentrations of upper basin Chinook salmon took place primarily in the Sprague River (Lane and Lane Associates 1981). There is no information indicating that high densities of polychaetes occur in the Sprague River (Foott et al. 2011). Thus, the synergistic factors that contribute to an infectious nidus for emigrants below Iron Gate Dam and near the Iron Gate Hatchery are unlikely to occur here either. There is some concern regarding a disease zone in the lower Williamson River downstream from the confluence with the Sprague River (Hurst et al. 2012). However, some Chinook emigrants from both these tributaries may very well emerge

from groundwater areas early, then rear in Upper Klamath Lake, with growth opportunities that allow them to migrate when they can minimize exposure to *C. shasta*.

Algal Toxins

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir This region is upstream of any proposed dam removal; therefore, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would not affect fish health as related to algal toxins. Any changes in algal toxin production in this region would be a result of other factors, including TMDL implementation. The effects in this area would be similar to those described for the No Action/No Project Alternative.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would eliminate growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa* in the Hydroelectric Reach, alleviating high seasonal concentrations of algal toxins and associated bioaccumulation of microcystin in fish tissue for species in this reach. While some microcystin may be transported downstream from large blooms occurring in Upper Klamath Lake, the levels would not be as high as those currently experienced due to the prevalence of seasonal in-reservoir blooms. Overall, bioaccumulation of algal toxins in fish tissue would be expected to decrease in the Hydroelectric Reach and would be beneficial.

Lower Klamath River: Downstream from Iron Gate Dam The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would eliminate growth conditions for toxin-producing nuisance algal species such as *M. aeruginosa*, alleviating the transport of high seasonal concentrations of algal toxins to the Klamath River downstream from Iron Gate Dam. This would also decrease the associated bioaccumulation of microcystin in fish and mussel tissue for species downstream from the dam. While some microcystin may be transported downstream from large blooms occurring in Upper Klamath Lake, the levels would not be as high as those currently experienced due to the prevalence of seasonal in-reservoir blooms. Overall, bioaccumulation of algal toxins in fish and mussel tissue would be expected to decrease in the Klamath River downstream from Iron Gate Dam and would be beneficial.

Aquatic Habitat

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, flow increases would provide more habitat than under existing conditions for redband/rainbow trout and other resident riverine species, as well as any anadromous fish or lamprey that reestablish in the Hydroelectric Reach, but habitat gains would be less than under the Proposed Action. The removal of the two dams would eliminate existing habitat in Copco 1 and Iron Gate Reservoirs for adult shortnose and Lost River suckers, as well as nonnative species, while habitat within J.C. Boyle Reservoir would remain. This alternative would restore around 19 miles of riverine habitat (Cunanan 2009) for resident and anadromous fish through removal of reservoirs. The current reservoirs

inundate sections of the river that had high sinuosity and complex channels that historically provided excellent salmonid spawning and rearing habitats (Hetrick et al. 2009).

The alternative would incorporate barriers to prevent juvenile salmonid entrainment into turbines. There would also be substantial changes to hydroelectric operations. J.C. Boyle would no longer generate in peaking mode, and higher flow releases would be made through the J.C. Boyle Bypass Reach than under existing conditions. Higher base flows would also be provided in the Copco 2 Bypass Reach, and ramping rates would be slower than they are currently. These modifications would benefit fish in this reach, including redband trout and anadromous fish. Seasonal high flows will contribute to improving the quality of riparian habitat in the J.C. Boyle bypass reach by increasing the sediment deposit within the channel and decreasing reed canary grass (Administrative Law Judge 2006). The more normative flow regime associated with this alternative would provide these seasonal high flows. As described for the Proposed Action, under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, flow-related habitat changes for species downstream from Iron Gate Dam would increase over existing and historical conditions (Hetrick et al. 2009).

Following drawdown of the reservoirs, revegetation efforts would be initiated to support establishment of native wetland and riparian species on newly exposed reservoir sediment. No short-term effects are anticipated from these reservoir restoration efforts; however, aquatic habitat would likely be improved from restored riparian vegetation in the long term.

Aquatic Resources Effects

Critical Habitat

As described below, reservoir drawdown associated with dam removal under this alternative could alter the quality of critical habitat. In addition, the removal of two dams and two reservoirs could alter the availability and quality of critical habitat.

Coho Salmon The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would increase the amount of habitat available to coho salmon (currently upstream of designated critical habitat) and the quality of the existing critical habitat by improving water quality in the mainstem Klamath River. NOAA Fisheries Service may consider whether to designate the newly available habitat as critical habitat as part of its 5 year status review or as a separate reconsideration of the critical habitat designation for the species (J. Simondet, NOAA Fisheries Service, pers. comm., 2011). The effects of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative on critical habitat for coho salmon would be similar to those for the Proposed Action, but somewhat reduced by the ongoing presence of Copco 2 and J.C. Boyle Reservoirs. The same habitat expansion expected under the Proposed Action would occur, with the exception of habitat under Copco 2 and J.C. Boyle Reservoirs and the downstream portion of Spencer Creek, which would continue to be inundated by J.C. Boyle Reservoir. Fish passage would be provided past the two remaining dams.

Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through elimination of peaking operations and higher baseflows.

Copco 1 and Iron Gate Reservoirs also cause the majority of the water temperature and water quality issues in the Hydroelectric Reach, so water quality conditions would be improved relative to existing conditions within the Hydroelectric Reach and to areas downstream from Iron Gate Dam as well.

Although upstream of current designated critical habitat, implementation of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would expand the geographic extent of habitat available to coho salmon. Water quality within currently designated critical habitat is anticipated to improve relative to existing conditions. **Based on reduced habitat quality during reservoir drawdown affecting PCEs, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a significant effect on coho salmon critical habitat in the short term. Based on benefits to the PCEs downstream from Iron Gate Dam, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a beneficial effect on critical habitat for coho salmon in the long term.**

Bull Trout The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be expected to have a similar effect on critical habitat for bull trout as the Fish Passage at Four Dams Alternative. **Based on the restricted distribution of bull trout, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a less-than-significant impact on critical habitat for bull trout in the short- and long term.**

Southern Resident Killer Whales The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be expected to have a similar impact on critical habitat for Southern Resident Killer Whales as the Proposed Action. Chinook salmon would be provided access to areas upstream of Iron Gate Dam and into the upper watershed, boosting natural production. Water quality issues would be improved both in the Hydroelectric Reach and in the Lower Klamath River. Fish parasitism would likely decrease as conditions became less favorable for the polychaetes host of *C. shasta* and *P. minibicornis*. However, because Chinook salmon from the Klamath River make up a very small proportion of the Southern Resident Killer Whale diet, this benefit to Southern Resident Killer Whales is expected to be small. **Based on small influence of the Klamath River on PCEs of Southern Resident Killer Whales, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a less-than-significant impact on critical habitat for Southern Resident Killer Whales in the short- and long term.**

Essential Fish Habitat *As described below, reservoir drawdown associated with dam removal under this alternative could alter the quality of EFH. In addition, the removal of two dams and two reservoirs could alter the availability and quality of EFH.*

Chinook and Coho Salmon EFH The effects of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative on EFH for Chinook and coho salmon would be similar to those for the Proposed Action, but would be somewhat reduced by the ongoing presence of Copco 2 and J.C. Boyle Reservoirs. Water quality in the mainstem Klamath River is expected to be improved. Most of the habitat expansion expected (upstream of currently designated EFH) under the Proposed Action would occur, with the exception of habitat under Copco 2 and J.C. Boyle Reservoirs and the downstream portion of Spencer Creek, which would continue to be inundated by J.C. Boyle Reservoir. Fish passage would be improved over existing conditions by providing passage past the remaining two dams.

Copco 1 and Iron Gate reservoirs also cause the majority of the water temperature and water quality issues in the Hydroelectric Reach, so these conditions would be improved relative to existing conditions. These water quality improvements would accrue to areas downstream from Iron Gate Dam as well.

Based on a substantial reduction in EFH quality during reservoir drawdown, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a significant effect on EFH for Chinook and coho salmon in the short term. Based on benefits to the habitat quality, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a beneficial effect on EFH for Chinook and coho salmon in the long term.

Groundfish EFH The effects of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be similar to those of the Proposed Action Alternative, with similar effects on SSCs, bedload and water quality.

Based on short duration of poor water quality during reservoir drawdown in the estuary, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a less-than-significant effect on EFH for groundfish in the short- and long term.

Pelagic Fish EFH The effects of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative on pelagic fish EFH would be similar to those described for the Proposed Action.

Based on short duration of poor water quality during reservoir drawdown in the estuary, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a less-than-significant effect on EFH for pelagic fish in the short- and long term.

Species-Specific Impacts

As described below, reservoir drawdown associated with dam removal under this alternative could affect aquatic species. In addition, the removal of two dams and two reservoirs could alter the availability and quality of habitat, resulting in effects on aquatic species.

Fall-Run Chinook Salmon

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, dam removal and the addition of fish passage facilities at J.C. Boyle and Copco 1 Dams would allow fall-run Chinook salmon to regain access to the upper Klamath River upstream of J.C. Boyle Reservoir. The access would expand the Chinook salmon's current habitat to include historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds miles of additional potentially productive habitat (DOI 2007), including access to groundwater discharge areas resistant to effects of climate change (Hamilton et al. 2011). Poor water quality (e.g., severe hypoxia, temperatures exceeding 25 °C, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009; USGS 2010). However, evidence indicates that Upper Klamath Lake habitat is presently suitable to support Chinook salmon for at least the October through May period (Maule et al. 2009).

Dispersal of spawners and carcasses under this alternative would diminish disease conditions. Flow variability would not be as great as under the Proposed Action; therefore, although removal of the two reservoirs would reduce the amount of lentic habitat available, some low-velocity habitats favorable to polychaetes might persist. Removal of the two dams would likely result in more favorable water temperature for salmonids than under existing conditions as well as improve water quality and reduce instances of algal toxins.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

Implementation of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would restore fall-run Chinook salmon access to the Hydroelectric Reach. Suspended and bedload sediment effects would be similar to those described for the Proposed Action.

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would include removal of Copco 1 and Iron Gate Reservoirs, with continued power generation at J.C. Boyle and Copco 2 hydroelectric plants. Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through elimination of peaking operations and higher baseflows. The reservoir drawdowns would allow tributaries and springs such as Fall and Shovel creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). Spencer Creek would continue to flow into J.C. Boyle Reservoir at its upstream end. Anadromous fish provided access to these reaches would have access to the tributaries as well. The potential habitat under the two remaining reservoirs for the

production of anadromous salmonids, redband trout, and Pacific lamprey would however not be reached under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative.

Lower Klamath River: Downstream from Iron Gate Dam

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would result in the release of sediment stored within Copco 1 and Iron Gate Reservoirs downstream to the Lower Klamath River. Of the reservoirs in the Hydroelectric Reach, J.C. Boyle Reservoir stores the least amount of sediment, less than 10 percent of the total amount. As such, suspended and bedload sediment conditions and effects on fall-run Chinook salmon in the Lower Klamath River reach would be similar to those described for the Proposed Action, but would be of slightly lesser magnitude.

The removal of two dams and restoration of free flowing sections of river would likely result in more favorable water temperatures for salmonids than under existing conditions. As it would be under the Proposed Action, migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to reduced water quality from increased suspended sediment concentrations, but these effects would be short term. Flow variability likely would not be as great as under the Proposed Action, but would still likely reduce habitat conditions favorable for polychaetes and algal toxins.

Disease conditions would be reduced under this alternative. Dispersal of spawners and carcasses would diminish myxospore proximity to the intermediate host. A more mobile bed relative to current conditions would disrupt habitat for the intermediate host.

Estuary

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative is not expected to substantially change or affect fall-run Chinook salmon estuarine habitat. Sediment, flow, and water temperature effects would likely not extend downstream to the estuary.

Summary: Fall-Run Chinook Salmon

*As described for the Proposed Action, reservoir drawdown associated with dam removal under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative could alter SSCs and bedload sediment transport and deposition and affect fall-run Chinook salmon. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be significant for fall-run Chinook salmon in the short term.***

As described for the Proposed Action, in the long term, removal of dams under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, could result in alterations in habitat availability, flow regime, water quality, temperature variation, fish disease incidence, and algal toxins which could affect fall-run Chinook salmon. As stated above, dam removal would also restore connectivity to hundreds of miles of potentially usable habitat in the Upper Klamath Basin and would create

additional spawning and rearing habitat within the Hydroelectric Reach. **Based on increased habitat availability and improved habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be beneficial for fall-run Chinook salmon in the long term.**

Spring-Run Chinook Salmon

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, dam removal and the addition of fish passage facilities at J.C. Boyle and Copco 1 Dams would allow spring-run Chinook salmon to regain access to the upper Klamath River upstream of J.C. Boyle Reservoir. The access would expand the spring-run Chinook salmon's current habitat to include historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood Rivers (Hamilton et al. 2005). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds of miles of additional potentially productive habitat (DOI 2007), including access to important thermal refugia within areas influenced by groundwater exchange that are more resistant to climate change (Hamilton et al. 2011). Some of these areas, such as the lower Williamson River, have habitat that would provide substantial holding areas for spring-run Chinook salmon (Hamilton et al. 2010). Other holding areas with suitable temperatures upstream of J.C. Boyle Reservoir include groundwater influenced areas on the west side of Upper Klamath Lake, and the Wood River (Gannett et al. 2007).

As described for the Proposed Action, this alternative is not expected to result in changes to suspended or bedload sediment, flow-related habitat, or algal toxins. Facilitating the movement of anadromous fish via prescribed fishways presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006).

Poor water quality (e.g., severe hypoxia, temperatures exceeding 25 °C, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009; USGS 2010; both as cited in Hamilton et al. 2011). However, evidence indicates that Upper Klamath Lake habitat is presently suitable to support Chinook salmon for at least the October through May period (Maule et al. 2009). Historically, adult spring-run Chinook salmon migrated upstream of the current location of Iron Gate Dam perhaps as early as February and March (Klamath Republican articles in Fortune et al. 1966) and likely held over in large holding pools in the mainstem in tributaries fed by cool water, and in refugia habitat upstream of Upper Klamath Lake (CDFG 1990c; Moyle 2002; Snyder 1931). One benefit of such early migration would be the avoidance of periods of poor water quality. The restored water temperature regime under the Proposed Action may restore upstream migration timing of adult spring-run Chinook salmon because of the shift in water temperatures downstream from Iron Gate dam (Bartholow et al. 2005).

Huntington (2006) reasoned that spring-run Chinook salmon likely accounted for the majority of the Upper Klamath Basin's actual salmon production under historical

conditions. Huntington (2006) cautioned that while access to the Upper Klamath Basin provides considerable promise of increasing spring-run abundance, the existing potential for Chinook salmon production within the Basin upstream of Upper Klamath Lake is clearly much lower than his estimate of historical potential. However, Huntington (2006) did not fully account for the historical (and unknown) production potential of Upper Klamath Lake itself, which could have been considerable, as suggested by a recent experimental reintroduction into Upper Klamath Lake (Maule et al. 2009).

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Implementation of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would restore spring-run Chinook salmon access to the Hydroelectric Reach. Suspended and bedload sediment effects would be similar to those described for the Proposed Action.

Habitat in the J.C. Boyle bypass and peaking reaches and the Copco 2 Bypass Reach would be improved through eliminating peaking operations and increasing base flows. The reservoir drawdowns would allow tributaries and springs such as Fall and Shovel creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). Spencer Creek would continue to flow into J.C. Boyle Reservoir at its upstream end. Anadromous fish provided access to these reaches would have access to the tributaries as well.

Removal of the two dams would likely result in more favorable water temperature for salmonids than under existing conditions as well as improve water quality and reduce instances of algal toxins. As with conditions for fall-run Chinook salmon, disease conditions would be reduced under this alternative.

Lower Klamath River: Downstream from Iron Gate Dam The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would result in the release of sediment stored within Copco 1 and Iron Gate reservoirs downstream to the Lower Klamath River. Of the reservoirs in the Hydroelectric Reach, J.C. Boyle stores the least amount of sediment, less than 10 percent of the total amount. As such, suspended and bedload sediment conditions and effects on spring-run Chinook salmon in the Lower Klamath River reach would be similar to those described for the Proposed Action, but of slightly lesser magnitude.

The removal of two dams and restoration of free flowing sections of river would likely result in more favorable water temperatures for salmonids than under existing conditions. As it would be under the Proposed Action, migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to reduced water quality, but these effects would be short term. Flow variability likely would not be as great as under the Proposed Action, but would still likely reduce habitat conditions favorable for polychaetes and algal toxins.

Estuary

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, habitat in the estuary could be affected by elevated turbidity from sediment releases during dam removal for about 3 months. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see the subsection of Section 3.2.4.3.2). However, this alternative not expected to substantially change or affect spring-run Chinook salmon estuarine habitat. Sediment, flow, and water temperature effects would likely not extend downstream to the estuary.

Summary: Spring-Run Chinook Salmon

*As described for the Proposed Action, reservoir drawdown associated with dam removal under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative could alter SSCs and bedload sediment transport and deposition and affect spring-run Chinook salmon. **Based on minimal reduction in the abundance of a year class in the short term, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be less-than-significant for spring-run Chinook salmon in the short term.***

*As described for the Proposed Action, in the long term, removal of dams under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, could result in alterations in habitat availability, flow regime, water quality, temperature variation, fish disease incidence, and algal toxins which could affect spring-run Chinook salmon. **Based on increased habitat availability and improved habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be beneficial for spring-run Chinook salmon in the long term.***

Coho Salmon

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir As described for the Proposed Action, coho salmon did not historically occur upstream of J.C. Boyle Reservoir, and are not anticipated to occupy this reach after implementation of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative access would be restored for the upper Klamath River Population coho salmon to the Hydroelectric Reach, expanding their distribution to include historical habitat along the mainstem Klamath River and all tributaries upstream at least as far as Spencer Creek; including in Jenny, Shovel, and Fall Creeks (Hamilton et al. 2005), including around 76 miles of potential habitat within the Hydroelectric Reach, as described in the No Action/No Project Alternative analysis above. The NRC of the National Academy of Science reviewed causes of decline and strategies for recovery of endangered and threatened fishes of the Klamath Basin. The NRC concluded that “removal of Iron Gate Dam... could open new habitat, especially by making available

tributaries that are now completely blocked to coho” (NRC 2004). Spencer Creek flows into the upstream end of J.C. Boyle Reservoir and would still be partially inundated under this alternative, but suitable habitat in the Spencer Creek would be accessible to coho salmon. Suspended and bedload sediment effects would be similar to those described for the Proposed Action. Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through eliminating peaking operations and increasing base flows.

Removal of the two dams would likely result in more favorable water temperature for salmonids than under existing conditions as well as improve water quality and reduce instances of algal toxins. As described for fall-run and spring-run Chinook salmon above, disease conditions would be reduced under this alternative.

Lower Klamath River: Downstream from Iron Gate Dam The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would result in the release of sediment stored within Copco 1 and Iron Gate Reservoirs downstream to the Lower Klamath River. Suspended and bedload sediment conditions and effects on coho salmon in the Lower Klamath River reach would be similar to those described for the Proposed Action, but of slightly lesser magnitude.

The removal of two Dams and restoration of free flowing sections of river would likely result in more favorable water temperatures for salmonids than under current conditions. As it would be under the Proposed Action, migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to reduced water quality, from increased SSCs, but these effects would be short term. Flow variability likely would not be as great as under the Proposed Action, but would still likely reduce habitat conditions favorable for polychaetes and algal toxins.

Estuary

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative is not expected to substantially change or affect coho salmon estuarine habitat. Sediment, flow, and water temperature effects would likely not extend downstream to the estuary.

Summary: Coho Salmon

*As described for the Proposed Action, reservoir drawdown associated with dam removal under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative could alter SSCs and bedload sediment transport and deposition and affect coho salmon. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be significant for the coho salmon from the Upper Klamath River, Mid-Klamath River, Shasta River, Scott River, and Salmon River population units in the short term. Based on indistinguishable effects predicted to occur during reservoir drawdown, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be less-than-significant for the coho salmon from the three Trinity River population units, and the Lower Klamath River Population Unit in the short term.***

As described for the Proposed Action, in the long term, removal of dams under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, could result in alterations in habitat availability, flow regime, water quality, temperature variation, fish disease incidence, and algal toxins which could affect coho salmon. Dam removal would restore connectivity to habitat on the mainstem Klamath River up to and including Spencer Creek and would create additional habitat within the Hydroelectric Reach. It is anticipated that as a result of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative the upper Klamath River, mid-Klamath River, Lower Klamath River, Shasta River, Scott River, and Salmon River coho salmon population units would have an increase in abundance, productivity, population spatial structure, and genetic diversity. It is anticipated that as a result of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative the three Trinity River population units would have increased productivity. **Based on increased habitat availability and improved habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be beneficial for the coho salmon from the Upper Klamath River, Mid-Klamath River, Lower Klamath River, Shasta River, Scott River, and Salmon River population units in the long term. Based on improved habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be less-than-significant for the coho salmon from the three Trinity River population units in the long term.**

Steelhead

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the Fish Passage at Two Dams Alternative, dam removal and the addition of fish passage facilities at J.C. Boyle and Copco 1 would allow steelhead to regain access to the upper Klamath River upstream of J.C. Boyle Reservoir. This would expand the population's distribution to include historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood rivers (Hamilton et al. 2005). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds of miles of additional potentially productive habitat (DOI 2007). As described for the Proposed Action, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative is not expected to result in changes to suspended or bedload sediment, flow-related habitat, or algal toxins. Facilitating the movement of anadromous fish presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006). Poor water quality (e.g., severe hypoxia, temperatures exceeding 25 °C, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009; USGS 2010; both as cited in Hamilton et al. 2011). However, evidence indicates that Upper Klamath Lake habitat is presently suitable to support salmonids for at least the October through May period (Maule et al. 2009).

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Implementation of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1

and Iron Gate Alternative would restore steelhead access to the Hydroelectric Reach. Suspended and bedload sediment effects would be similar to those described for the Proposed Action.

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would include removal of Copco 1 and Iron Gate reservoirs, with continued power generation at J.C. Boyle and Copco 2 hydroelectric plants. Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through eliminating peaking operations and increasing base flows. The reservoir drawdowns would allow tributaries and springs such as Fall and Shovel creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). Spencer Creek would continue to flow into J.C. Boyle Reservoir at its upstream end. Anadromous fish provided access to these reaches would have access to the tributaries as well.

Removal of the two dams would likely result in more favorable water temperature for salmonids, as well as improved water quality and reduced instances of algal toxins.

Lower Klamath River: Downstream from Iron Gate Dam The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would result in the release of sediment stored within Copco 1 and Iron Gate reservoirs downstream to the Lower Klamath River. Of the reservoirs in the Hydroelectric Reach, J.C. Boyle Reservoir stores the least amount of sediment, less than 10 percent of the total amount. As such, suspended and bedload sediment conditions and effects on steelhead in the Lower Klamath River reach would be similar to those described for the Proposed Action, but of slightly lesser magnitude.

The removal of two dams and restoration of free flowing sections of river would likely result in more favorable water temperatures for salmonids than under current condition. As it would be under the Proposed Action, migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to reduced water quality from increased SSCs, but these effects would be short term. Flow variability likely would not be as great as under the Proposed Action, but would still likely reduce habitat conditions favorable for algal toxins.

Estuary

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative is not expected to substantially change or affect steelhead estuarine habitat. Sediment, flow, and water temperature effects would likely not extend downstream to the estuary.

Summary: Steelhead

As described for the Proposed Action, reservoir drawdown associated with dam removal under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative could alter SSCs and bedload sediment transport and deposition and affect

steelhead. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be significant for summer and winter steelhead in the short term.**

As described for the Proposed Action, in the long term, removal of dams under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, could result in alterations in habitat availability, flow regime, water quality, and temperature variation, which could affect steelhead. Implementation of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would restore connectivity to hundreds of miles of potentially usable habitat in the Upper Klamath Basin and would create additional spawning and rearing habitat within the Hydroelectric Reach, as described for the Proposed Action. **As described for the Proposed Action, based on increased habitat availability and improved habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be beneficial for summer and winter steelhead in the long term.**

Pacific Lamprey

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Pacific lamprey occurred historically at least to Spencer Creek (Hamilton et al. 2005) although there is some uncertainty in this regard (Administrative Law Judge 2006). Pacific lamprey below Iron Gate dam would migrate above the dam if access was provided through fishways (Administrative Law Judge (2006).

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Pacific lamprey below Iron Gate Dam would migrate above the dam if access was provided (Administrative Law Judge 2006). Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, dam removal and the addition of fish passage facilities at J.C. Boyle and Copco 1 Dams would provide Pacific lamprey access to the Hydroelectric Reach, which would expand the population's current range to include habitat within the mainstem Klamath River and its tributaries upstream at least as far as Spencer Creek, including Jenny, Shovel, and Fall Creeks (Hamilton et al. 2005). Spencer Creek flows into the upstream end of J.C. Boyle Reservoir and would still be potentially accessible to lamprey. Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through eliminating peaking operations and increasing base flows. Suspended and bedload sediment effects would be similar to those described for the Proposed Action.

The reservoir drawdowns would allow tributaries and springs such as Fall and Shovel Creeks and Big Springs to flow directly into the mainstem Klamath River. Removal of the two dams would likely result in more favorable water temperature for lamprey and other native fishes, and would improve water quality.

Lower Klamath River: Downstream from Iron Gate Dam The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would release sediment stored within Copco 1 and Iron Gate Reservoirs downstream to the Lower

Klamath River. Of the reservoirs in the Hydroelectric Reach, J.C. Boyle Reservoir stores the least amount of sediment—less than 10 percent of the total. As such, suspended and bedload sediment conditions and effects on Pacific lamprey in the Lower Klamath River reach would be similar to those described for the Proposed Action, but of slightly lesser magnitude.

The removal of two dams and restoration of free flowing sections of river would likely result in water temperature more favorable for Pacific lamprey occurring in the mainstem, as well as improve water quality. As it would be under the Proposed Action, migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to reduced water quality from increased SSCs, but these effects would be short term.

Estuary

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative is not expected to substantially change or affect Pacific lamprey estuarine habitat. Sediment, flow, and water temperature effects would likely not extend downstream to the estuary.

Summary: Pacific Lamprey

*As described for the Proposed Action, reservoir drawdown associated with dam removal under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative could alter SSCs and bedload sediment transport and deposition and Pacific lamprey. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be significant for Pacific lamprey in the short term.***

*As described for the Proposed Action, in the long term, removal of dams under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, could result in alterations in habitat availability, flow regime, water quality, temperature variation, fish disease incidence, and algal toxins which could affect Pacific lamprey. Dam removal would restore connectivity among the Lower Klamath Basin, the Hydroelectric Reach and its tributaries among the Lower Klamath Basin, the Hydroelectric Reach and its tributaries, and would rehabilitate and increase availability of riverine habitat within the Hydroelectric Reach. **Based on increased habitat availability and improved habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be beneficial for Pacific lamprey in the long term.***

Green Sturgeon

Upper Klamath River Green sturgeon did not historically occur upstream of Iron Gate Dam (Hamilton et al. 2005) and are not anticipated to occupy this reach after implementation of this alternative. The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would not affect green sturgeon upstream of Iron Gate Dam.

Lower Klamath River: Downstream from Iron Gate Dam The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would result in the release of sediment stored within Copco 1 and Iron Gate reservoirs downstream to the Lower Klamath River. Of the reservoirs in the Hydroelectric Reach, J.C. Boyle stores the least amount of sediment, less than 10 percent of the total amount. As such, suspended and bedload sediment conditions and effects on green sturgeon in the Lower Klamath River reach would be similar to those described for the Proposed Action, but of slightly lesser magnitude.

Bedload sediment effects related to dam-released sediment or sediment resupply would likely extend as far as the Cottonwood Creek. Current green sturgeon distribution extends from the mouth of the Klamath River upstream to the Ishi Pishi Falls (Moyle 2002; FERC 2007), with some observed migrating into the Salmon River. Short- and long-term changes to bedload sediment under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative are not expected to affect green sturgeon.

The removal of two dams and restoration of free flowing sections of river would likely result in water temperature more favorable for green sturgeon occurring in the mainstem, as well as improve water quality and reduce instances of algal toxins. As with SSCs, migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to poor water quality due to dam removal, but these effects would be short term.

Estuary

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative is not expected to substantially change or affect estuarine habitat. Sediment, flow, and water temperature effects would likely not extend downstream to the estuary.

Summary: Green Sturgeon

*As described for the Proposed Action, reservoir drawdown associated with dam removal under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative could alter SSCs and affect green sturgeon. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be significant for green sturgeon in the short term.***

*As described for the Proposed Action, in the long term, removal of dams under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, could result in alterations in flow regime, water quality, temperature variation, and algal toxins which could affect green sturgeon. **Based on small improvements in habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be less-than-significant for green sturgeon in the long term.***

Shortnose and Lost River Sucker

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Shortnose and Lost River suckers upstream of Keno Dam would not be affected by the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative. Effects on populations downstream from Keno Dam are detailed below in the description of the Hydroelectric Reach. The KBRA would not be implemented under this alternative. However, ongoing restoration activities will continue to occur.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam Federally endangered shortnose and Lost River suckers are found within reservoirs in Hydroelectric Reach, but in lower abundance than in reservoirs and lakes upstream. As described for the Proposed Action, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would reduce reservoir habitat as dams within the Hydroelectric Reach were removed and sediment was allowed to move downstream. Adult Lost River and shortnose suckers in Iron Gate and Copco 1 reservoirs would be captured and relocated to Upper Klamath Lake (Buchanan et al. 2011a). Those not relocated to the Upper Klamath Basin would likely be lost, but with little or no successful reproduction (Buettner et al. 2006), the populations downstream from Keno Dam contribute minimally to conservation goals and insignificantly to recovery (Hamilton et al. 2011). Lost River and shortnose suckers are listed as fully protected species under California Fish and Game; thus any take of these species is prohibited. However, if there is an Affirmative Determination by the Secretary, and a concurrence by the State of California, CDFG will provide draft legislation to the other KHSA/KBRA parties which would authorize limited take of these fully protected species.

Facilitating the movement of anadromous fish via prescribed fishways presents a relatively low risk of introducing pathogens to resident fish above Iron Gate Dam (Administrative Law Judge 2006). Generally, with the exception of *F. columnaris* and Ich, pathogens associated with anadromous fish do not impact non-salmonids (e.g. suckers) (Administrative Law Judge 2006).

Based on the low occurrence of suckers within Iron Gate and Copco 1 reservoirs, only a small reduction in abundance could occur, and therefore the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be less-than-significant for Lost River and shortnose sucker populations in the short- and long term.

Redband Trout

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, dam removal and the addition of fish passage facilities at J.C. Boyle and Copco 1 dams would allow redband trout to migrate more successfully from the Hydroelectric Reach to the Upper Klamath Basin (Hamilton et al. 2011) than under existing conditions.

Under this alternative, a flow regime that more closely mimics natural conditions would not be established downstream from Keno Dam; therefore, the increases in stream habitat upstream of J.C. Boyle Dam might not be realized under this alternative.

Redband could be affected by the reintroduction of anadromous fish, including the potential for competition, predation, and exposure to disease, as described for the Proposed Action above.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam As described for the Proposed Action, dam removal under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would allow redband trout to migrate between tributaries and reservoirs to complete their lifecycle, and would restore around 19 miles of reservoir habitat to riverine habitat (Cunanan 2009). Habitat in the J.C. Boyle Bypass and Peaking Reaches and the Copco 2 Bypass Reach would be improved through eliminating peaking operations and increasing base flows. The current reservoirs inundate sections of the river that had high sinuosity and complex channels that historically provided excellent salmonid spawning and rearing habitats (Hetrick et al. 2009). Under this alternative this habitat would be restored. Suspended and bedload sediment effects would be similar to those described for the Proposed Action. However, sediment would continue to be trapped in J.C. Boyle, and spawning habitat would not likely improve for redband trout in the mainstem.

Summary: Redband Trout

*As described for the Proposed Action, reservoir drawdown associated with dam removal under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative could alter SSCs and affect redband trout. **Based on a small proportion of the population with a potential to be exposed to short-term effects, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be less-than-significant for redband trout in the short term.***

*As described for the Proposed Action, in the long term, removal of dams under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, could result in alterations in habitat availability and flow regime, which could affect redband trout. As described for the Proposed Action, dam removal would restore connectivity among the Lower Klamath Basin, the Hydroelectric Reach and its tributaries, and the Upper Klamath Basin, and would rehabilitate and increase availability of riverine habitat within the Hydroelectric Reach. **Based on increased habitat availability and improved habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be beneficial for redband trout in the long term.***

Bull Trout

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir As described for the Proposed Action, under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative bull trout upstream of J.C. Boyle Reservoir

could be affected by increased predation from reintroduced salmonids, but this loss might be offset by an increase in available food sources (e.g., eggs, fry, and juveniles of reintroduced salmonids) (Buchanan et al. 1997).

Based on the restricted distribution of bull trout, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a less than significant impact on bull trout in the short and long term.

Eulachon

Lower Klamath River: Downstream from Iron Gate Dam Under this alternative, suspended sediment conditions and effects on eulachon in the Lower Klamath River would be similar to those described for the Proposed Action, but of slightly lesser magnitude. Short-term decreases in water quality might also be associated with this alternative and would affect adults and larvae in the mainstem Klamath River. As with SSCs, these effects could be muted by tributary inputs.

Estuary Based on the lower magnitude of SCC, the Remove Copco 1 and Iron Gate Alternative is not expected to substantially change or affect estuarine habitat.

Based on no substantial reduction in the abundance of a year class, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be a less-than-significant effect on eulachon in the short term. Based on short duration of poor water quality during reservoir drawdown in the estuary, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a less-than-significant effect on eulachon in the long term.

Longfin Smelt The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would release dam-stored sediment downstream to the Lower Klamath River, but would not be expected to reach the area potentially used by longfin smelt. Longfin smelt using the Lower Klamath River after January 2020 could be exposed to high SSCs for a portion of their migration period. SSCs would likely decrease in the downstream direction from Iron Gate Dam due to dilution from tributaries, so the magnitude of the effect would likely be low. Short-term decreases in water quality could also affect adults and larvae in the mainstem Klamath River. As with SSCs, these effects could be muted by tributary inputs.

Estuary

As described for the Proposed Action, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative is not expected to substantially change or affect estuarine habitat.

Based on short duration of poor water quality during reservoir drawdown in the estuary, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have a less-than-significant effect on longfin smelt in the short- and long term.

Introduced Resident Species

Upper Klamath River: Upstream of the Influence of J.C. Boyle Reservoir

Introduced resident species upstream of J.C. Boyle Reservoir would not be affected by the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative.

Hydroelectric Reach: From Upstream End of J.C. Boyle Reservoir to Iron Gate Dam

As described for the Proposed Action, implementation of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would eliminate reservoir habitat associated with the two largest reservoirs Copco 1 and Iron Gate Dam, but would retain the habitat associated with the smaller J.C. Boyle and Copco 2 reservoirs. This would be detrimental to nonnative fishes upstream of Iron Gate Dam. Abundance of these species would decline substantially as the majority of their preferred reservoir habitat would be eliminated (Buchanan et al.2011a).

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would reduce habitat for introduced resident species in the Hydroelectric Reach.

Because these species were introduced and they occur in other nearby water bodies, their loss would not be considered important from a biological perspective, and would benefit native species. This impact would be less than significant from a biological perspective. Their loss would, however, decrease opportunities for recreational fishing for these species, as discussed in Section 3.20, Recreation.

Interactions Among Species

The Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would restore access for anadromous salmon, lamprey, and steelhead to habitat upstream of Iron Gate Dam, as described in detail above. Restoration of access would result in anadromous salmon and steelhead potentially interacting with resident redband trout and bull trout. Juvenile salmonids and lamprey would be subject to some level of predation by introduced resident species including largemouth bass, catfish, and yellow perch in J.C. Boyle and Copco 2 Reservoirs, resulting in mortality rates that would depend largely on their size (larger migrants will do better) (Administrative Law Judge 2006), as described for the Fish Passage at Four Dams Alternative. Based on the reservoir dynamics and the predator population that currently occurs, predation of outmigrating salmonids above Iron Gate Dam is anticipated to be low (Administrative Law Judge 2006). In restoration efforts elsewhere in the Pacific Northwest, anadromous juveniles successfully pass through reservoirs under similarly difficult circumstances (Administrative Law Judge 2006). The other effects of interactions among these species would be the same as described for the Proposed Action.

Freshwater Mussels

Suspended Sediment Concentrations Most stored sediment that would affect downstream Klamath River resources is stored in Iron Gate Reservoir, and SSCs resulting from implementation of this alternative would be the same as, or very similar to, those levels described previously for the Proposed Action.

Therefore, SSCs resulting from the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would have the same effects on freshwater mussels, as previously described for the Proposed Action.

Changes in Bed Elevation Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, free-flowing river conditions would be restored through most of the mainstem Klamath River. The release of sediment currently stored behind Iron Gate and Copco 1 Dams would occur and changes in streambed elevation downstream from Iron Gate Dam would be similar, but slightly smaller in magnitude than those of the Proposed Action because the J.C. Boyle and Copco 2 Dams would remain in place and the sediment stored behind them would not be removed. Therefore, the effects of this alternative on bedload elevation changes would be similar, but perhaps slightly smaller in magnitude, than those associated with the Proposed Action.

Changes in Bed Substrate

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, changes in bed substrate would be similar as those described for the Proposed Action. Therefore, this alternative would have similar effects on freshwater mussels in the mainstem Klamath River as the Proposed Action.

Based on substantial reduction in the abundance of multiple year classes in the short term and the slow recovery time of freshwater mussels, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be significant for freshwater mussels in the short term.

Based on increase in habitat availability, the effects of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be beneficial to freshwater mussels in the long term.

Benthic Macroinvertebrates

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, Klamath Hydroelectric Project peaking operations would no longer kill, through stranding, large numbers of young fish and aquatic invertebrates that are the primary prey food for resident trout (Administrative Law Judge 2006).

Suspended Sediment Concentrations

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, the release of sediment currently stored behind Iron Gate and Copco 1 Dams would occur. The effects of SSCs on BMIs would be the same as, or very similar to, those described for the Proposed Action.

Changes in Bed Elevation

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, the effects on BMIs resulting from bedload elevation changes are expected to be similar, if not the same as, those associated with the Proposed Action.

Changes in Bed Substrate

Under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, the effects on BMIs resulting from changes in bed substrate in the mainstem Klamath River would be similar to those described for the Proposed Action.

Summary: Benthic Macroinvertebrates

*As described for the Proposed Action, the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative could alter SSCs and bedload sediment transport and deposition and affect benthic macroinvertebrates. **Based on substantial reduction in the abundance of a year class in the short term, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be significant for macroinvertebrates downstream from Iron Gate Dam in the short term.***

*As described for the Proposed Action, in the long term, removal of dams under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative, could result in alterations in habitat availability, flow regime, water quality, and temperature variation, which could affect macroinvertebrates. While a large proportion of their populations in the Hydroelectric Reach and in the mainstem Klamath River downstream from Iron Gate Dam would be affected, their populations would be expected to recover quickly because of the many sources for recolonization and their rapid dispersion through drift or aerial movement of adults. Habitat quality would also be improved in the Hydroelectric Reach by the ending of deleterious Klamath Hydroelectric Project peaking operations (Administrative Law Judge 2006). **Based on increased habitat availability and improved habitat quality, the effect of the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative on macroinvertebrates would be beneficial in the long term.***

Trap and Haul – Programmatic Measure

*Implementation of trap and haul measures could affect aquatic species. The trap and haul measures around Keno Impoundment/Lake Ewauna and Link River would have the same impacts under the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative as the Fish Passage at Four Dams Alternative. **Based on access to additional, historical habitat and the anticipated improvements in fish health, implementation of trap and haul measures in the Fish Passage at J.C. Boyle and Copco 2, Remove Copco 1 and Iron Gate Alternative would be beneficial for fall-run Chinook salmon.***

3.3.4.4 Mitigation Measures

3.3.4.4.1 AR-1: Protection of Mainstem Spawning

It is anticipated that short-term effects of the Proposed Action (SSCs and bedload movement) will result in up to 100 percent mortality of fall Chinook and coho salmon embryos and pre-emergent alevin within redds that were constructed in the mainstem in the fall of 2019. In addition, any steelhead or Pacific lamprey migrating within the mainstem Klamath River after December 30th could be directly affected. As described in

Appendix E, around 2,100 fall-Chinook salmon redds are predicted to be affected, and around 13 redds from the Upper Klamath River Population Unit for coho salmon.

Deleterious short-term effects of the Proposed Action on mainstem spawning could be reduced by capturing migrating adult fish (Chinook, coho, steelhead, or Pacific lamprey) in the mainstem Klamath River and relocating them to suitable habitat. Capture of adult fish could be accomplished with the use of an Alaskan-style weir and box trap, similar to that currently used at the Willow Creek and Trinity River site. The most suitable location for the trap appears to be directly upstream of the Shasta River, where the mainstem Klamath River is small enough to effectively trap, and would ensure that fish returning to key tributaries downstream from, and including the Shasta River would not be interrupted. The weir would be installed at the beginning of the fall migration and continue past the initial dam drawdown period until high flows require the trap to be dismantled. Captured fish would periodically be transported to receiving tributaries. Fish could be released either in under-seeded tributaries downstream from Iron Gate Dam (e.g., Scott River), or in tributaries upstream of Iron Gate Dam if that were consistent with post-dam removal management goals. The relocated fish would then spawn naturally in the tributary streams and their progeny would not be affected by the SSCs and bedload movement during the dam removal process. In addition, the trap would only be operated periodically, so that some volitional passage upstream of the Shasta River would occur, allowing fish to return to Bogus Creek and the hatchery during 2019.

Additional surveys in the mainstem downstream from Shasta River could be conducted to locate coho salmon spawning in the mainstem. Any identified adult coho, Chinook, steelhead, or Pacific lamprey could be captured using dip-nets, electrofishing, or seines and transported to tributary habitat. Surveys should be conducted in December 2019, immediately prior to the first release of sediment associated with facilities removal. A detailed plan describing capture techniques, release locations, and monitoring methods would be developed by the Dam Removal Entity (DRE) prior to 2019.

Effectiveness of Mitigation in Reducing Impacts

The effectiveness of the measure will depend on how effectively adults can be captured with the weir. Based on operation of similar traps in other rivers, it is anticipated that when operational the trap could capture nearly all upstream migrants. However, it is the intention to allow a portion of the adult to migrate volitionally to access Bogus Creek or the hatchery. Therefore it is assumed some fall Chinook salmon will continue to spawn within the mainstem during 2019. Depending on the condition of captured adults, some may be injured during transport, or may not spawn when released. However, the progeny of these adults is predicted to suffer 100 percent mortality if they spawn in the mainstem, so relocation is considered worth the risk of reduced spawning success. Overall effectiveness of the adult relocation operation would be measured by using radio-tagged individuals to track the -tagged fish to determine spawning success and location.

3.3.4.4.2 AR-2: Protection of Outmigrating Juveniles

It is anticipated that short-term effects of the Proposed Action (SSC) will result in mostly sublethal, and in some cases lethal impacts to a portion of the juvenile Chinook, coho,

steelhead, and Pacific lamprey that are outmigrating from tributary streams to the Klamath River upstream of Orleans during late winter and early spring of 2020 (Appendix E).

Deleterious short-term effects on outmigrating juveniles could be reduced by capturing juveniles outmigrating from tributaries prior to their entry into the mainstem. This measure includes the installation of downstream migrant traps on up to 13 key tributary streams downstream from Iron Gate Dam including Bogus Creek, Dry Creek, Walker Creek, Shasta River, Seiad Creek, Oneil Creek, Scott River, Grider Creek, Tom Martin Creek, Horse Creek, Beaver Creek, Cottonwood Creek, and Humbug Creek. Results of spawning surveys in fall 2019 could be used to focus trapping efforts within these or other tributaries. Trapping on all of these streams is proposed to help preserve the genetic integrity and varied life history tactics that are represented by this group of streams that have a high diversity with respect to size, channel types, water temperature regimes, geographic distribution, and other attributes.

The trapping would involve the standard CDFG/USFWS rotary screw trap/fyke net/pipe trap methods currently in use. However, placement of a second trap downstream from the first would increase the number of captures. Captured fish could then be placed in aerated tank trucks and transported to a release site downstream from the Trinity River or other locations that have suitable water quality.

The procedures of trapping, handling, trucking, and releasing outmigrating salmonids could result in harm or mortality to some individuals, and releasing fish at downstream locations could reduce natal cues and increase stray rates. Therefore fish will be captured and transported only if conditions within the mainstem are as poor as predicted. Due to the uncertainties with suspended sediment modeling, water quality monitoring during spring 2020 would be used to trigger the initiation and cessation of the capture program and inform suitable release locations. Release locations should be varied to prevent predators from congregating at release locations. Alternatively, in a portion of tributaries juveniles could be held in temporary facilities within tributaries and released when SSC in the mainstem were non-stressful. This would prevent any decrease in the natal cue, as well as any potential associated effects of fish transport.

A detailed plan describing trapping techniques, release locations, and monitoring methods would be developed by the DRE prior to 2019.

Effectiveness of Mitigation in Reducing Impacts

The effectiveness of this measure depends on the efficiency of trapping efforts. Trap efficiency varies with species and tributary. Current trapping efforts in the Shasta River and Scott River typically have trap efficiencies between around 5 and 30 percent, averaging around 15 percent (Underwood et al. 2010). It is anticipated that trapping efficiency could be increased over current efforts by more aggressive trapping efforts using either multiple traps and/or increased weir panels. However, not all tributaries with outmigrating juveniles will be trapped, and within trapped tributaries some individuals will avoid traps and migrate to the mainstem (particularly during high flows). Overall, it

is assumed 50 percent of juveniles outmigrating to the mainstem could be captured. Current predictions of mortality estimate a total of 2,668 to 6,536 smolts for an impact of 9 to 22 percent from the upper Klamath River, mid-Klamath River, Scott River, and Shasta River population units depending on a most-likely-to-occur or worst case scenario. Assuming 50 percent capture efficiency this mitigation measure would reduce mortality a total of 1,334 to 3,268 smolts for an impact of 4 to 11 percent depending on a most-likely-to-occur or worst-case scenario. To evaluate the effectiveness of the mitigation measure, the trapping procedures would need to assess trap efficiency that would lead to the development of estimates of stream production and numbers of fish assumed missed by trapping effort.

3.3.4.4.3 AR-3: Fall Flow Pulses

It is anticipated that short-term effects of the Proposed Action (SSCs) will result in sublethal effects for green sturgeon adults remaining in the mainstem Klamath River during fall 2019, mortality for mainstem spawning fall-run Chinook salmon, mortality for migrating adult winter steelhead, and sublethal effects for adult coho salmon remaining in mainstem prior to entering tributaries.

Deleterious short-term effects on adults could be reduced by augmented flows during fall 2019 prior to dam removal. It has been observed that fall pulse flows result in the downstream migration of post-spawned green sturgeon out of the Klamath River (Benson et al. 2007), and increased flows during fall prior to dam removal may increase the rate and proportion of fall-run Chinook salmon, steelhead, and coho salmon spawning in tributaries, and thus reducing the proportion of the population spawning in the mainstem or being exposed to SSCs in the mainstem during migration (Stillwater Sciences 2009a).

Water releases in the fall prior to dam removal should mimic the natural hydrograph that would have existed in the Klamath River during a “wet year” prior to the Reclamation project, consistent with recommendations in NRC (2004). However, if the water year during dam removal is dry, managers will need to balance the benefits of increased flows during fall with the risk of impacts to the Basin if less water is available during the following spring (during smolt outmigration). Increases in fall flows would likely be most successful if conducted synchronously with increased flows in unregulated tributaries, to help create enough of a pulse of water to encourage migration. Doing so will also ensure that adults that are attracted up the mainstem by increasing fall flows are not blocked from accessing their natal streams due to natural low flow conditions.

A detailed plan describing target flows and monitoring methods would be developed by the DRE prior to 2019.

Effectiveness of Mitigation in Reducing Impacts

It is anticipated that this measure will be effective for reducing deleterious short-term effects on adult green sturgeon during fall 2019. Benson et al. (2007) reported that the majority of adult green sturgeon outmigrating during the first major flow event of the fall. Analysis of the mainstem natural spawner fraction versus flow suggests that, generally, increased numbers of naturally produced fall-run Chinook salmon adults spawn in the

mainstem during years when fall flows are low (Stillwater Sciences 2009a). The minimum proportion of fall-Chinook salmon spawning in the mainstem is 5.3 percent, suggesting that if fall-pulse flows are successful at increasing tributary spawning the proportion of fall-run Chinook salmon spawning in the mainstem could be reduced to this level.

Currently on average less than 4 percent of coho salmon migrate into monitored tributaries after December 15th, and in many years no fish are observed migrating after this date (Appendix E). Migration of coho salmon adults into tributaries also appears to be affected by flow, with earlier tributary entrance times observed in Blue Creek, Shasta River, Bogus Creek and other tributaries during years with high flows during fall (Stillwater Sciences 2009a). A fall pulse-flow is anticipated to be effective at ensuring nearly all adult coho salmon migrate into tributaries prior to initiation of reservoir drawdown on December 15. The effectiveness of the measure could be monitored with spawning surveys during 2019. The proportion of steelhead migrating upstream after December 15th is highly variable (USFWS 1998). Although no analysis has been conducted, it is possible that increased fall flows could result in a greater proportion of steelhead migrating upstream and into tributaries prior to dam removal, as is observed in some years (USFWS 1998).

3.3.4.4.4 AR-4: Hatchery Management

It is anticipated that short-term effects of the Proposed Action (SSC) will result in mostly sublethal, and in some cases lethal impacts to a portion of the juvenile Chinook, coho, and steelhead smolts outmigrating from tributary streams to the Klamath River upstream of Orleans during late winter and early spring of 2020 (Appendix E).

Deleterious short-term effects on outmigrating hatchery Chinook and coho salmon smolts could be reduced by adjustments to hatchery management. Hatchery managers could adjust the timing of hatchery releases during spring 2020. Although it would be out of synch with natural life history timing, if smolts are released later in the spring (e.g., mid-May), survival is anticipated to be higher based on current conditions (Beeman et al. 2008), as well as avoiding the peak in spring release of sediment in the year following dam removal.

An alternative to adjusting the hatchery release timing would be to allow the sub-yearling and yearling smolts to imprint at the hatchery and then truck them to release locations downstream where SSC effects may be muted by tributary accretion flow. Trucking could be accomplished during the normal releasing timing period.

The implementation of this mitigation measure is dependent on the hatchery remaining open and having a suitable water supply. A detailed plan describing adjustments to hatchery management would be developed by the DRE prior to 2019.

Effectiveness of Mitigation in Reducing Impacts

It is anticipated that this measure will effectively reduce short-term lethal effects on hatchery released smolts to sublethal effects.

3.3.4.4.5 AR-5: Pacific lamprey Capture and Relocation

Based on predictions of low dissolved oxygen and the analysis of SSC that was conducted (Appendix E), high rates of mortality are predicted in the short term as a result of the Proposed Action. An action to mitigate this deleterious short-term effect would be to salvage and relocate lamprey ammocoetes from preferred habitat areas where dissolved oxygen levels would be particularly low, including pools, alcoves, backwaters, and channel margins that experience low water velocities and sand and silt deposition (Streif 2009) from areas downstream from Iron Gate Dam. The focus of relocation efforts would be within 3 km of Iron Gate Dam, where SSC is predicted to be highest, and dissolved oxygen levels the lowest. However, the density of lamprey within this reach is not known, and reconnaissance surveys should be conducted prior to the implementation of this measure to assess if enough ammocoetes are present to warrant mitigation.

The salvage operation, if implemented, would be conducted by first identifying preferred (and high risk) areas and then utilize a specialized electrofisher to capture ammocoetes. Collection of lamprey ammocoetes has been demonstrated in the Klamath River (Karuk Tribe and USFWS unpublished data). Captured individuals would be transported to suitable locations (with current low occurrences of lamprey) within tributaries upstream or upstream of Keno Dam. A detailed plan describing lamprey capture and relocation would be developed by the DRE prior to 2019.

Effectiveness of Mitigation in Reducing Impacts

It is expected that implementation of this mitigation measure would reduce dissolved oxygen and SSC-related stress or mortality for a proportion of lamprey ammocoetes. An unknown number of lamprey ammocoetes remaining in the mainstem Klamath River downstream from Iron Gate Dam would still experience stress and mortality resulting from elevated SSC and bedload movement. Mitigation effectiveness monitoring would consist of reporting the number of individuals captured, release location, and their condition upon release.

3.3.4.4.6 AR-6: Sucker Rescue and Relocation

It is anticipated that short-term effects of the Proposed Action will result in mostly sublethal, and in some cases lethal impacts to Lost River and shortnose suckers within reservoirs in Hydroelectric Reach. Under this measure adult Lost River and shortnose suckers in reservoirs downstream from Keno Dam could be captured and relocated to Upper Klamath Lake (Buchanan et al. 2011a).

If deemed feasible in 2019 prior to dam removal, Klamath smallscale suckers will be collected directly downstream from J.C. Boyle Dam and terminating approximately 2 miles downstream in the approximate area of the current powerhouse. Fish will be collected using electro-fishing techniques. Salvaged Klamath smallscale sucker will be relocated to Spencer Creek immediately downstream from the Spencer Creek hook up road (upper limits for sucker in Spencer creek). Smallscale suckers will not be relocated upstream of Keno Dam.

Lost River and shortnose suckers can also be captured using electrofishing and trammel nets. It is recommended that these and other approved capture techniques be utilized for this relocation effort. Captured Lost River and shortnose suckers could then be placed in aerated tank trucks and transported to suitable release sites in Upper Klamath Lake. A detailed plan describing sucker rescue and relocation would be developed by the DRE prior to 2019.

Effectiveness of Mitigation in Reducing Impacts

It is expected that implementation of this mitigation measure would reduce the deleterious short-term effects from the Proposed Action. However, it is not known how many suckers inhabit the Hydroelectric Reach reservoirs, therefore it is unknown what proportion of the population would be captured and successfully relocated. Those Lost River and shortnose suckers not relocated to the Upper Klamath Basin would likely be lost, but with little or no successful reproduction (Buettner et al. 2006), and no connection to upstream populations, the individuals downstream from Keno Dam contribute minimally to conservation goals or recovery (Hamilton et al. 2011).

3.3.4.4.7 AR-7: Freshwater Mussel Relocation

Freshwater mussels in the Hydroelectric Reach and in the Lower Klamath River, downstream from Iron Gate Dam, are likely to be deleteriously affected by prolonged SSCs and bedload movement during the later part of reservoir drawdown and subsequent dam removal. Freshwater mussels cannot move to avoid these impacts, and some species are very long lived, and may not reproduce successfully (or at all) each year. An action to mitigate this effect is to relocate freshwater mussels prior to drawdown. Freshwater mussels could be relocated to tributary streams or upstream of the Hydroelectric Reach, then moved back to their approximate location or to other suitable habitat in the river after dam removal has been completed.

Freshwater mussel relocation success depends on a variety of factors including the availability of suitable habitat (for juveniles, adults, reproduction, feeding, growth, and host fish), population density at the relocation site, and handling during relocation (Hamilton et al. 1997; Bolden and Brown 2002). While many (and still unknown) factors influence the survival and reproduction of freshwater mussels in their natural environment, relocation adds an additional stress. Thus, the variables associated with the characteristics of freshwater mussel habitat at the source and destination sites as well as with the relocation methods should be as similar as possible for all life stages (Cope and Waller 1995; Cope et al. 2003). Previous studies indicate varied success of freshwater mussel relocation projects, with most mortality observed within one year (Thomas 2008). Habitat selection is important for success, as changes in habitat (e.g., substrate size) from the original site appear to influence mortality (Cope and Waller 1995; Bolden and Brown 2002). As such, the presence of existing freshwater mussel populations should guide site selection. Cope et al. (2003) found that proper handling and transport and selection of suitable habitat improved survivorship of relocated freshwater mussels.

Luzier and Miller (2009) developed some general guidelines for freshwater mussel relocation projects, including 1) an initial evaluation of freshwater mussel populations to

site evaluation for relocation to determine (among other factors) habitat quality and presence of appropriate fish hosts, 3) careful and quick transport to minimize stress, and 4) monitoring relocated populations to determine initial survival, recruitment, and persistence through the range of environmental conditions at the site. Following these guidelines, prior to drawdown (e.g., fall 2019 or before) surveys would be conducted to evaluate current freshwater mussel species and habitat downstream from Iron Gate Dam and to identify potential sites for relocation. Freshwater mussels would be relocated to suitable habitats and monitored over the duration of high SSCs. After dissipation of effects, original locations could be resurveyed to determine habitat suitability. If suitable, then the relocated freshwater mussels could be returned to their source location. Most relocation projects are conducted during warm periods when reproductive stress is presumably low for most species, and their metabolic rates are sufficient for burrowing in the substrate (Cope and Waller 1995).

If suitable in-stream habitat cannot be found for the time period of increased SSCs, it may be possible to temporarily house relocated freshwater mussels in fish hatchery raceways at facilities near to the removal sites. However, many freshwater mussels need to burrow to reduce the energy needs of holding their valves closed for extended periods. Thus, such artificial holding areas should not be used for long periods. Aquaculture ponds have sometimes been used as well (Cope et al. 2003).

This mitigation measure would benefit from a pilot program prior to initiation, to assess the success and potential levels of mortality associated with relocation. Relocation should also consider the potential for transmission of disease or interbreeding between genetically distinct populations. A detailed plan describing freshwater mussel rescue and relocation would be developed by the DRE prior to 2019.

Effectiveness of Mitigation in Reducing Impacts

With the proposed mitigation, these impacts freshwater mussels would be reduced.

3.3.4.4.8 Summary of Mitigation Measures

The DRE would be responsible for implementation of Mitigation Measures AR-1 through AR-7. Although all proposed mitigation measures would reduce short-term deleterious effects of the Proposed Action, significant effects would continue to occur for some species, as described in detail in the Proposed Action Species-Specific impacts analysis provided in Section 3.3.4.3.2.2.3 and detailed in Tables 3.3-11 through 3.3-18.

Table 3.3-11. Comparison of Short-term SSC Effects from the Proposed Action with and without Mitigation Measures; Most-likely Scenario (i.e., 50% Exceedance Probabilities) for Fall- and Spring-Chinook and Coho Salmon

Species/Run	Life History Stage				
	Adult migration	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Fall Chinook Salmon	Proposed Action				
	No effects	Up to 100% mortality of the progeny of mainstem spawners (about 8% of escapement)	No juvenile progeny anticipated rearing in mainstem due to impacts during incubation. Most other juveniles assumed to rear in tributaries prior to outmigration.	N/A	Type I: Major stress and reduced growth for Type I fry (about 60% of production)
					Type II: No effects
					Type III: Major stress, reduced growth, and up to 20% mortality for Type III outmigrants (less than 1% of production)
	Proposed Action with Mitigation Measures AR-1, 2, 3, and 4				
	Increased escapement into tributaries due to augmented attraction flows	Reduced effects due to increased hatchery production, trapping and relocation of adult spawners and additional redds being constructed in tributaries	Reduced effects due to mainstem progeny now rearing in hatchery and tributary streams.	N/A	Type I: Major stress on smolts not rescued and relocated; Growth-related effects for non-hatchery smolt; reduced effects on hatchery smolts due to delayed release
Type II: Same as above for naturally spawned progeny. Reduced effects for hatchery-reared fish due to release timing modification. Reduced effects for rescued and relocated smolts.					
Type III: Major stress, reduced growth, and up to 20% mortality for Type III outmigrants. Reduced effects for rescued and relocated smolts.					

Table 3.3-11. Comparison of Short-term SSC Effects from the Proposed Action with and without Mitigation Measures; Most-likely Scenario (i.e., 50% Exceedance Probabilities) for Fall- and Spring-Chinook and Coho Salmon

Species/Run	Life History Stage				
	Adult migration	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Spring Chinook Salmon	Proposed Action				
	Spring Migration: Major stress, impaired homing for adults returning to Salmon R. (about 5% of run)	Most spawning takes place in tributaries; no effects predicted	Juveniles primarily rear in tributaries; no effects predicted	Juveniles primarily rear in tributaries; no effects predicted	Type I: Major stress for Type I fry from Salmon R. (about 80% of Salmon R. production)
	Summer Migration: No effects				Type II: Major to moderate stress for 1 to 3 days
					Type III: Major stress, reduced growth, but no mortality
	Proposed Action with Mitigation Measures AR- 2 and 3				
	Spring Migration: Same as above	Same as above	Same as above	Same as above	Type I: Major stress on smolts not rescued and relocated
Summer Migration: Same as above	Type II: Same as above for non-rescued and relocated fish.				
	Type III: 20-40% mortality (about 31 smolts)				

Table 3.3-11. Comparison of Short-term SSC Effects from the Proposed Action with and without Mitigation Measures; Most-likely Scenario (i.e., 50% Exceedance Probabilities) for Fall- and Spring-Chinook and Coho Salmon

Species/Run	Life History Stage				
	Adult migration	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Coho Salmon	Proposed Action				
	Major stress and impaired homing	Up to 100% mortality of progeny of mainstem spawners (typically <1% of run)	Age 0+ summer: Reduced growth for age 0+ from 2020 cohort in upper mainstem (<50% of fry). No effect on juveniles rearing in tributaries	Age 1+ winter: Major stress, reduced growth, and up to 60% mortality for age 1+ juveniles from 2019 cohort in mainstem (assume <1% of juveniles). No effect on juveniles rearing in tributaries	Early spring outmigration: Major stress, reduced growth, and up to 20% mortality for smolts coming from tributaries in upper mainstem in early spring (about 44% of production) Late spring outmigration: Major stress and reduced growth for smolts coming from tributaries in the upper mainstem in late spring (about 56% of production)
	Proposed Action with Mitigation Measure AR-2 and 3				
	Same as above	Reduced effects due to relocation of adult spawners and additional redds being constructed in tributaries upstream of Hydroelectric Reach	Age 0+ summer: Same as above	Age 1+ winter: Same as above	Early spring outmigration: Major stress, reduced growth, and up to 4% mortality; Reduced mortality Late spring outmigration: Major stress and mortality on smolts not rescued and relocated; Growth-related effects

Table 3.3-12. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Most-likely scenario (i.e., 50% Exceedance Probabilities) for Steelhead and Pacific Lamprey

Species/Run	Life History Stage					
	Adult migration	Runbacks/Half-pounder residency	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Summer and Winter Steelhead	Proposed Action					
	Summer run: Major stress and impaired homing for fish spawning in mid- and upper-Klamath tributaries (about 45% of escapement) Winter run: Major stress, impaired homing, and up to 36% mortality for fish spawning in mid- and upper-Klamath tributaries (about 1,008 adults)	Adult runbacks: Major stress; depending on time spent in mainstem Half-pounder residency: Most assumed to remain in tributaries; major stress for any remaining in mainstem	Most spawning takes place in tributaries; no effects predicted	Major stress resulting in reduced growth and up to 100% mortality for juveniles in that migrate from tributaries to the mainstem	Age 1+ rearing: Major stress, reduced growth, and up to 100% mortality for juveniles in that migrate from tributaries to the mainstem Age 2+ rearing: Reduced growth and up to 60% mortality for juveniles in mainstem	Major stress and reduced growth; about 57% outmigrate from Trinity R. and would have less exposure

Table 3.3-12. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Most-likely scenario (i.e., 50% Exceedance Probabilities) for Steelhead and Pacific Lamprey

Species/Run	Life History Stage					
	Adult migration	Runbacks/Half-pounder residency	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Summer and Winter Steelhead	Proposed Action with Mitigation Measure AR-2					
	Summer run: Same as above Winter run: Same as above	Adult runbacks: Same as above Half-pounder residency: Same as above	Same as above	Reduced effects for those migrating fish that are captured and relocated. Same effects as above for non-relocated fish.	Age 1+ rearing: Reduced effects for those migrating fish that are captured and relocated. Same effects as above for non-relocated fish. Age 2+ rearing: Reduced effects for those migrating fish that are captured and relocated. Same effects as above for non-relocated fish.	Major stress and reduced growth for that portion of the population not captured by the outmigrant rescue program.

Table 3.3-12. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Most-likely scenario (i.e., 50% Exceedance Probabilities) for Steelhead and Pacific Lamprey

Species/Run	Life History Stage					
	Adult migration	Runbacks/Half-pounder residency	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Pacific Lamprey	Proposed Action					
	Major stress, reduced growth, and up to 36% mortality; later-returning adults and those returning to lower tributaries would have less exposure	N/A	See adult migration	Ammocoete rearing: Major stress, reduced growth, and up to 52% mortality for multiple year classes of ammocoetes in mainstem; majority rear in tributaries and would not suffer mortality		Spring outmigration: Major stress
						Fall and winter outmigration: Moderate stress
	Proposed Action with Mitigation Measure AR-5					
Same as above	N/A	Same as above	Ammocoete rearing: Reduced effects for ammocoetes that are captured and relocated. Major stress, reduced growth, and up to 52% mortality for lamprey not captured and relocated.		Spring outmigration: Same as above	
					Fall and winter outmigration: Same as above	

Table 3.3-13. Comparison of Short-term SSC Effects from the Proposed Action with and without Mitigation Measures; Most-Likely Scenario (i.e., 50% Exceedance Probabilities) for Green Sturgeon and Suckers

Species/Run	Life History Stage			
	Adult migration	Adult Post-spawning Holding	Spawning through larvae	Juvenile Rearing (year-round) and Outmigration
Green Sturgeon	Proposed Action			
	Major stress; 75% of adults not expected to migrate in 2020	No effects	76% mortality for all mainstem production; about 30% that spawn in Trinity R. would be unaffected (based on salmonid literature; effects likely overestimated)	Reduced growth and up to 20% mortality; about 30% of juveniles rear in Trinity R. and would be unaffected (based on salmonid literature; effects likely overestimated)
	Proposed Action with Mitigation Measure AR-4			
	Reduced effects due to fall flow pulse moving adults downstream; 75% of adults not expected to migrate in 2020.	Same as above	Same as above	Same as above
Suckers (spp)	Proposed Action			
	NA	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach.	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach.	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach.
	Proposed Action with Mitigation Measure AR-6			
	NA	Beneficial in upper Klamath Lake due to more habitat area. Loss of all adults within the Hydroelectric Reach that were not captured and relocated.	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach since larvae and juveniles will not be captured and relocated.	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach since larvae and juveniles will not be captured and relocated.

Table 3.3-14. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measure AR-8 for Freshwater Mussels

Species/Run	Adults	Spawning	Larvae
Freshwater mussels	Proposed Action		
	Major physiological stress and substantial mortality	Major physiological stress and substantial mortality during the spawning season	Major adult physiological stress and mortality will significantly reduce larval production. No information on effects of SSC on larvae. Larvae produced in downstream reaches or tributaries may contribute to population recovery.
	Proposed Action with Mitigation Measure AR-8		
	Major physiological stress and substantial mortality. Some individuals would be relocated and would assist in reseeding the population.	Major physiological stress and substantial mortality during the spawning season. Relocated individuals may spawn in upstream reaches.	Major adult physiological stress and mortality will significantly reduce larval production. No information on effects of SSC on larvae. Larvae produced by relocated individuals, in downstream reaches, or in tributaries may contribute to population recovery.

Table 3.3-15. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-Case Scenario (10% Exceedance Probabilities) for Fall- and Spring-run Chinook Salmon

Species/Run	Life History Stage				
	Adult migration	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Fall-run Chinook Salmon	Proposed Action				
	No effect	Up to 100% mortality of the progeny of mainstem spawners (about 8% of escapement)	No juvenile progeny anticipated rearing in mainstem due to impacts during incubation. Most other juveniles assumed to rear in tributaries prior to outmigration.	N/A	Type I: Major stress and reduced growth for the about 40% of fry entering mainstem in April/May
					Type II: Moderate to major stress for the about 60% of Type II juveniles entering mainstem in Sept/Nov
					Type III: Major stress, reduced growth, and up to 71% mortality for about 0.18% of all juveniles entering mainstem in Feb-April
	Proposed Action with Mitigation Measures AR-1, 2, 3, and 4				
	Increased escapement into tributaries due to augmented attraction flows	Reduced effects due to increased hatchery production, relocation of adult spawners and additional redds being constructed in tributaries	Reduced effects due to mainstem progeny now rearing in hatchery and tributary streams	N/A	Type I: Major stress on smolts not rescued and relocated; Growth-related effects for non-hatchery smolt; reduced effects on hatchery smolts due to delayed release
Type II: Same as above for naturally spawned progeny. Reduced effects for hatchery-reared fish due to release timing modification.					
Type III: Major stress, reduced growth, and up to 60% mortality; Reduced mortality					

Table 3.3-15. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-Case Scenario (10% Exceedance Probabilities) for Fall- and Spring-run Chinook Salmon

Species/Run	Life History Stage				
	Adult migration	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Spring-run Chinook Salmon	Proposed Action				
	Spring Migration: Major stress and impaired homing	Most spawning takes place in tributaries; no effects predicted	Juveniles primarily rear in tributaries; no effects predicted	Juveniles primarily rear in tributaries; no effects predicted	Type I: Major stress for Type I fry from Salmon R. (about 80% of Salmon R. production)
	Summer Migration: Impaired homing				Type II: Moderate stress for Type II juveniles from Salmon R. (about 20% of Salmon R. production)
					Type III: Major stress for Type III juveniles from Salmon R. (<1% of Salmon R. production)
	Proposed Action with Mitigation Measure s AR- 2				
	Spring Migration: Same as above	Same as above	Same as above	Same as above	Type I: Reduced impacts for those fish that are rescued and relocated. Same impacts as above for fish not rescued.
	Summer Migration: Same as above				Type II: Reduced impacts for those fish that are rescued and relocated. Same impacts as above for fish not rescued.
Type III: Reduced impacts for those fish that are rescued and relocated. Same impacts as above for fish not rescued.					

Table 3.3-16. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-Case Scenario (10% Exceedance Probabilities) for Coho Salmon and Steelhead

Species/Run	Life History Stage					
	Adult migration	Runbacks/Half-pounder residency	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Coho Salmon	Proposed Action					
	Major stress and impaired homing	N/A	Up to 100% mortality of progeny of mainstem spawners (typically <1% of run)	Age 0+ summer: No growth for 2020 cohort rearing in upper mainstem (< 50% of fry). No effect on juveniles rearing in tributaries	Age 1+ winter: Major stress, reduced growth and up to 52% mortality for 2018 age-1+ cohort in mainstem (assume <1% of juveniles). No effect on juveniles rearing in tributaries	Early spring outmigration: Major stress, reduced growth, and up to 49% mortality for smolts coming from Upper Klamath, Mid-Klamath, Shasta River, and Scott River populations during early spring (approximately 44% of the run outmigrates in early spring). (Mortality for approximately 8% of total population)
						Late spring outmigration: Major stress and reduced growth for smolts coming from tributaries in the upper mainstem in late spring (about 56% of production)
	Proposed Action with Mitigation Measures AR-2 and 3					
	Same as above	N/A	Reduced effects due to relocation of adult spawners and additional redds being constructed in tributaries upstream of Hydroelectric Reach	Age 0+ summer: Same as above	Age 1+ winter: Same as above	Early spring outmigration: Major stress, reduced growth, and up to 11% mortality; Reduced mortality
						Late spring outmigration: Reduced impacts for those fish that are rescued and relocated.

Table 3.3-16. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-Case Scenario (10% Exceedance Probabilities) for Coho Salmon and Steelhead

Species/Run	Life History Stage					
	Adult migration	Runbacks/Half-pounder residency	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Summer and Winter Steelhead	Proposed Action					
	<p>Summer run: Major stress, impaired homing, and up to 20% mortality (From 0 to 130 adults, or from 0 to 9 percent of the basin-wide escapement).</p> <p>Winter run: Major stress, impaired homing, and up to 71% mortality. The proportion migrating prior to January would not be affected. (Up to 1,988 adults, or up to 28 percent of the basin-wide escapement).</p>	<p>Adult runbacks: Major stress; exposure dependant on time it takes runbacks to return to sea</p> <p>Half-pounder residency: Major stress and reduced growth for any in mainstem; Most assumed to remain in tributaries;</p>	Most spawning takes place in tributaries; no effects predicted	Major stress and reduced growth for age 0+ juveniles in mainstem (about 60% of juveniles)	<p>Age 1+ rearing: Stress, reduced growth, and up to 71% mortality Up to 11,207 juveniles or around 19% of total age 1 production).</p> <p>Age 2+ rearing: Stress, reduced growth and up to 71% mortality (Up to 9,412 juveniles or around 18% of total age 2 production).</p>	Major stress resulting in reduced growth, about 57% outmigrate from Trinity R. and will have less exposure
	Proposed Action with Mitigation Measures AR-2					
	<p>Summer run: Same as above</p> <p>Winter run: Same as above</p>	<p>Adult runbacks: Same as above</p> <p>Half-pounder residency: Same as above</p>	Same as above	Same as above	<p>Age 1+ rearing: Same as above</p> <p>Age 2+ rearing: Same as above</p>	Major stress and reduced growth for that portion of the population not captured by the outmigrant rescue program.

Table 3.3-17. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-case Scenario (10% Exceedance Probabilities) for Pacific Lamprey, Green Sturgeon, and Suckers

Species	Life History Stage				
	Adult migration	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Pacific Lamprey	Proposed Action				
	Major stress, reduced growth, and up to 71% mortality; later-returning adults and those returning to lower tributaries would have less exposure	See adult migration	Ammocoete rearing: Major stress, reduced growth, and up to 71% mortality for multiple year classes of ammocoetes in mainstem; majority rear in tributaries and would not suffer mortality		Spring outmigration: Moderate to major stress and reduced growth
					Fall and winter outmigration: Major stress
	Proposed Action with Mitigation Measure AR-5				
	Same as above	Same as above	Ammocoete rearing: Same as above for any ammocoetes not captured and relocated		Spring outmigration: Same as above
				Fall and winter outmigration: Same as above	

Table 3.3-17. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-case Scenario (10% Exceedance Probabilities) for Pacific Lamprey, Green Sturgeon, and Suckers

Species	Life History Stage				
	Adult migration	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Green Sturgeon	Proposed Action				
	Major stress; about 25% of adults expected to be exposed in 2020	Adult Post-spawning Holding: Short period (<1 wk) of relatively low SSCs, not expected to result in deleterious effects; about 75% of adults hold in mainstem after spawning; remainder return to ocean	95% mortality for all mainstem production; about 30% that spawn in Trinity R. would be unaffected (based on salmonid literature; effects likely overestimated)	Juvenile Rearing (year-round) and Outmigration: Reduced growth and up to 36% mortality; about 30% of juveniles rear in Trinity R. and would be unaffected	N/A
	Proposed Action with Mitigation Measure AR-3				
	Reduced effects due to fall flow pulse moving adults downstream	Adult Post-spawning Holding: Reduced effects due to fall flow pulse moving adults downstream	Same as above	Juvenile Rearing (year-round) and Outmigration: Same as above	N/A

Table 3.3-17. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-case Scenario (10% Exceedance Probabilities) for Pacific Lamprey, Green Sturgeon, and Suckers

Species	Life History Stage				
	Adult migration	Spawning through fry emergence	Age 0+ rearing	Age 1+ rearing	Outmigration
Suckers (spp)	Proposed Action				
	NA	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach.	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach.	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach.	NA
	Proposed Action with Mitigation Measure AR-6				
	NA	Beneficial in upper Klamath Lake due to more habitat area. Loss of all adults within the Hydroelectric Reach that will not be captured and relocated.	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach since larvae and juveniles will not be captured and relocated.	Beneficial in upper Klamath Lake due to more habitat area. Loss of all individuals within the Hydroelectric Reach since larvae and juveniles will not be captured and relocated.	NA

Table 3.3-18. Comparison of Short-term SSC effects from the Proposed Action with and without Mitigation Measures; Worst-Case Scenario (i.e., 10% Exceedance Probabilities) for Freshwater Mussels

Species	Adults	Spawning	Larvae
Freshwater mussels	Proposed Action		
	Major physiological stress and substantial mortality	Major physiological stress and substantial mortality during the spawning season	Major adult physiological stress and mortality will significantly reduce larval production. No information on effects of SSC on larvae. Larvae produced in downstream reaches or tributaries may contribute to population recovery.
	Proposed Action with Mitigation Measure AR-8		
	Major physiological stress and substantial mortality. Some individuals would be relocated and would assist in reseeded the population.	Major physiological stress and substantial mortality during the spawning season. Relocated individuals may spawn in upstream reaches.	Major adult physiological stress and mortality will significantly reduce larval production. No information on effects of SSC on larvae. Larvae produced by relocated individuals, in downstream reaches, or in tributaries may contribute to population recovery.

3.4 Algae

3.4.1 Area of Analysis

This section of the Klamath Facilities Removal Environmental Impact Statement/ Environmental Impact Report (EIS/EIR) analyzes potential effects of the Proposed Action and alternatives on algal communities in the Klamath Basin, excluding the Lost River watershed, Tule Lake watershed, and most of the Trinity River.

The area of analysis for algae is generally the same as for Aquatic Resources (Section 3.3, Aquatic Resources, Figure 3.3-1). Potential impacts were assessed within and across reaches of the Klamath Basin, as separated by changes in physiography (e.g., Upper and Lower Klamath Basins), the presence of the Four Facilities under analysis, and degree of marine influence. The area of analysis for algae has the following reaches:

1. Upstream of the influence of J.C. Boyle Reservoir, including the following:
 - a. Upper Klamath Lake and Agency Lake
 - b. Tributaries to Upper Klamath Lake (Sprague, Sycan, Wood and Williamson Rivers)
 - c. Reclamation's Klamath Project facilities (e.g., Link River Dam, Keno Impoundment /Lake Ewauna)
2. Hydroelectric Reach: from the upstream end of J.C. Boyle Reservoir to Iron Gate Dam, including all sections categorized as mainstem, bypass, and peaking reaches and including tributaries to the Klamath River (examples include Jenny, Spencer, Slate, Shovel, and Fall creeks).
3. Lower Klamath River: downstream from Iron Gate Dam, including the following:
 - a. Major tributaries to the Klamath River (Shasta, Scott, and Salmon Rivers)
 - b. Minor tributaries to the Klamath River (examples include Bogus, Beaver, Humbug, and Cottonwood creeks)
4. Klamath Estuary
5. Pacific Ocean marine nearshore environment (see Figure 3.2-1)

3.4.2 Regulatory Framework

Beneficial uses and water quality objectives for Oregon, California, the United States Environmental Protection Agency (USEPA), and the Hoopa Valley, Yurok and Karuk Tribes provide the regulatory framework for algae listed below. These uses and objectives are described in detail in Section 3.2.2. Oregon includes a narrative nuisance algae growth objective in which impairment of beneficial uses by algal growth is not allowed. Additionally, for natural lakes that do not thermally stratify, reservoirs, rivers and estuaries, the numeric average of 0.015 mg/L chlorophyll-*a* identifies Oregon water bodies where phytoplankton may impair the recognized beneficial uses (Table 3.2-3).
